Selecting Screening Equipment and Protocols

Deciding what equipment to use and what protocol to follow is one of the first steps in setting up a newborn hearing screening program. During the past 20 years, many different pieces of equipment have been successfully used in newborn

hearing screening programs—transient-evoked OAEs, distortion product OAEs, and A-ABR. Each type of equipment has its proponents and detractors, but it is clear that the particular brand and type of equipment is not the primary determinant of whether a program will be successful.

In fact, the type and degree of hearing loss that is targeted by the screening program is much more important than the type and/or brand of screening equipment that will be used. This was demonstrated by Johnson et al. (2005) who evaluated how many infants are diagnosed with permanent hearing loss after passing a two-stage hearing screening protocol in which all infants are screened first with OAE and some are screened with A-ABR. In this protocol, no additional testing is done with infants who pass the OAE, but infants who fail the OAE are next screened with A-ABR. Those infants who fail the A-ABR screening are referred for diagnostic testing to determine if they have permanent hearing loss. Those who pass the A-ABR are assumed to have normal hearing and are not tested further. The objective of this multicenter study was to determine whether a substantial number of infants who fail the initial OAE and pass the A-ABR have permanent hearing loss at approximately 9 months of age.

Seven geographically dispersed birthing centers that had been successfully using a two-stage OAE/A-ABR screening protocol were included in the study. Almost 87,000 babies were screened at these centers during the period of the study. Infants who failed the OAE but passed the A-ABR in at least one ear (1.8%) were enrolled in the study and invited back for a diagnostic audiologic evaluation when they were on average 9.3 months of age. Diagnostic audiologic evaluations were completed for 64% of the enrolled infants (1,432 ears from 973 infants). Twenty-one infants (30 ears) who had failed the OAE but passed the A-ABR were identified with permanent bilateral or unilateral hearing loss, with most of them (77%) having mild hearing loss.

The results of this study suggest that if all infants were screened for hearing loss using the two-stage OAE/A-ABR hearing screening protocol currently used in many hospitals, approximately 23% of those with permanent hearing loss at approximately 9 months of age would have passed the A-ABR with the presumption that they had normal hearing. This happens in part because most currently used A-ABR screening equipment uses a 35-dBnHL click, which is best for identifying infants with moderate or greater hearing loss. Thus, program administrators should be certain that they are using equipment and protocols that are appropriate for identifying the type of hearing loss they wish to target.

Another example of why it is important to pay attention to selecting the equipment and protocol used in a newborn hearing screening program is the need to identify babies who are DHH because of auditory neuropathy spectrum disorder (ANSD). Such babies are a challenge to identify in some newborn hearing screening programs because they

have normal or near-normal OAEs but an absent/abnormal auditory brainstem response (ABR). Thus, a program that uses only OAE for screening would miss such babies. Although it does occur in well-baby nurseries, most babies with ANSD have spent time in the NICU. For this reason, the JCIH (2007) recommends ABR technology as the only appropriate screening technique for use in the NICU. Berlin et al. (2010) provide additional information about the diagnosis and management of children with ANSD.

Regardless of the screening technology used, program administrators also need to be thoughtful about the number of screening tests that are done for each infant. To keep referral rates low at the time of hospital discharge, many programs repeat screening tests a number of times if the baby does not pass on the first test. JCIH (2007, p 903) cautions that “the likelihood of obtaining a pass outcome by chance alone is increased when screening is performed repeatedly.” Because of this caution, many state EHDI programs have guidelines that babies should not be screened more than two or three times before leaving the hospital. Although screening a baby too many times is often not an efficient use of the screener’s time, it does little to increase the probability of obtaining “a pass outcome by chance alone.” Nelson and White (2014) had testers who were DHH repeat OAE tests in their own ear 1,000 times to determine how often a pass result would be obtained for an ear that has moderate to severe permanent hearing loss. They found an average of 1 false-negative result per 1,000 tests. Statistical probability calculations were then used to show that if the screening test was repeated three times for EVERY baby in a state with 100,000 annual births, only 1 baby who is DHH would be missed and 300 babies who are DHH would be correctly identified. If every baby were screened 10 times, only three babies who are DHH would be missed. In short, the negative consequences of repeat testing with respect to babies passing the screening test by chance have been greatly exaggerated.

Operating an Effective Newborn Hearing Screening Program

Regardless of the technology and protocol used, several procedural issues are important for an efficient, successful program.

RESPONSIBILITY AND LEADERSHIP

If everyone is responsible for a task, no one feels responsible for failure. Successful newborn hearing screening programs are being conducted in hundreds of different ways, but any successful program requires attention to detail and someone who makes sure all elements of the program are systematically addressed. The person responsible for day-to-day operation of the program does not need specific professional certification, but he or she needs to have good connections with the nursery, understand how screening

happens, and, most of all, be committed to the success of the program.

ENSURING COMPETENT SCREENERS

Thousands of successful programs have demonstrated that screening can be done by a wide variety of people, including nurses, audiologists, technicians, healthcare assistants, volunteers, and students. Some states have laws about who can do hearing screening and how they must be supervised—others do not. Whoever does the screening should have received hands-on training under the supervision of someone who has already demonstrated his or her ability to be a successful screener. Although it is often said that practice makes perfect, it is more accurate to say that practice makes permanent. Consequently, it is important to provide timely feedback to people who are just learning to screen so errors can be corrected before they become ingrained. After initial training is completed, there should be regular one-on-one observation and feedback. It is useful to have a regular report of each screener's performance with regard to the number of babies screened, babies passed, invalid tests, and screens completed per hour of work. Such data are useful in identifying screeners who are having difficulty and need assistance. Feedback should be given in a way that is viewed as assistance instead of punishment.

WHEN SHOULD SCREENING BE DONE?

Regardless of how screening is done, it will be faster and more effective if babies are quiet and the environment is not too noisy. Most programs do screening in the early morning or during the night when fewer people need to have access to the baby. However, depending on how the hospital nursery is organized, screening can be done at almost anytime that fits with the routine of that hospital. Whatever decision is made, dozens of other hospitals are doing it at approximately the same time, so there really is no wrong time to do newborn hearing screening.

WRITTEN PERMISSION FOR SCREENING IS SELDOM NECESSARY

In most hospitals, hearing screening is done routinely as a part of the standard medical care provided to all newborns. As with other procedures, parents are not expected to explicitly consent to each procedure. However, it is best if parents understand what happens during newborn hearing screening so they can make an informed decision about whether they want their baby to be screened. Such parent education can be accomplished with information in the preadmission materials, prenatal classes, media materials, or placed in the baby's crib. If, based on this information, parents do not want their baby to be screened for hearing, they have the right to refuse.

Communicating with Parents and Healthcare Providers

Many people have a stake in the results of a newborn hearing screening program. Parents are among the most important stakeholders because they have the long-term responsibility to ensure that the child receives appropriate care and services. They are also the ones who have the strongest feelings (but often limited experience) about what it means to have a child who is DHH. It is essential that each parent be told the results of their baby's hearing screening test and this should involve more than just being informed that the baby passed or failed. Based on data collected from a national sample of hundreds of parents using individual interviews and focus groups Arnold et al. (2006) concluded that "the most opportune time to begin discussion of newborn hearing screening is before the birth." Arnold et al. (2006) also provided suggestions and sample materials about how to communicate with parents at all stages of the EHDI process. A web-based instructional module based on these suggestions is available at NCHAM (2013b). Most successful hearing screening programs use a variety of materials (often available in multiple languages) to educate, inform, and follow-up with parents, including pamphlets about the screening program, parent education materials, letters sent to parents about the results of the test, and cards used to make return appointments for rescreens or diagnostic evaluations.

The discussion with parents about the result of the newborn hearing screening test is an ideal time to help parents understand that passing the newborn hearing screening test does not mean that the child will never have future problems with hearing or language development. Parents understand that the newborn hearing screening test only provides information about the status of the infant's hearing at the time of discharge. Late-onset loss can occur at any time for a number of reasons (JCIH, 2007). Parents should request another hearing evaluation at any time they have concerns about their child's hearing or language development.

It is also very important for the child's PHCP to understand that medical evaluation is an essential part of the diagnostic process and that healthcare providers are a critical part of that multidisciplinary team. It is also important that everyone involved in the baby's medical management understand how detrimental it is when the diagnostic process requires several months, instead of being completed within a few weeks. For babies without other medical complications, the goal should be to have a definitive diagnosis, be fit with hearing aids (if parents choose to do so), and begin early intervention within a few weeks of birth. There should be a system for notifying every baby's PHCP about the screening results for his or her patients with a clear recommendation of what should happen next. Few things will undermine the success of a newborn hearing screening program as much as the baby's PHCP telling the parent during a well-baby check that it is really not that important to

follow up with the outpatient screen or diagnostic evaluation procedures.

Does Hearing Screening Create Excessive Anxiety for Some Parents?

Many people (e.g., Nelson et al., 2008; Paradise, 1999) have suggested that UNHS creates unduly high levels anxiety, worry, and concern for parents and might even interfere with parent–child bonding—particularly for parents of babies who fail the initial screen and are found on subsequent testing to have normal hearing (the false positives from screening). Tueller (2006) found dozens of studies that had examined this issue, with most reporting that 4% to 15% of parents in the general population and 14% to 25% in the false-positive group experienced increased levels of anxiety. The problem with most of these studies is that there was no explicit basis for comparison (i.e., were parents any more worried about their child’s hearing than they were about other aspects of the child’s development?).

To more accurately assess whether the worry expressed by parents was unduly high, Tueller collected data from 191 mothers (split between those whose babies had passed the initial screening test and those who failed the initial test in the hospital and passed a rescreen when they were 1 to 4 weeks of age). Data were collected when the baby was 1 week of age, and again at 6 weeks of age (which was after the time that babies received a rescreen if they failed the initial screen). Mothers were asked to rate whether they were “not at all, somewhat, moderately, or very worried” about the baby’s hearing as well as 20 other aspects of infant development (e.g., irritability, sleeping habits, eyesight). When babies were 1 week old, 14.6% of the mothers reported that they were moderately worried or very worried about their child’s hearing (similar to what has been reported in other studies). But, hearing was ranked sixth on the list of 21 items about which they might be concerned and it was not statistically significantly different from 14 of the other items.

At 1 week of age, mothers whose babies had failed the initial hearing screening test ranked hearing as the item about which they were most worried, but it was not statistically significantly different from 15 of the other items. But, at 6 weeks of age (after the baby passed the hearing rescreen test) mothers ranked hearing as eighth on their list of possible concerns and none of the mothers indicated that they were either moderately or very worried.

Tueller’s results suggest that mothers worry somewhat about lots of issues related to their new baby. If asked whether they are worried about only hearing, about 15% will say yes. But this is no different than the percentage who worry about other aspects of their child’s development (e.g., eating, sleeping, irritability). Of course, newborn hearing screening programs should educate parents about the screening process and why hearing and language development are important. However, there is no convincing evidence that the newborn

hearing screening process causes parents to be unduly concerned about their baby’s hearing.

Complying with Federal Privacy Protection Laws

Successful EHDI programs share personally identifiable information about infants and young children among people who are responsible for screening, diagnosis, early intervention, family support, and medical home services. Many people involved with EHDI programs complain that federal privacy laws (e.g., HIPAA, FERPA, Part C Privacy Regulations) make it impossible for EHDI programs to be successful (Houston et al., 2010). Most of these concerns are based on misperceptions or false information about the requirements of those laws. For example, HIPAA expressly allows for sharing of information among healthcare providers to facilitate healthcare services and for reporting information to public health programs. There is nothing in HIPAA that prevents screening program personnel from reporting screening results to other hospitals, state EHDI programs, pediatricians, or Part C Early Intervention programs. All of these can be done even if informed consent is not obtained from parents (NCHAM, 2013h). To help parents be full partners in the EHDI process, it makes sense to inform them before sharing information about their family with anyone in the EHDI system. Even though it is not legally required under HIPAA, one of the best ways to ensure that parents are well informed is to have a signed consent.

FERPA and Part C Privacy Regulations are more restrictive than HIPAA, but these regulations are not in force until an agency that is receiving federal funds provides services to the child. Thus, in most cases, screening and diagnosis of hearing loss and referral to an early intervention program will be completed before the provisions of Part C Privacy Regulations or FERPA take effect. Once a child has been referred to Part C, information about that child cannot be given by the Part C program staff to the EHDI program, the audiologist who did the diagnostic evaluation, or a pediatrician—unless the parent provides informed consent. Effective strategies are listed below and examples of the forms and documents being used by state EHDI programs to support many of these strategies are available from NCHAM (2013h):

1. Coordinated consent forms that comply with the requirements of HIPAA and Part C Privacy Regulations can be used to streamline the referral process and to relieve parents of the burden of completing similar forms for the same purpose.
2. Memoranda of Agreement that designate EHDI programs as participating agencies of the Part C system are useful in those cases where EHDI is more than a primary referral source for child-find.
3. Parents should always be given copies of diagnostic evaluation reports, treatment plans, Individualized Family

Service Plans (IFSPs), and signed consent forms. This enables the parent to provide information at will and provide back-up documentation for services the child is receiving.

4. Although not required by HIPAA, FERPA, or Part C Privacy Regulations, state laws that mandate reporting of screening, diagnostic, and early intervention information to EHDI programs and to the child's pediatrician are often helpful.
5. The IFSP should include an option for parents to give permission for the document to be shared with EHDI staff, the child's pediatrician, and other healthcare providers.

Implementing the preceding strategies requires strong interagency and personal relations among key stakeholders, including EHDI programs, Part C Early Intervention programs, the child's pediatrician, and family support groups. Consistent training is usually needed at the community level to ensure that all stakeholders understand the importance of sharing information and helping families to be full participants in the process.

Data Management and Tracking

Arranging for a data and patient information management system is a task that is easy to procrastinate. The amount of information that needs to be managed continues to multiply as more and more babies are born. If a system is not in place when the screening programs starts, program staff will soon be overwhelmed in piles of paper and yellow sticky notes. The importance of including an effective information management system in newborn screening programs has been emphasized by the Joint Committee on Infant Hearing (JCIH, 2007, p 913):

Information management is used to improve services to infants and their families; to assess the quantity and timeliness of screening, evaluation, and enrollment into intervention; and to facilitate collection of demographic data...[it is also] used in measuring quality indicators associated with program services.

An appropriate data management system depends on how the screening program is designed. In its simplest form, screening, diagnosis, and early intervention are each provided by a single source or homogenous group of sources. Infants flow seamlessly from the initial screening process to a diagnostic center and receive appropriate treatment or intervention (including family support). In this type of program, a data management system is relatively simple and straightforward. More commonly, however, the screening system has multiple screening sites, several diagnostic facilities, and many different providers who must be involved in the delivery of treatment, intervention, and family support services. Tracking infants through such a system, although

challenging, is the only way to ensure that program goals are met.

Creating an effective data management system is one of the most challenging aspects of operating an effective newborn screening program. If all that was required was to count and report the total number of births, the number of infants screened, and the number who passed and failed, data management would be easy. When all the other information necessary to follow-up and track babies is added, designing a data management system becomes much more complex. Even the simplest of programs generates an astounding amount of data that can quickly overwhelm the capacity of a poorly conceived data management system.

Implementing an effective and efficient newborn hearing screening program is more difficult than it sounds and well-designed and managed data management systems play the following important roles:

1. A "safety net" to ensure that all babies are screened and to identify those babies who need, but have not received, follow-up screening or testing
2. A communication tool that automatically generates emails or letters to parents, healthcare providers, and/or education programs about the results of screening tests, follow-up procedures needed, and/or reminders of upcoming appointments
3. A protocol management assistant that reminds screening program personnel about who should be tested and what procedures should be followed
4. A quality assurance/quality improvement tool that identifies facilities or screeners who are performing above or below acceptable standards so that training and support can be efficiently targeted or superior performance recognized and rewarded
5. A system for documenting system performance so that reports can be made to funding agencies, public officials, consumers, and law makers about what the program is accomplishing and areas where additional resources are needed
6. A basis for integrating data from various health-related programs so that children and families can be provided with better and more efficient services.
7. A tool for collecting data to be used for research about such things as the prevalence, incidence, etiology, comorbidity, predictability, and treatment of various conditions.

The successful accomplishment of all of these purposes requires that the right data be collected in a timely manner and that the data are reliable and valid.

Not only does a good data management system help ensure that babies and their families are receiving timely and appropriate services, but it also helps to document what has been accomplished, identifies areas that need improvement, and provides information necessary for continued improvement and expansion. It is important that the creation and

operation of such systems be done thoughtfully and carefully, because computer-based systems are capable of generating incredibly large amounts of data. If not done carefully, administrators of newborn screening programs may find themselves drowning in information, but starving for knowledge. The key to success is to make sure that the purposes of a newborn hearing screening management system are thoughtfully considered by all stakeholders before a system is purchased or developed. Then the features and capabilities of the selected system must be carefully matched to those goals and purposes. The advice attributed to Mark Twain should be kept in mind, “Data is like garbage. You’d better know what you are going to do with it before you collect it.”

CONCLUSIONS

The current status of EHDI programs in the United States is like the proverbial glass that can be viewed as being either half full or half empty. Certainly, the likelihood of an infant or toddler who is DHH receiving timely and appropriate services is better than ever. The substantial accomplishments of the last 25 years provide an excellent foundation for future progress.

- Ninety-eight percent of all newborns are now being screened for hearing loss prior to discharge and all states and territories have formally established EHDI programs.
- The fact that legislation or regulations related to UNHS have been approved in 43 states bodes well for the sustainability of these programs.
- Although not guaranteed for the long term, federal funding continues to be available for all states to refine, expand, and improve statewide EHDI programs and the Affordable Care Act covers hearing screening as a preventive service.
- There is substantial involvement and support from prestigious federal and professional organizations such as MCHB, CDC, NIH, the American Academy of Pediatrics, the American Academy of Audiology, the American Speech Language Hearing Association, and March of Dimes.
- Screening equipment and protocols continue to improve, and progress is being made on improving connections to diagnostic and early interventions programs and reducing the loss to follow-up/loss to documentation rates that have been so troubling for so long.

According to the National Goals established by CDC, all children who are DHH should be diagnosed before 3 months of age. But we are still a long way from achieving the more modest goal set by Dr. Koop in 1990 that “no child [would reach] his or her first birthday with an undetected hearing loss.” To effectively identify children who are DHH and provide them and their families with the services they need, significant improvement must be made in the availability of pediatric audiologists, tracking and data management, program evaluation and quality assurance, availability of appropriate early intervention programs, and linkages with medical home providers.

In contrast to the early 1990s, there is now a solid research and an experiential basis for addressing all of these issues, but it will continue to require the commitment and resources of state health officials, hospital administrators, healthcare providers, and parents. As pointed out by Wilson and Jungner (1968, p 7 and 26)

... in theory, screening is an admirable method of combating disease ... [but] in practice, there are snags ... The central idea of early disease detection and treatment is essentially simple. However, the path to its successful achievement ... is far from simple though sometimes it may appear deceptively easy.

The issues that need to be resolved are complex and will require stakeholders to continue working together over a sustained period of time. As a result of continuing such work, infants and young children who are DHH will be able to acquire the “fundamental language, social, and cognitive skills that provide the foundation for later schooling and success in society” as foreseen almost 30 years ago in establishing the goals for *Healthy People 2000*.

CREDITS

Supported in part by the Health Resources and Services Administration (HRSA), Maternal and Child Health Bureau under Grant No. U52MC043916. The opinions and conclusions in this article are those of the author and do not necessarily represent the official position of the Health Resources and Services Administration.

FOOD FOR THOUGHT

1. Virtually all newborns in the United States are now screened for hearing loss before leaving the hospital. CDC’s National Goals for EHDI Programs still recommend that “hospitals and others [report] information about risk factors for hearing loss to the state, who will monitor the status of children with risk factors and provide appropriate follow-up services.” What are the pros and cons of continuing to monitor the status of children with risk factors with respect to issues such as identifying childhood hearing loss, costs, demands on the health care system, and burden for families?
2. Although the percentage of children failing a newborn hearing screening test who are lost to follow-up and or documentation is slowly declining, it remains a very significant issue. What approaches, programs, or initiatives are likely to significantly reduce the percentage of children being lost to follow-up?
3. There continues to be a critical shortage of audiologists who have the expertise, experience, and desire to provide comprehensive audiological services to infants and young children. What can be done to increase the number of fully qualified pediatric audiologists?

Assessment of Hearing Loss in Children

Allan O. Diefendorf

INTRODUCTION

Current policy in public health advocacy and primary healthcare delivery has focused on detecting hearing loss in infants and young children within the first 3 months of life through universal newborn hearing screening and timely diagnostic follow-up. This emphasis in hearing health care represents a standard of service delivery that has evolved over the past 45 years of advocacy by the Joint Committee on Infant Hearing (JCIH), and subsequently endorsed by the Centers for Disease Control and Prevention (CDC-P), the National Institutes of Health (NIH), and numerous coalitions of professional organizations.

It should be noted that all professional groups involved in the early detection of hearing loss have endorsed the terminology “early hearing detection and intervention (EHDI) programs.” Experience has shown that, to successfully identify and serve infants and young children (including their families) with hearing loss, professionals had to expand their emphasis from screening to include comprehensive, coordinated, and continuous audiologic care, hence the adoption of the terminology EHDI. To be successful, all components of follow-up from newborn hearing screening need to be included to meet and serve the child’s and family’s complex needs, through coordinated care and collaboration with other professionals, as well as frequently communicated care plans that include intervention goals and strategies for hearing loss. Early referral for suspected hearing loss has evolved into best practice and is supported by undisputable evidence that the earlier confirmation of hearing loss occurs, the earlier intervention can begin, thereby increasing the likelihood of optimizing a child’s full potential in all developmental areas.

The purpose of this chapter is to focus on the audiologic assessment and early diagnosis of infants and young children with hearing loss. Additionally, this chapter is developed with an emphasis on the following premise: Audiologic procedures must be age appropriate, outcome based, and cost-effective, and all procedures must have demonstrated validity and reliability. In addition, audiologic care must be comprehensive, collaborative, coordinated, culturally sensitive, and continuous.

Evidence Supports Early Detection of Hearing Loss

Undetected hearing loss in infants and young children compromises optimal language development and personal achievement. Without appropriate opportunities to learn language, children fall behind their hearing peers in language, cognition, social-emotional development, and academic achievement. However, research demonstrates that when hearing loss is identified early (prior to 6 months of age) and followed immediately (within 2 months) with appropriate intervention services, outcomes in language development, communication competency, and social-emotional development will be significantly better when compared with children with later identified congenital hearing loss (Moeller, 2000; Yoshinaga-Itano et al., 1998). It was also noted that when the same identification and intervention benchmarks are achieved (prior to 6 months of age), children perform as much as 20 to 40 percentile points higher on school-related measures (reading, arithmetic, vocabulary, articulation, intelligibility, social adjustment, and behavior) (Yoshinaga-Itano, 2003).

Early Detection Facilitates Favorable Outcomes

To achieve beneficial outcomes for children who are hard of hearing and deaf, families must be informed about how to find facilities and audiologists who are able to provide age-appropriate, comprehensive, and family-centered follow-up in a timely manner. The CDC-P provides resources to maximize and achieve this outcome (www.cdc.gov/ncbddd/hearingloss/ehdi-goals.html). To facilitate early intervention, audiologists must provide detailed diagnostic evaluation of hearing status within weeks of referral.

The diagnostic evaluation provides the first opportunity for developing a supportive relationship with the family and for initiating an audiologic care plan (diagnosis, counseling, referral if necessary, intervention, and ongoing care coordination as indicated). The interaction with the family during the diagnostic evaluation is critical because the support, counseling, guidance, and education a family receives

at this time helps to facilitate smooth transitions between referral source and early intervention programs. In turn, well-adjusted and well-informed families become empowered to make informed decisions, resulting in a unified approach to audiologic care plans and desired outcomes. Best practices indicate that each stage of the early detection process must be coordinated, collaborative, and communicated with all parties (families, pediatricians, relevant agencies). For a comprehensive review of these practices, see Chapter 44.

ESTABLISHING THE ETIOLOGY OF HEARING LOSS

As with all disorders, early diagnosis enables early intervention and improves prognosis. The importance of early audiologic diagnosis cannot be overstated; often the identification of hearing loss may be the first indication of a com-

promised sensory system or additional health problems. As the child's medical profile develops, a multidisciplinary team may become involved in the child's treatment plan.

After hearing loss is confirmed, consideration should be given to identify the etiology of the hearing loss. Current data indicate that 50% to 60% of congenital hearing loss is because of hereditary factors, with the balance due to environmental causes and, occasionally, interactions between genetics and environment (Dent et al., 2004). Table 24.1 provides a framework for delineating an etiology distribution of hearing loss with selected examples.

Historically, the past 30 years of demographic data have consistently reported that 30% to 40% of children with hearing loss have one or more *additional disabilities* (Gallaudet Research Institute, 2005). Table 24.2 lists physical and cognitive/intellectual conditions that are frequently reported to accompany hearing loss. (See Chapter 31 for more information regarding concomitant disorders.)

TABLE 24.1

Framework for Delineating the Etiology of Hearing Loss

Hereditary Hearing Loss: 50–60% of Hearing Loss

Single gene [nonsyndromic: 60–70%]

Gap junction protein, beta 2: The GJB2 gene provides instructions for connexin proteins which form channels called gap junctions that permit transport of nutrients. Channels made with connexin 26 help to maintain correct levels of potassium ions

Myosin VI: The MYO6 gene provides instructions for proteins that play a role in the development and maintenance of stereocilia

TECTA: The TECTA gene provides instructions for a protein called alpha-tectorin. This protein interacts with other proteins to form the tectorial membrane

Chromosomal abnormality [syndromic: 30–40%]

Usher syndrome: Hearing loss accompanied with eye disease

Jervell and Lange-Nielsen syndrome: Hearing loss accompanied with cardiac defect

Pendred syndrome: Hearing loss accompanied with thyroid goiter [endocrine defect]

Wardenburg syndrome: Hearing loss accompanied with pigment defect [eyes, skin, hair]

Alport syndrome: Hearing loss accompanied with chronic nephritis [kidney disease]

Environmental Hearing Loss: 25–35% of Hearing Loss

Maternal influences

Viral disease: Cytomegalovirus, rubella, mumps

Bacterial disease: Bacterial meningitis, bacterial sepsis

Environmental: Lead, mercury, radiation

Drugs: Substance abuse

Complications after birth

Respiratory distress

Hyperbilirubinemia

Peri/intraventricular hemorrhage

Perinatal asphyxia

Combination of Genes and Environment: <10% of Hearing Loss

Medicines, but only in individuals who have certain mutations in genes

Various

TABLE 24.2

Physical and Cognitive/Intellectual Conditions Accompanying Hearing Loss in Children

Physical Conditions Accompanying Hearing Loss in Children

Pulmonary	Pulmonic stenosis Cystic fibrosis Asthma
Cardiovascular	Cardiac conduction defect Cardiac rhythm disturbance Obstructive congenital heart defects
Ophthalmic	Legal blindness Progressive eye degeneration Cataracts
Neurologic	Cerebral palsy Muscular dystrophy Myoclonic epilepsy
Orthopedic	Syndactyly Hip dysplasia Rickets
Endocrine	Thyroid gland disorders Adrenal gland disorders Pituitary gland disorders
Immunologic	HIV/Aids Allergies Leukemia
Renal	Chronic nephritis Malformations of the kidney Infantile renal tubular acidosis

Cognitive/Intellectual Conditions Accompanying Hearing Loss in Children

Intellectual disability	
Specific learning disability	Attention deficit disorder Auditory perceptual difficulties Visual perceptual difficulties
Emotional/behavioral disorders	Hyperactivity Obsessive/compulsive behavior Aggressive/abusive behavior

Tables 24.1 and 24.2 should be viewed together. The manner in which multiple conditions coexist and the manner in which multiple conditions are expressed (by degree of involvement) contribute to each child's unique developmental profile and subsequent rehabilitation recommendations.

As the widespread use of newly developed vaccines decreases the prevalence of etiologies such as measles, mumps, rubella, and childhood meningitis, the percentage of early-onset hearing loss attributable to genetic etiologies

should increase. The multidisciplinary team should include a geneticist to help establish the etiologic basis for hearing loss to improve outcomes in coordinated and comprehensive care and to provide families necessary information as they consider planning for subsequent children.

COMPREHENSIVE SERVICE DELIVERY IN AUDIOLOGY

The goal of the initial diagnostic assessment of infants and young children is to confirm or rule out hearing loss, to quantify the extent and configuration of hearing loss, and to determine the functional health of the auditory system. Additionally, comprehensive assessment should be provided for each ear even if only one ear was in question from the newborn hearing screening.

Thorough and valid diagnostic information is essential in a timely manner to permit early intervention services. For this reason, age-appropriate, cost-effective, and efficient diagnostic protocols are critical at the earliest opportunity for optimizing early intervention services. In addition, an emphasis on timely scheduling of diagnostic follow-up should occur for children and families whose initial audiometric profile is incomplete.

Additionally, follow-up visits are essential to monitor infant's overall auditory status and changes in hearing, as well as verifying the development of auditory skills and functional use of hearing. It should also be recognized that ongoing surveillance for fluctuating and/or progressive hearing loss must be closely coordinated between the child's primary care provider (medical home) and other service providers in the child's habilitation plan.

Age-appropriate Assessment

The use of age-appropriate techniques in diagnostic audiology is vital in the evaluation of infants and young children. It requires clinicians to select differential diagnostic techniques that are within the child's developmental capabilities. Because children undergo rapid sensory, motor, and cognitive development and because some children will present with multiple health concerns and subsequent developmental challenges, it is vital that assessment tools are appropriate for the neurodevelopmental status of the child. Factors (physical and cognitive) that can influence developmental status must be considered prior to the selection of an assessment strategy. For example, with the goal of audiologic diagnosis by 3 months of age (JCIH, 2007), it is likely that some infants with hearing loss and multiple health concerns will not have had these other disorders identified at the time of the audiologic assessment. Some problems may be relatively easy to identify (e.g., cerebral palsy). Others (e.g., learning disabilities or Asperger syndrome) are more difficult to identify. For this reason, audiologists face challenges when dealing with the variety of characteristics that may

be encountered. Of course, knowledge of the handicapping conditions will enable audiologists to plan effective and age-appropriate diagnostic strategies. Therefore, audiologists should investigate factors involved in each individual by use of interviews, case histories, assessments by other professionals, and close observation. As pointed out by Tharpe (2009), audiologists must be mindful of the possibility that unexpected and/or undiagnosed conditions may influence their testing and subsequent audiologic outcomes.

The Test Battery Approach

It is strongly recommended that the initial audiologic test battery to confirm hearing loss include auditory-evoked potentials (AEPs), physiological measures, and, when developmentally appropriate, behavioral methods. The use of any test alone for assessing children's hearing sensitivity is discouraged. The desirability of using multiple tests in clinical practice is based on the complex nature of the auditory mechanism and the fact that auditory dysfunction may result from pathology at one or more levels of the auditory system. In test battery selection, audiologists use test procedures that are outcome based and cost-effective, and greater weight should be given to the results of those tests for which validity and reliability are highest. If test results are not in agreement, the reason for the discrepancy must be explored before arriving at an audiologic diagnosis.

Jerger and Hayes (1976) promoted the concept of a test battery approach so that a single test is not interpreted in isolation but, instead, various tests act as *cross-checks* of the final outcome (see Chapter 8). Thus, audiologists benefit by having a battery of tests appropriate for the diagnosis of hearing loss in infants and young children. As pointed out by Turner (2003), the purpose of multiple tests is to increase the accuracy of audiologic diagnosis. This accuracy is accomplished when appropriate diagnostic tests are selected for the individual's test battery. Subsequently, tests must be carefully administered and data appropriately interpreted, followed by a clinical decision based on the entire test battery. After weighing the agreement/disagreement between tests, audiologists can reach a confident diagnosis. Clinical decisions involve not only test selection, but also determining the number of tests administered during a single session, interpreting individual test data, and drawing conclusions based on the performance of the entire test battery.

Multicultural Considerations

The US population is becoming increasingly multicultural. Over one-third of the population is represented by racial and ethnic minority groups and approximately 25% of the population over age 5 speaks a language other than English at home (Institute of Medicine, 2002). In addition, these population statistics are expected to increase over the next 30 years.

The Institute of Medicine (2002) reviewed over 100 studies that assessed the quality of health care for various ethnic and racial minority groups. The report highlighted existing disparities in the quality of health care provided to minorities and concluded that very few of these differences in healthcare quality for minorities can be attributed to patient attitudes and preferences. More significant contributors to these disparities include two primary areas: (1) The characteristics of healthcare systems and environmental factors which include cultural or linguistic barriers (e.g., lack of interpretative services), and fragmentation of healthcare systems; and (2) discrimination, including biases, stereotyping, and uncertainty. The report suggests that these disparities might originate from the provider, that is, prejudice against minorities, clinical uncertainty when interacting with minorities, and stereotypes held about minorities.

Linguistic barriers can minimize effective communication and compromise rapport with a family, both leading to poor compliance with audiologic recommendations. Clearly, linguistic barriers degrade the family's expectations of quality service delivery. Poor communication may also discourage familiarity with accessing resources and keeping future appointments.

A useful skill that audiologists must master is the effective use of interpreters when dealing with families who speak other languages. Some techniques to consider for ensuring successful exchange of information include using short concise sentences and pausing frequently between them to allow the interpreter to organize and effectively translate. Additionally, it is necessary to be mindful of nonverbal gestures that may be interpreted differently by different cultures and certain words that may not have the same meaning when translated. Appropriate eye contact and appropriate physical space between individuals are also important considerations in achieving effective communication.

As healthcare professionals, audiologists need to be respectful of and responsive to the needs of a diverse patient population by increasing their knowledge and skill in cultural competence. Perceptions regarding hearing loss differ across cultures. Some cultures may not attribute much significance or urgency to hearing loss and families may only pursue services relative to their specific attitudes and beliefs. Additionally, people from different cultures may not view hearing loss as a disability and may choose to embrace only those recommendations/interventions that are consistent with their cultural values, religious beliefs, or societal norms.

Continued Surveillance

Concern for hearing loss must not stop at birth. It must be recognized that limiting hearing screening to the neonatal period will result in a significant number of children with hearing loss excluded from the benefits of early detection. Some newborns and infants may pass initial hearing screening but require periodic monitoring of hearing to detect

delayed-onset hearing loss. The JCIH (2007) identified 11 risk indicators associated with either congenital or delayed-onset hearing loss, including family history and maternal illness (www.jcih.org/ExecSummFINAL.pdf). Therefore, heightened surveillance of all infants with risk indicators is recommended.

Unlike the newborn and school-age populations when nearly all of the children can be evaluated in hospitals or schools, preschoolers are generally not available in large, organized groups that lend themselves to universal detection of hearing loss. For this reason, an interdisciplinary, collaborative effort is particularly important for this age group. Physicians and other professionals who make up the child's medical home and other professionals who specialize in child development should be included in the planning and implementation of hearing screening programs to increase the likelihood of prompt referral of children suspected of hearing loss.

PEDIATRIC AUDIOLOGIC PRACTICES

Audiologic assessment of infants and young children includes a thorough patient history, otoscopic inspection, and both physiological and behavioral measures. As stated earlier, the need for a battery of tests in pediatric assessment is essential to optimally plan for and meet the diverse needs of the pediatric population.

During the diagnostic process, the integrity of the auditory system is evaluated for each ear, and the status of hearing sensitivity across the frequencies important for speech understanding is described, as well as the type and configuration of hearing loss. In turn, these data provide essential information for medical management when indicated and the data required to begin the amplification process. Finally, these data are further used as a baseline for continued audiologic monitoring.

Patient History

The case history is a component of the audiologic assessment that guides the audiologist in constructing an initial developmental profile based on the child's physical, developmental, and behavioral status. The outcome of the patient history is particularly important because it will often guide the strategy for the audiologic assessment and for making subsequent recommendations and referrals. It can also serve as the first cross-check on the audiologic test outcome.

The patient history process begins as early as calling the child's name in the waiting room. Time spent observing the child from the waiting room to the assessment area can provide valuable information about the child's physical and developmental status.

Some background health-related and developmental information (American Speech-Language-Hearing Associ-

ation, 2004) can be obtained prior to the initial evaluation (by telephone and/or mail). The case history questionnaires are used to gather information regarding the family history, birth history, developmental history (including hearing and speech/language development), and medical history. This information guides the clinician to generate questions as each child's status may require a meaningful history intake process. See "Food for Thought" about the kinds of questions an audiologist should consider while taking a case history.

It is recommended that time for obtaining a patient history be viewed as a valuable opportunity to observe and interact with the child and family, build rapport, and instill confidence and comfort in the child and family, while acquiring patient-specific history information. The single most important thing that may determine the comfort level of the child is the communication between the family (parent/caregiver) and the audiologist.

Otoscopic Inspection

Otoscopy is intended as a general inspection of the external ear and tympanic membrane for obvious signs of disease, malformations, or blockage from atresia, stenosis, foreign bodies, cerumen, or other debris. To promote health and prevent disease it is appropriate to change specula before examining each ear to avoid cross-contamination. In addition, because several audiologic assessment procedures require the insertion of a probe into the external auditory canal, visual inspection serves to verify that there is no contraindication to placing a probe in the ear canal. For further information dealing with infection control, see Chapter 46.

AUDIOLOGIC TEST BATTERY: BIRTH TO 6 MONTHS OF AGE

The goal for both behavioral and physiological procedures is ear-specific assessment. Determining hearing sensitivity for each ear facilitates medical/surgical diagnosis and treatment, selecting and fitting amplification when appropriate, establishing baseline function, and monitoring auditory status when progressive, fluctuating, or late-onset hearing loss is suspected.

Electrophysical Assessments

The audiologic test battery for young infants, birth through 6 months, consists primarily of AEPs to estimate hearing thresholds at specific audiometric frequencies. These measures currently include the auditory brainstem response (ABR) and the auditory steady-state response (ASSR). Other physiological measures that make up the test battery include distortion product otoacoustic emissions (DPOAEs) or transient-evoked otoacoustic emissions (TEOAEs) and acoustic

immittance. (For a more complete discussion of these procedures, see Chapters 11, 13, 14, and 15.)

Measurement of AEPs provides accurate estimates of threshold sensitivity in young infants, with the clinical goal of achieving accurate estimations of frequency-specific, behavioral thresholds from the AEPs. In turn, these data provide the basis for appropriate medical intervention and facilitate early intervention, particularly the selection and fitting of amplification systems.

The differences between estimated and actual thresholds vary for ABR and ASSR. The four most important variations are associated with (1) frequency of the stimulus, (2) degree of hearing loss, (3) age of the patient, and (4) duration of the recording. Of utmost importance is controlling/maximizing the signal-to-noise ratio in all AEP recordings. In infants, noise levels are often higher than in young adults, and the responses are smaller. When the duration of the recording is longer, the residual noise of the electroencephalogram (EEG) is less, making small, near-threshold responses easier to recognize. Specifically, the amplitude of the residual noise decreases by the square root of the number of sweeps. A longer time spent in the recording will result in less background EEG noise, making it easier to recognize responses and be more precise in threshold estimation.

Additionally, because residual EEG noise levels vary from patient to patient, in part because of the level of muscle activity in the recording, it is optimal when patients are relaxed or sleeping during recording. Many children in this age group can be tested during natural sleep, without sedation, using sleep deprivation with nap and feeding times coordinated around the test session. However, active or older infants may require sedation to allow adequate time for acquisition of high-quality recordings and sufficient frequency-specific information.

MODERATE SEDATION

To gain the cooperation of some infants and young children during measurements of AEPs, sedation may be required. However, sedation of pediatric patients, with or without other health problems, may be contraindicated because of factors such as airway obstruction, apnea, cardiopulmonary impairment, and hypoventilation. Therefore, moderate sedation should only be administered by, or in the presence of, individuals skilled in airway management and cardiopulmonary resuscitation. Additionally, the oversight by a sedation team and the availability of age- and size-appropriate equipment, medications, and continuous monitoring are essential during procedures and for resuscitating a child should an adverse sedation event occur.

The ASSR is a synchronized brainstem response elicited by a continuous frequency-specific stimulus that is modulated (i.e., frequency and/or amplitude modulated) and presented at a given frequency. The recorded response is generated in the EEG response rather than specifically

in the auditory brainstem pathway, as is the case with the ABR. Whereas the ABR response is determined through the identification of peaks and troughs in the time domain, the presence or absence of the ASSR is determined through statistical algorithms in the frequency domain.

One shortcoming of the ABR technique is that only one ear and one frequency can be tested at the same time (single-frequency sequential techniques). Another challenge of the ABR to brief tones is that detection of a response in the waveform depends on skilled, subjective assessment of replicated responses, allowing for error in judgment of the presence of responses depending on the experience of the clinician.

On the other hand, ASSRs are detected objectively using statistical tests; as such, their detection does not rely on the experience of the clinician. In addition, the ASSR technique may have other advantages over the ABR beyond automated response detection, including increased frequency specificity, the ability to test simultaneously at multiple frequencies, resulting in more time-efficient protocols, and higher stimulus presentation levels for comprehensive description of severity of hearing loss in the severe-to-profound categories (Picton et al., 2005; Stapells et al., 2004).

The advantage of a test battery in a comprehensive diagnostic assessment of frequency-specific thresholds is that multiple tests enhance our ability to “cross-check” results to arrive at the most responsible diagnosis. This is certainly the case in ASSR and ABR evaluations where the combination of each approach will facilitate the accuracy of low-frequency threshold measures, delineate the complexity of varying configurations of hearing loss, facilitate the accuracy of bone-conduction-measured outcomes, and delineate site-of-lesion assessment, particularly in the diagnosis of neural hearing loss.

If there are risk indicators for neural hearing loss (auditory neuropathy/auditory dyssynchrony [AN/AD]) such as hyperbilirubinemia or anoxia, then audiologic assessment should include click-evoked ABR. When recording a high-level (80 to 90 dB normal hearing level [nHL]) click ABR, responses should be measured separately for condensation and rarefaction single-polarity stimuli, and responses should be displayed in such a way as to identify the cochlear microphonic (CM) (i.e., superimposing averages to identify out-of-phase components). In these instances, precautions must be taken to distinguish the CM from a stimulus artifact.

The JCIH (2007) has included neural hearing loss (e.g., AN/AD) in infants admitted to the neonatal intensive care unit in their targeted definition of hearing loss. The audiologic community must be vigilant concerning this disorder because intervention and management is different from those with sensory hearing loss.

Otoacoustic emissions (OAEs) expand the pediatric audiology test battery by providing a physiological means of assessing preneural auditory function. OAEs are generated by the outer hair cells in the cochlea and serve as an indirect

measure of these cells. OAEs are not, in and of themselves, necessary for hearing, nor are they a mechanism of hearing, but rather, they reflect the status of structures that are necessary for hearing (see Chapter 19).

Transient-evoked OAEs (TEOAEs) are elicited following a transient (click) stimulus at approximately 80 dB peak sound pressure level (SPL). Although the transient click stimulus is a broadband stimulus that is not frequency specific, the response is analyzed in the frequency domain, thus providing information across frequencies from 500 to 5,000 Hz, although test performance is best for mid to high frequencies. DPOAEs are elicited following stimulation with two tones. DPOAEs are measured in response to two tones (primaries) that interact to produce nonlinear distortions in the cochlea. The two tones are typically selected so that the frequency ratio between the tones (f_2/f_1) is 1.22, which is known to produce the largest distortion product at most test frequencies in humans.

Evoked OAEs occur in response to an external auditory stimulus and are present in nearly all normal-hearing individuals. Thus, the presence of OAEs is consistent with normal or near-normal-hearing thresholds in a given frequency region. Response criteria typically include SNR and/or have a response reproducibility of greater than an established percentage at defined frequencies (see Chapter 19 for further details). Schemes for trying to determine the degree of hearing loss and/or predicting thresholds using OAEs have been investigated (Dorn et al., 2001; Gorga et al., 2003). Although some strategies have met with success, there is so much variability that threshold predictions should be viewed cautiously.

Because of their remarkable stability over time within the same ear, OAEs are also useful for monitoring the status of disease conditions that are progressive, including certain genetic disorders such as Usher syndrome (Meredith et al., 1992). In addition, over shorter time courses, OAEs are advantageous for monitoring the effects of treatments that are potentially damaging to the ear, like those involving such ototoxic antibiotics as tobramycin (Katbamna et al., 1999) or such antitumor agents as cisplatin (Ress et al., 1999).

Immittance

Acoustic immittance measures are an integral part of the pediatric assessment battery. Clinical decisions should be made on a quantitative assessment of the tympanogram, including consideration of equivalent ear canal volume, peak-compensated static acoustic admittance, tympanometric width, gradient, and tympanometric peak pressure (see Chapters 9 and 10 for a detailed description of the components of the acoustic immittance test battery).

Under the age of approximately 4 months, interpretation of tympanograms may be compromised when a conventional low-frequency (220- or 226-Hz) probe tone is used (Purdy and Williams, 2000). As such, a higher probe-tone

frequency (e.g., 1,000 Hz) is recommended for identifying middle ear disorders in infants less than 4 months of age, and normative data for 1,000-Hz tympanometry are available for neonates and young infants (Margolis et al., 2003). Once a child reaches the age of 7 months, a low-frequency (226-Hz) probe tone is appropriate. Between 5 and 7 months of age, however, there is still a possibility of false-negative tympanograms in ears with middle ear effusion. Therefore, use of a 1,000-Hz probe tone for tympanometry in this subset of infants is recommended when attempting to identify middle ear effusion.

When a quantitative assessment of a tympanogram is used, care must be taken to ensure that there is correspondence between the graphic representation of the tympanogram and the absolute quantities indicated. With the pediatric population, sometimes there are irregularities in the tympanogram shape (because of movement artifact, crying, or vocalizing) that may be mistaken for a tympanogram peak by the instrument and may provide misleading absolute values.

In addition to providing confirmation of middle ear status, acoustic reflex measurement is useful in the interpretation of other components in the audiologic test battery. That is, the acoustic reflex may provide supplemental information dealing with the functional status of the middle ear, cochlea, and brainstem pathway (see Chapter 10). For example, acoustic reflexes are absent when AN/AD exists (Starr et al., 1996). Although there are insufficient data for routine use of acoustic reflex measurements in the initial diagnostic assessment under the age of 4 months, the acoustic reflex should be used to supplement the test battery at older ages. Together, these measures are fundamental components of the pediatric audiology test battery.

AUDIOLOGIC TEST BATTERY: INFANTS 6 MONTHS OF AGE AND OLDER

Assessing *auditory sensitivity* in older infants and children (>6 months) can be completed efficiently and effectively with behavioral, physiological, and AEPs as necessary. The audiologic test battery for infants 6 months of age and older includes conditioned behavioral audiometry (either visual reinforcement audiometry [VRA] or conditioned play audiometry [CPA]), speech detection and/or recognition measures (i.e., speech recognition threshold), acoustic immittance, and OAEs.

It is also important to establish *auditory responsivity* in selected children. For example, for children who have just received a cochlear implant, it is necessary to observe their initial responses to suprathreshold sounds. Additionally, children with multiple disabilities, including intellectual challenges, also represent a population for whom auditory responsivity is essential. Auditory responsiveness can be evaluated with behavioral observation audiometry (BOA), described in the next section.

AEPs should be performed, as necessary, when behavioral measures are not sufficiently reliable to provide ear-specific estimates of type, degree, and configuration of hearing loss or when these data are necessary to support other clinical questions (e.g., neurologic status). Importantly, the desire for behavioral hearing test results should not delay the selection and fitting of amplification when valid and reliable frequency-specific threshold information is available by AEPs.

As valuable as physiological procedures are in the early confirmation of hearing loss, the audiologist inevitably returns to behavioral testing to substantiate test results and monitor a child's hearing longitudinally. As advocated by Tharpe (2009), "We must bear in mind that behavioral tests provide an indication of how an individual uses his or her hearing, a very important factor when considering management needs" (p. 667).

Behavioral Observation Audiometry

This section will describe techniques in which the audiologist observes a child's responses to sounds to estimate hearing levels. However, before reviewing these techniques, a caution to the reader is essential: Unconditioned behavioral observation techniques with infants and young children are easily confounded by poor test–retest reliability and high inter- and intra-subject variability. This places cautious limitations on the use of BOA for determining *auditory sensitivity*. Therefore, BOA is no longer recommended for assessing frequency-specific threshold sensitivity in newborns, young infants (<5 months), or those children whose developmental disabilities preclude them from learning operant conditioning procedures. However, another goal in pediatric assessment is to examine auditory function by examining *auditory responsivity*. Although AEPs can quantify auditory sensitivity in infants with compromised cognitive function, BOA may provide useful insight into the quality of the child's auditory responsiveness. BOA may also provide an estimate of functional capabilities useful in planning intervention for selected children. That is, the audiologist can predict potential difficulties in auditory development and recommend aural habilitation strategies intended to improve the child's functional use of sound.

PROCEDURAL GUIDELINES

Infants whose motor, cognitive, and/or social development is under 6 months of age generally display a variety of reflexive and orienting responses to external stimuli at suprathreshold levels. Improving the accuracy of observing and judging the presence of these behaviors, however, often requires the use of multiple examiners/observers. That is, a number of examiners/observers are necessary to judge response behaviors to reduce two common errors of observation: (1) Judging that a response occurred when, in real-

ity, there was no response and (2) judging that no response occurred when, in reality, a response did occur.

Observers monitor a range of behaviors, for example, head or limb reflex, increased motion, decreased motion, whole-body startle, eye widening, nonnutritive sucking, searching, eye blink or flutter, localization, smiling, laughing, and pointing. Because of behavior variability, it is important to minimize judgment errors by a single examiner. To add objectivity to BOA, observers should not be informed about presentation levels, should wear headphones with masking during the assessment process, and should be unaware of previous test results.

Response behaviors seen during BOA can be separated into those that are attentive-type, orienting behaviors (e.g., increased and decreased motion, eye widening, searching, localization, smiling, laughing, pointing) and those considered reflexive (e.g., head or limb reflex, whole-body startle [Moro reflex], sucking, eye blink or flutter). Analyzing response behaviors may provide useful information in children with developing auditory behaviors, as well as determining how youngsters attach functional meaning to sound.

Renshaw and Diefendorf (1998) listed three categories into which results of BOA testing may be placed: (1) No observable response to sound, (2) responses only to high-intensity stimuli (70 to 80 dB HL), and (3) responses to relatively soft and comfortable stimuli (30 to 50 dB HL). These categories provide some delineation about results obtained from BOA testing. In concert with BOA as a test of *auditory responsivity* (not *auditory sensitivity*), the categories promote the use of BOA as a behavioral measure, useful to support physiological findings and to verify the presence of a general level of functional hearing.

Instrumental (Operant) Conditioning: Basic Principles

The behavioral assessment of infants and young children can be approached through instrumental conditioning paradigms, specifically through an operant conditioning procedure. Operant behavior is frequently spoken of as wilful or purposeful behavior. In the operant procedure, a behavioral response is elicited by a target stimulus and is then *controlled* by the consequences of that behavior (introducing positive reinforcement). Skinner (1953) stated the term "operant" emphasizes the fact that the conditioned behavior *operates* to generate the desired consequences (receiving positive reinforcement).

In operant conditioning, a stimulus is used as a cue for the listener to respond with a specifically defined behavior (e.g., head-turning for infants). In turn, operant behavior (the head-turning response in infants) is increased by the application of positive reinforcement. Positive reinforcement is used to strengthen the response (operant) behavior and keep the child in an aroused and motivated state to continue to discriminate the target stimulus.

FIGURE 24.1 Test room arrangement commonly used in visual reinforcement audiometry (VRA). A second examiner maintains the interest of an infant in a midline position.

Test Room Arrangement

Figure 24.1 presents a room arrangement commonly used for VRA. The audiologist in the control room has full view of the testing situation. The ability to selectively darken only the audiologist's side of the test booth can be helpful. The infant, parent, and a second examiner are located within the test suite. The visual reinforcers, whether housed in smoked plexiglass enclosures (three-dimensional animated toys) or presented via monitors, are within 3 to 4 feet of the child and placed at 90-degree angles to the side of the child. Providing visual reinforcers on both the right and left of the child increases the complexity and novelty of the VRA procedure. From an instrumentation standpoint, it is a simple and relatively inexpensive matter to use several visual reinforcers on each side, in a stacked configuration. The application of multiple visual reinforcers serves to postpone habituation (Thompson et al., 1992), increasing the number of VRA responses that can be obtained in a given clinical visit.

The second examiner, seated in front of the infant, maintains the infant's head in a midline position by quietly encouraging the child to observe passively or to casually, but quietly, play with colorful, nonnoisy toys (Figure 24.1). An appealing toy is manipulated by the examiner in front of the infant as a distracter. The examiner's role is to maintain the infant's attention at midline and return the infant to this position once a response is made and reinforcement is completed. The audiologist must be creative in keeping the child alert and in a listening posture without the child becoming so focused on the activity. The toys used for this purpose should be appealing but not so attractive as to overly occupy the infant's attention. The closer the audiologist is to the child, the more easily the child is engaged in the activity. If the infant under test shows too much interest in the colorful, nonnoisy toys, then the potential exists for reduced responding during testing or for elevated response levels because of decreased attention. Conversely, if the examiner and toys are not sufficiently interesting, the likelihood of false responses (random head-turning toward the visual reinforcer) will be high.

Often, a touch of the hand on a child's shoe or leg will quietly redirect the child to a midline position. Actually sitting on the floor in front of the child allows for a totally unobstructed view of the child for the control room audiologist and being located slightly below the level of the child is a nonthreatening position. Clearly, the challenge for the second examiner is to balance between distracting the child without overly entertaining the child and consuming too much of the child's attention.

A single examiner approach from the control room can be accomplished by using a distracting "centering toy" positioned at midline in the test room for maintaining a child's midline gaze. Although the use of a "centering toy" is a frequent alternative to the more classical approach of using two examiners, this approach distances the examiner (in the control room) from the infant (in the exam room). Although a single examiner may be more cost-effective and practical in busy clinical settings, eliminating the second examiner reduces the ability to maintain the infant at midline with multiple distraction toys, that is, the "centering toy" is always the same toy, is somewhat noisy, and may be overly distracting for some infants. The fact that the "centering toy" is usually not housed in a dark plexiglass box raises the concern that the constant viewing of the colorful toy may eventually compromise the infant's interest in the visual reinforcement.

Depending on the child's acceptance, insert earphones are preferable over standard headphones. Inserts are useful for a number of reasons, including their comfort and light weight, their increased interaural attenuation compared to conventional earphones, and the reduced risk of ear canal collapse. And, although sound field data alone are better than no data, individual ear data are always preferable and the ultimate goal.

Visual Reinforcement Audiometry

In audiology, an operant discrimination (target) procedure conditions a child to discriminate changes in the listening environment. This approach is used as a threshold procedure where the target stimulus (e.g., puretones, warbled tones, filtered noise, speech) is *discriminated from a quiet background*. This specific procedure in audiology is called visual reinforcement audiometry (VRA), in which the child is reinforced with a visual “reward” (moving toys or video clips) for detecting the stimulus by responding with a head-turn. As demonstrated by Moore et al. (1977), audiometric signals (e.g., puretones or warble tones, and human speech) have limited reinforcing properties. Consequently, a positive reinforcement having high interest value (appealing to the infant) must be used to prolong response behavior in operant conditioning.

This approach also has application in assessing supra-threshold sound discriminations (i.e., visually reinforced infant speech discrimination—VRISD). In this application of the operant discrimination procedure, an infant is conditioned to *detect a discriminative stimulus from a repetitive background*. For example, when trying to determine developmental changes in speech sound discrimination, infants are presented with two of contrastive stimulus items (e.g., /va/ from /sa/) where the discriminative challenge is to detect a change (e.g., the syllable /va/) from a repetitive background stimulus (e.g., the syllable /sa/). Again, the infant is reinforced for discriminating the stimulus change by responding with a head-turn (Eilers et al., 1977).

AGE CONSIDERATIONS AND VRA

Normally developing infants initiate head-turns toward a sound source in the first few months of life. In fact, by the time a normally developing infant has reached a chronological age of 5 to 6 months (Moore et al., 1977), this developmental behavior coupled with operant conditioning enables audiologists to implement VRA.

The success of VRA is related to the fact that the response, followed by visual reinforcement, is well suited to typically developing children between 6 months and 2½ years of age. However, delays in a child’s developmental age can influence assessment outcomes in VRA.

Developmental age adjustments that must be considered in VRA include the influence of prematurity and the influence of mental age on VRA performance. Moore et al. (1992) concluded that VRA performance is related to corrected age for prematurity. They studied 60 premature infants (36 weeks of gestation or less) at corrected ages of 4 to 9 months. Their results imply that premature infants with a corrected age of 8 or 9 months are likely to perform acceptably in response to VRA (can be conditioned and respond with high success before habituation to task); that premature infants with a corrected age of 6 or 7 months may

perform but with less success (can be conditioned but have limited responses before habituation to the task); and that premature infants with a corrected age of 4 or 5 months are not likely to respond to the VRA procedure. A comparison of these data to results of previous studies on full-term infants demonstrates that although full-term infants are likely to respond with high clinical success to VRA by a chronological age of 6 months (Moore et al., 1977), premature infants are not likely to respond to VRA with good clinical success until approximately a corrected age of 8 months.

Widen (1990) also evaluated VRA as a function of developmental age in premature, high-risk babies. Clearly, the developmentally mature babies were more often tested successfully (the ability to be conditioned and provide threshold for at least one stimulus). The data from Moore et al. (1992) and Widen (1990) are highly consistent, that is, both reports indicate that VRA success with premature infants is related to corrected age and that VRA success with these infants is greater as they approach 8 to 9 months corrected age.

Why is it that premature infants, even after prematurity is corrected for, lag several months behind normally developing, full-term infants? Premature infants have been shown to display significantly poorer performance on standardized measures of mental ability when compared to full-term infants of the same postpartum age (Rubin et al., 1973). Kopp (1974) concluded that preterm infants engage in less cognitive exploration compared with full-term infants, which may also account for reduced motor development.

Several studies have reported on the use of VRA in children with Down syndrome and other developmental disabilities. Greenberg et al. (1978) reported on the use of VRA in 46 children with Down syndrome between the ages of 6 months and 6 years. As would be expected, the proportion of successful tests increased as age increased. Because it is expected that chronological age would be a very poor predictor of success with the VRA procedure in these children, the Bayley Scales of Infant Development (Bayley, 1969) were used to provide an estimate of developmental level. If children with Down syndrome are considered on the basis of their developmental age, in contrast to chronological age, it would be logical to assume that results might be similar to those found with normally developing infants. However Moore et al. (1977) found that normally developing infants 6 months of age and older accomplished the VRA procedure with a high rate of success, but Greenberg et al. (1978) found that individuals with Down syndrome did not achieve a high rate until 10 to 12 months BSID mental age equivalent. These investigators further pointed out that when one is predicting potential success with the VRA procedure for children with Down syndrome, the BSID mental age equivalent score provides the most distinct distribution between successful and unsuccessful tests, with the dividing point being a BSID mental age equivalent of at least 10 months. Similarly, Wilson et al. (1983) reported that 80%

of the children in their study with Down syndrome were testable by 12 months of age using VRA.

Although these data provide guidance, attempting behavioral audiologic evaluation on children presenting with any neurologic or development condition, including Down syndrome, under the age of 10 months is encouraged. In a clinical setting with a diverse and complex patient population, it is helpful to obtain any behavioral information that leads to more informed decision making and recommendations.

In summary, when VRA is implemented audiologists must consider (1) corrected age adjusted for prematurity rather than chronologic age or (2) mental age/developmental age when disparities exist between corrected age and the child's developmental status. Of the two predictors of VRA performance (corrected age and mental age), corrected age may be the more practical one to use in most cases because it can be obtained from parental report, case history information, and/or hospital records and does not require testing to determine mental age.

CONDITIONING IN VRA

In clinical assessment, the first phase of VRA is the conditioning process. An examiner must be skilled in response training and sensitive to the various stages of response acquisition. Evidence suggests that different signals (e.g., tones, filtered noise, speech) are equally effective during the conditioning phase (Primus and Thompson, 1985).

Response shaping is critical to the success of the operant procedure. Two different, but commonly used approaches can be implemented to condition the head-turn response: (1) *Pairing* a suprathreshold auditory stimulus with the visual reinforcer or (2) presenting a suprathreshold auditory stimulus and *observing a spontaneous* response from the infant, *followed by* activation of the visual reinforcer. Successful completion of the training phase is the achievement of a pre-established criterion of consecutive head-turn responses (usually two, but no more than three consecutive responses following the response shaping trials). If the criterion is not reached, retraining is necessary until the criterion is met. The number of training trials needed before phase 2 trials begin varies, but the training phase is usually brief.

For the child with special needs, conditioning may take longer to establish the conditioned behavior. Successful completion of the conditioning phase occurs when the child is making contingent responses and random head-turning is at a minimum.

A key to response shaping is the presentation of a suprathreshold stimulus. For most infants, suprathreshold will be 30, 50, and, in some cases, 70 dB. Occasionally, some children, particularly those children with moderately severe to severe hearing loss, may require 90 dB or higher to qualify as a suprathreshold stimulus. Because

hearing status is unknown, suprathreshold estimates are also unknown. Therefore, the possibility exists that the stimulus selected to shape the response behavior might be inaudible. Given that many infants referred for diagnostic work-up can be expected to have normal hearing, the most efficient test is one that uses a low starting level, approximately 30 dB. However, failure to condition rapidly should alert the audiologist to a potential equipment/calibration problem or a child who requires a greater starting intensity for conditioning. Attention to either issue must be immediate for a successful outcome.

When the infant's head-turn is not being shaped via air conduction, a bone oscillator can be placed on the infant's mastoid, in the hand, or rested against the arm to use as a vibrotactile stimulus. The traditional conditioning procedure is initiated, that is, pairing the stimulus with the reinforcement. The stimulus usually selected for bone-conducted conditioning is a 250-Hz narrowband noise presented at 60 dB HL. An infant with severe or profound hearing loss with no other developmental disabilities will show appropriate behavioral responses as long as the stimulus is salient (can be felt, even if not heard). Responses are obtained in this manner; subsequently, insert ear phones or headphone presentations follow with starting intensity levels dependent on the bone-conduction responses.

If the child fails to display conditioned responding, other issues such as compromised physical status, developmental delay, or immaturity are raised. For example, Condon (1991) noted several cognitive attainments necessary for a child to be assessed reliably using VRA. The child must be developing object permanence (i.e., knowing that objects exist in space and time, even when the child can no longer see them or act on them) and the ability to anticipate the reappearance of at least partially hidden objects, discover simple causality (i.e., an event or behavior is dependent on the other for its occurrence) and means-end relationships (i.e., behaviors that result in anticipated outcomes), and use simple schemes to explore toys.

Successful completion of training occurs when the child is making appropriate responses and random head-turning/false responses are at a minimum. Excessive false responses suggest that the infant is not under stimulus control. As such, audiologists should focus on two factors to improve clinical outcomes: (1) Reinstigate response shaping or (2) increase the distraction level of the activity to engage the child's interest at a midline position before presenting the auditory stimulus.

Following successful response shaping, the test phase of VRA begins (Figure 24.2). Signal intensity is attenuated 10 dB after every "yes" response or increased 5 dB after every "no" response (descending and ascending technique). Testing progresses until the stopping criterion (four reversals in the threshold search) has been achieved. Thresholds are defined as the mean of the four reversal points. Note: Thresholds are often called "minimum response levels (MRLs) in VRA

FIGURE 24.2 Algorithm commonly used in visual reinforcement audiometry (VRA).

because the term MRLs “serves as a reminder that improvement in response behavior at lower hearing levels should be anticipated with maturation” (Matkin, 1977, p. 130).

PROCEDURAL GUIDELINES

The recommended trial duration (incorporating the signal and response interval) is approximately 4 seconds (Primus, 1992). That is, although the signal duration is approximately 4 seconds, this 4-second duration also defines the interval of time during which a response should be judged to be present or not. Head-turn responses outside of the 4-second interval are typically not interpreted as valid responses, and therefore not reinforced. For some children with developmental and/or physical challenges, it may be necessary to increase the trial duration (beyond 4 seconds) during which a head-turn response is acceptable. However, by increasing trial duration beyond 4 seconds, audiologists also risk an increase in judging false responses as valid responses.

Conditioned head-turns are visually reinforced only for correct responses that occur during signal trials. Between the ages of 6 and 17 months, Lowery et al. (2009) demonstrated that infants are not more or less attentive to a dynamic video than to the three-dimensional animated toy as effective visual reinforcement. Therefore, when using colorful, three-dimensional toys as visual reinforcers it is sometimes judicious to use the light initially (showing the toy), eventually

adding animation. By starting with the light only, the audiologist can gauge any potential for a fearful response to the three-dimensional toy. The novelty and strength of visual reinforcement may be preserved longer by introducing more complex reinforcement (light plus animation) as the testing progresses. The novelty of VRA is clearly strengthened with somewhat older children by using moving images generated by a digital video disc (DVD) player/monitor. Schmida et al. (2003) used digital video with 19- to 24-month-old children. Their results demonstrated a greater number of head-turn responses before habituation when viewing video reinforcement than when viewing conventional animated toy reinforcement. These results support the hypothesis that the complex and dynamic nature of the video reinforcement would be more effective in achieving a greater number of responses than the conventional toy reinforcer prior to habituation in the 2-year-old age group.

In general, a 100% reinforcement schedule (reinforcement for every correct response) results in more rapid conditioning, yet more rapid habituation. Conversely, an intermittent reinforcement schedule produces slower conditioning but also a slower rate of habituation. Consequently, most clinicians recommend a protocol that begins with a 100% reinforcement schedule and then gradually shifts to an intermittent reinforcement schedule.

Primus and Thompson (1985) compared a 100% reinforcement schedule to an intermittent reinforcement schedule with 2-year-old children. The two reinforcement

schedules resulted in no differences in the infants' rate of habituation or the number of infant responses to stimulus trials. These findings provide an excellent guideline for delivering reinforcement. Since Primus and Thompson's data suggest that withholding reinforcement should not affect the amount of response behavior, reinforcement should only be provided when the audiologist is certain about the validity of an infant's head-turn response. The risk of reinforcing a random head-turn is that it may lead to confusion for a child during the test session and increase the child's rate of false responding. Conversely, failure to reinforce a valid head-turn will not degrade subsequent responding. In this scenario, withholding reinforcement for a valid but ambiguous response is simply viewed as intermittent reinforcement.

Reinforcement duration is also a factor influencing response outcome from children around the age of 2 years (Culpepper and Thompson, 1994). Decreasing the duration of a child's exposure to the visual reinforcer (e.g., 4 to 0.5 seconds) results in an increase in response behavior and a decrease in habituation. Audiologists may increase the amount of audiometric information obtained from children by decreasing their exposure to the visual reinforcer. For the child with special needs who may have a slower response, the visual reinforcer should be activated for a sufficient length of time for the child to very briefly observe it, but prolonged visual reinforcement should be avoided.

CONTROL TRIALS

Ensuring valid behavioral assessment outcomes depends on separating true responses from false responses during threshold acquisition. Infants are likely to produce a number of false responses during clinical assessment. To quantify false responding behavior in VRA, the use of control trials are necessary.

False responses are monitored by inserting control trials in the staircase algorithm (see Figure 24.2). A head-turn observed during a control trial is evidence of false responding. Thus, it is possible to systematically estimate errors or chance responding (false responses during signal trials) by calculating the number of false responses during control trials. Moore (1995) recommended that one out of four presentations should be a control trial and that test results are questionable if the false-positive rate exceeds 25%. Eilers et al. (1991) suggest that a false alarm rate of 30% to 40% is acceptable and adopting such a rate as acceptable does not compromise the accuracy of thresholds for clinical assessment. Clearly, high false alarm rates (>50%) require the audiologist to further consider that test results may be inaccurate.

Excessive false responses suggest that the infant is not under stimulus control. In this situation, audiologists should focus on two factors to rectify clinical outcomes: (1) Reinstating phase 1 shaping and conditioning and (2) increasing the entertainment level of the distraction activity to engage

the child's interest and attention at a midline position before starting a test trial. When in the test room, an examiner must be able to choose from a variety of toys available and judge when a toy change in either direction (enhanced distraction and more entertaining, or reduced distraction and less entertaining) is necessary to maintain the child's midline focus and optimum response readiness.

Occasionally, overactive parents can bias their children to respond, thereby resulting in excessive false responses. Therefore, parents may need to wear headphones through which music or noise is delivered.

Threshold determination in audiometry is based on the lowest intensity level where responses are obtained approximately 50% of the time. In VRA, as the staircase algorithm is executed, how many reversals should be required before identifying the hearing threshold? Too few reversals may sacrifice response accuracy. However, too many will increase test time, in turn reducing the number of stimulus presentations that could be spent obtaining thresholds to other stimuli. Assessing a desired stimulus may be stopped once the infant has exhibited between three and four response reversals (Eilers et al., 1991). Eilers and her colleagues found that using six rather than three response reversals before discontinuing the threshold search had minimal effect on threshold. Yet, tests with a three-reversal stopping rule were significantly shorter than those with six reversals. As stopping rules are increased from three to six, there is about a 50% increase in the number of test trials, with no improvement in response accuracy. These results suggest that, by using relatively few reversals to estimate threshold, a staircase algorithm may be shortened to increase efficiency without sacrificing accuracy. Thus, there is no need to continue testing beyond three or four reversals since the results obtained are not substantially better.

Thresholds obtained with the VRA procedure for infants 6 to 12 months of age have been shown to be within 10 to 15 dB of those obtained from older children and adults (Nozza and Wilson, 1984). In addition, VRA thresholds are similar across the age span (6 to 24 months) and show good reliability when compared to thresholds obtained from the same child at older ages.

Throughout testing, audiologists must consider that the next response to a test stimulus may be the child's last response. However, audiologists can influence attention and motivation by being flexible with their clinical decision making. Often, if a child begins to habituate to a specific stimulus, response behavior can be increased by using a different stimulus, a different transducer, or moving to the other ear. This approach to clinical assessment can optimize air conduction/bone conduction, another puretone versus speech, and switching ears. Thompson et al. (1992) also demonstrated that when 1-year-old children habituate to testing and are given a 10-minute break, the children return and are likely to provide a significant amount of additional information. Even a few additional responses in the same

session may provide just enough additional information to be confident that hearing loss is not a factor concerning speech/language development and communicative functioning, thereby eliminating the need for a costly follow-up clinic visit.

Conditioned Play Audiometry

Operant conditioning of behavioral responses to sound continues to be an effective approach for older children. What changes as children age, however, are the operant behaviors and the reinforcement that is used. Similar to operant conditioning in VRA, CPA uses positive reinforcement to increase response behavior. In CPA, children learn to engage in an activity (e.g., putting rings on a spindle, putting pegs in a board, dropping or stacking blocks, putting together simple puzzles) each time they hear a test signal. These activities are usually fun and appealing to children, are within their motor capability, and represent a specific behavior that is used to denote a deliberate response to a stimulus.

When teaching children to perform CPA, it is usually not difficult to select a response behavior that children are capable of performing, as long as the audiologist is intuitive in matching the child's motor skill with an appropriate play activity. CPA follows the traditional operant conditioning paradigm of stimulus → response → reinforcement, in which the play activity/motor activity is the response behavior, and social praise or other positive reward is the reinforcement. Three decisions are needed in play audiometry: First, the audiologist must select a response behavior that the child is capable of performing. Second, the audiologist must consider how to teach the child to wait, listen, and respond only when the auditory signal is presented. The third decision is what social reinforcement (the most common reinforcement with young children) the audiologist should give that is natural and genuine at the appropriate time and interval.

Separation of response behavior and reinforcement is essential in CPA. Although the play activity is fun for the child, it is not the reinforcement. A separate reinforcement is essential to minimize habituation and maximize repeated response behavior. In addition to social praise, other forms of reinforcement have been suggested. Tokens that can be traded for small toys at the end of the test session, unsweetened cereal, and a changing computer display screen all have been used successfully with play audiometry.

Children with multiple health concerns present unique challenges during audiometric evaluation using CPA. Challenges to consider include obtaining verifiable responses, choosing reinforcements that will interest the child, and response time. For children who have visual and hearing impairments, Holte et al. (2006) suggest using tactile cues (bone oscillator or simple touch) to train a child to the CPA task. For youngsters with limited gross motor/fine motor skills, a variety of responses (e.g., finger swing, hand motion,

arm motion, eye motion, visual gaze) can be used to trigger an electronic switch, in turn activating a computer screen programmed for appropriate visual reinforcement. The goal is to select the most appropriate task and the most appropriate reinforcement while at the same time recognizing the physical limitations that may compromise the child's success. If the physical demands are too great, then the task will detract from maintaining a listening posture. If the task is too simple, the child will have less motivation to participate and will tire of the task. The critical decision for the audiologist is to select a specific operant behavior that is used to denote a specific response to a stimulus.

In general, the rate of success in obtaining detailed information with CPA is limited for children under the age of 30 months. However, some 2-year-olds can be conditioned to play audiometry (Thompson et al., 1989). In addition, when 2-year-olds are proficient with CPA, there is a greater likelihood that they will provide more responses before habituation than they would if tested by VRA. Because overlap exists between VRA and CPA as suitable techniques with children in this age range, the successful evaluation of a younger child with CPA ultimately depends on the following: The audiologist's observational skills of the child's developmental/maturational level, the interpersonal skills established between the audiologist and child, and the experience/comfort level of the audiologist with young children.

Striving to improve behavioral testing techniques is important because behavioral tests always are ultimately expected to define the response profile of young children. In addition, behavioral tests provide the critical link between AEPs and the child's demonstration of functional hearing.

TESTING SPEECH THRESHOLDS AND RECOGNITION

Speech Thresholds

Because language and vocabulary are emerging in infants and young children, it may not be feasible to establish a traditional speech reception threshold (SRT). An alternative approach is the determination of a speech detection threshold (SDT).

The SRT and SDT represent different criteria (intelligibility vs. detectability). The SRT is recognized as the intensity at which an individual is able to identify simple speech materials approximately 50% of the time. The SDT may be defined as the level at which a listener may just detect the presence of an ongoing speech utterance (e.g., bai-bai-bai presented with an overall duration of approximately 2 to 4 seconds). Speech can be detected at intensity levels lower than it can be understood, on the order of 8 to 12 dB.

The child who is ready for play audiometry typically has a communication strategy to express needs and wants at a more sophisticated level, whether with oral speech, signs, or a communication board. Family members often describe

various communication skills that the child possesses, such as following commands, pointing to body parts or pictures in a storybook, or identifying colors. The audiologist is then able to expand the test battery to include an SRT rather than an SDT. Additionally, at an age where play audiometry is successful, the SRT should be accomplished with insert earphones. The lighter weight of insert transducers coupled with increased comfort facilitates placement of the bone-conduction transducer for obtaining bone-conducted SRTs for each ear.

A spondee picture board can be very helpful in obtaining an SRT from a child who may be reluctant to respond in an unfamiliar test situation. Regardless of whether the response is verbal or pointing to a picture, it is recommended that a preliminary step in determining an SRT for young children is familiarizing the child with the test stimuli and eliminating those words that are not within the child's receptive vocabulary. The use of either picture or object pointing rather than a verbal response will require that the number of items be limited to less than 10. Otherwise, the visual scanning task and the demands placed on memory and attention become contaminating variables.

The utilization of a carrier phrase, such as "point to" or "show me," will often serve to focus the child's attention to the auditory task at hand. Moreover, since a child's attention span is limited and test time can be a factor, it is often more expedient to work in 10-dB rather than 5-dB steps when establishing an SRT.

The bone-conducted SRT can be extremely useful in obtaining additional data from children, and although it is typically underused, it is readily available to audiologists. The bone oscillator will deliver clear speech stimuli without any need for calibration correction or modification.

A bone-conducted SRT can offer valuable information in a very short period of time. Often the child will tolerate the bone oscillator during the more entertaining speech reception task but will not tolerate it for tonal testing. A frequently asked question regarding the use of the bone oscillator for speech reception testing relates to the potential for a false threshold that results in a vibratory response rather than a hearing response. It is true that the bone oscillator will vibrate for a speech stimulus, as well as low-frequency tonal stimuli, as the maximum output of the bone oscillator is approached. However, an important distinction must be made. A child will not be able to select the appropriate picture or item on the basis of a tactile sensation alone. If the child can complete the SRT, then a true hearing threshold by bone conduction has been obtained, and concerns regarding simply a vibratory response can be eliminated.

The value of the bone-conducted SRT becomes even greater with the introduction of masking. Many youngsters become confused when masking is introduced during puretone testing. With the bone-conducted SRT, it is relatively easy to introduce masking into the nontest ear without interruption of the SRT procedure. Confirmation of a bilat-

eral conductive component to a hearing loss is possible for many children who will not cooperate for masked puretone testing. Similarly, a unilateral sensory/neural or conductive hearing loss can be confirmed.

Speech Recognition

The measurement of speech recognition with the pediatric population must consider the selection of test materials within a child's receptive vocabulary competency. Haskins (1949) developed phonetically balanced (PB) lists composed of monosyllabic words selected from the spoken vocabulary of kindergartners (PB-K). Clinicians must exercise caution in administering this test unless there is a relatively good assurance that the receptive vocabulary age of the child approaches at least that of a normal-hearing kindergartner (i.e., 6 years of age or older) (see more detailed information below).

To bypass this problem, Ross and Lerman (1970) developed the Word Intelligibility by Picture Identification (WIPI) test. The WIPI test includes picture plates with six illustrations per plate. Four of the illustrations have words that rhyme and the other two illustrations are presented as foils to decrease the probability of a correct guess. The use of WIPI materials is appropriate for those children with receptive vocabulary ages of 4 years and greater.

There are differences between the PB-K words and WIPI test approach to speech perception testing besides the evident fact that the latter is pictorially represented. PB-K words represent an open response paradigm in which the child is forced to give a response from an unlimited set of possibilities, whereas the WIPI is a closed response set with the child's response being a forced choice. As such, the use of the WIPI as a closed-set test improves the discrimination scores by about 10%.

The Northwestern University-Children's Perception of Speech (NU-CHIPS) test by Elliott and Katz (1980) was developed as a speech perception test appropriate for younger children. Test materials are limited to monosyllabic words that are documented to be in the recognition vocabulary of children with normal hearing as young as age 3 years. Additionally, the authors report that children with hearing loss and a receptive language age of at least 2.6 years demonstrate familiarity with the words and pictures on the test.

Historically, several criteria were considered essential in selecting test items for measuring children's speech recognition including word familiarity, homogeneity of audibility, and phonetic balancing (i.e., to have phonemes within a word list represented in the same proportion as in English). When test item construction is constrained by phonetic balancing, the resulting word lists may contain words that are unfamiliar to children with hearing loss. A lexical approach to test construction, sensitive to the frequency of occurrence of words in the language and to the lexical similarity of target words, may result in measuring spoken word recognition with greater accuracy in children with hearing loss.

The Lexical Neighborhood tests (LNTs) (Kirk et al. 1995) assess word recognition and lexical discrimination in children with hearing loss. A primary goal in the development of these perceptual tests was to select words that were likely to be within the vocabulary of children with profound hearing losses. These tests approach speech perception from the perspective that word recognition performance is influenced by the lexical properties of the stimulus words.

Kirk et al. (1995) examined the effect of lexical characteristics on a group of pediatric cochlear implant users' spoken word recognition and compared their performance on the LNT and Multisyllabic Lexical Neighborhood Test (MLNT) with scores on the traditional, PB-K. Word recognition was significantly higher on the lexically controlled lists than on the PB-K. In fact, only 30% of the words on the PB-K were contained within the childhood language database from where the words for the LNT and MLNT were derived. It may be that the restrictions imposed by creating a PB word list result in the selection of test items that are unfamiliar to children with hearing loss.

SUMMARY

The standard of care in the United States for EHDI is founded on hearing screening by 1 month of age, audiologic diagnosis by 3 months of age, and intervention by 6 months of age. The accuracy and precision of our audiologic test battery is critical in achieving valid diagnostic outcomes in a timely manner. Important and fundamental decisions in management and intervention depend on the audiometric outcomes and diagnosis provided by audiologists. Clearly, information must be accurate, precise, timely, and cost-effective to provide optimal service and help families move forward with intervention. When achieved, the goal of optimizing a child's communication behavior and global development is positively influenced, and a family's empowerment is significantly enhanced.

FOOD FOR THOUGHT

1. What kind of information should be collected for a child's case history?
2. What is an age-appropriate, cost-effective, and efficient diagnostic protocol for a 12-month-old normal developing and cooperative child referred for suspected hearing loss?
3. What is the impact of receptive vocabulary on the measurement of speech perception with the pediatric population?

Genetic Hearing Loss

Carmen Brewer and Kelly King

INTRODUCTION

Although familial hearing loss has long been recognized, at the time of the first edition of the *Handbook of Clinical Audiology* (1972), our knowledge of hereditary hearing loss was limited to phenotypic descriptions and inheritance patterns. In his landmark manuscript, *Hereditary Deafness in Man*, Konigsmark (1969) described a classification system for hereditary hearing loss based on associations with deficits in other body systems (what we now call *syndromic* hearing loss). In 2003, the Human Genome project successfully sequenced the approximately 23,000 *protein coding genes* contained within human *chromosomes*, which provided a reference for normal genetic structure and function, and consequently, improved understanding of damaged genes and genetic mutations. These and other milestones, including identification of the first location for *nonsyndromic* hearing loss along a chromosome (Guilford et al., 1994) and the causative gene (Kelsell et al., 1997), have greatly influenced both research and clinical practice surrounding hereditary hearing loss.

The science of genetics now plays a significant role in our understanding of the auditory system. Genetics, quite simply, plays a part in most biologic aspects of living, and as our understanding of this branch of biology evolves, our application of this information in the diagnosis and management of patients becomes more commonplace. It is rapidly becoming apparent that the clinical audiologist must be knowledgeable about the fundamentals of genetics and hereditary hearing loss, including the common terminology, multitude and array of causative hearing loss genes, variety of associated syndromes, and usefulness of genetic diagnosis in patient counseling and management.

An introduction to genetics can feel like learning a new language, and although fundamental concepts are often accessible, assimilating new terminology may feel daunting. In an effort to facilitate learning, we provide a glossary of common terminology associated with hereditary hearing loss, available at the end of the book. The reader is referred to this glossary for any italicized term they are not familiar with, although most of these will be defined within the body of the text as well.

EPIDEMIOLOGY OF HEREDITARY HEARING LOSS

Based on extensive surveys conducted in schools for the deaf (Morton 1991) and newborn hearing screening statistics (Mehra et al., 2009), it is estimated that 2 to 3 of every 1,000 newborns has significant permanent hearing loss, and 90% of these children are born to hearing parents. Of these, 1:1,000 born in the United States will develop profound hearing loss in early childhood.

Etiologies of congenital or early-onset hearing loss can be environmental or genetic (Figure 25.1), of which at least 50% has a genetic origin. Of those children with a genetic hearing loss, approximately 30% have a recognized syndrome and the remaining 70% have nonsyndromic hearing loss. Approximately 80% of hereditary, nonsyndromic, prelingual hearing loss is inherited in an *autosomal recessive* pattern and 15% to 20% in an *autosomal dominant* pattern (see glossary and discussion below for definitions of *autosomal recessive* and *autosomal dominant*). Additionally, 1% to 2% of hereditary hearing loss is linked to genes on the sex chromosomes (*sex-linked inheritance*). An even smaller percentage is due to mutations in *mitochondrial DNA* (Arnos, 2013).

Epidemiologic figures describing the incidence and prevalence of hereditary hearing loss will no doubt evolve over the coming years as more children are identified through early detection programs and as our ability to identify and understand complex genetic conditions expands.

REVIEW OF BASIC HUMAN GENETICS

In humans, the repository of genetic information is the molecular material deoxyribonucleic acid, or *DNA*. DNA is passed from parent to offspring and contains the instructions necessary for development and survival. It is found in the nucleus and mitochondria of nearly all cells of an organism and is composed of long strands of *nucleotides*, made up of sugar, phosphate, and four chemical bases: *adenine* (A), *thymine* (T), *guanine* (G), and *cytosine* (C). These molecular building blocks are woven into strands that form the now widely recognized double helix shape. The organization of

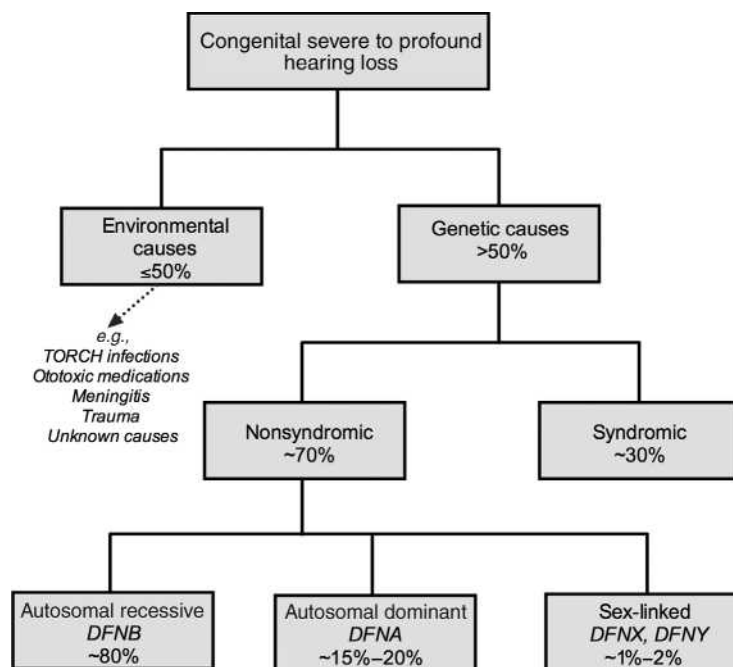

FIGURE 25.1 Causes of congenital severe-to-profound hearing loss in children.

these strands is dictated by a specific pairing of the bases (referred to as *base pairs*); A always pairs to T, and G always pairs to C. For example, a strand of DNA may look like AATGGGCTACTA, and its complementary, paired strand would be TTACCCGATGAT.

The chemical instructions contained within a strand of DNA are determined by the order, or sequence, in which the bases are arranged. A segment of coding DNA that contains enough information for the production of a protein or proteins is called a *gene*, the basic unit of *heritability*. The DNA contained within the human *genome* holds approximately 23,000 genes, which, collectively, control a great variety of biologic functions necessary for life.

Genes

Specific regions of DNA within a gene can be defined by their function; *exons* contain sequences of DNA that instruct (encode) for the arrangement of *amino acids*, which link and form proteins through a process known as *translation*. The nucleotides in a coding region are arranged into groups of three, forming *codons* each of which command production of a specific amino acid. There are a total of 20 amino acids used to form proteins in humans, and the beginning and end of the chemical translation into a protein is determined by specific coding regions, called *start* and *stop codons*. Noncoding segments of DNA (e.g., *introns*) are interspersed among exons and, although the function of these regions is not entirely understood, they are removed, or spliced, during the process of *transcription*. Additionally, there are regulatory segments of DNA that control aspects of transcription and genetic expression.

Chromosomes

To pack the nearly 3 billion base pairs of the human genome into the nucleus of a cell, DNA is tightly organized into chromosomes. Humans have 46 chromosomes, arranged into 23 *homologous* (corresponding) pairs. One copy of the chromosome pair is inherited from the female parent's egg cells and the other copy is inherited from the male parent's sperm cells. The first 22 pairs of chromosomes, called *autosomes*, are the same in males and females and are numbered (1 to 22) from largest to smallest, based on their relative size. The remaining pair of chromosomes, the sex chromosomes, determines a person's gender. In females, there are two X chromosomes, whereas males have one X and one Y. As DNA replicates in preparation for cell division, chromosomes play a critical role in ensuring that molecular information is copied accurately and carried into the new cell. Chromosomes can be viewed using a light microscope, and collectively, their number, structure, and organization is known as a *karyotype*. Notably, genes associated with either syndromic or nonsyndromic hearing loss have been identified on all 23 chromosomes in humans (Figure 25.2).

Except for the Y chromosome, which has only a few genes, there are thousands of genes contained within each chromosome. Each gene has a specific physical location on a chromosome, called a *locus* (pl. *loci*). To understand the strategy for identifying a gene and its position on a chromosome, one must appreciate how chromosomes are organized. Each chromosome has a short and a long extension, or arm (identified as *p* and *q* arms, respectively). The p and q arms are connected by a *centromere*. The ends of chromosomes are called *telomeres*. In *cytogenetics*, the branch of biology concerned primarily with studying chromosomes,

Loci and genes for nonsyndromic deafness and usher syndrome

1/9/2014

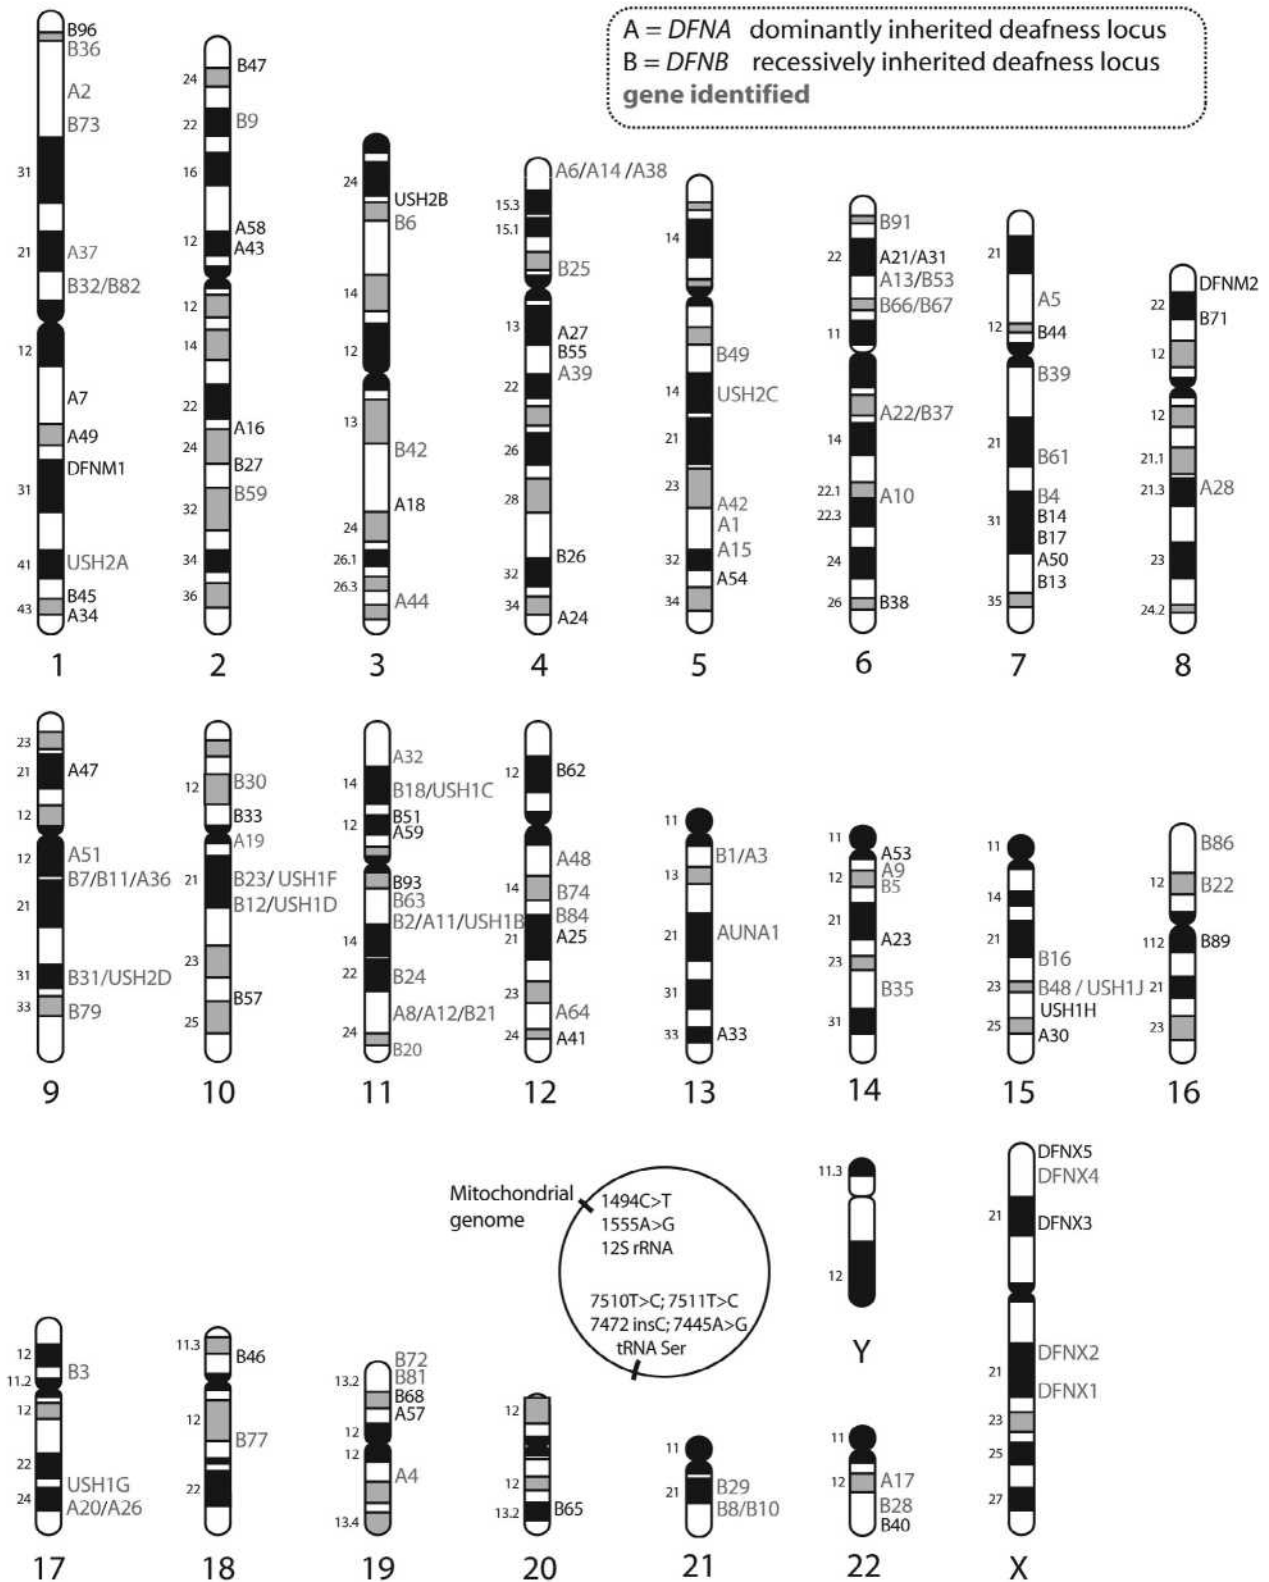

FIGURE 25.2 Nonsyndromic deafness loci and genes shown by chromosome [autosomes and sex chromosomes] as well as the mitochondrial genome, updated from Friedman and Griffith [2003].

staining is used to examine the chromosome, which results in light and dark horizontal segments, or bands. Each chromosome has a unique pattern of banding and each band is numbered. Therefore, regions along a chromosome can be mapped, or identified, by providing the chromosome number, the arm of the chromosome, the region along the arm, and the corresponding band and subband, if applicable. For example, the locus for the gene *GJB2* is 13q12.11. This gene is located on chromosome 13, on the long arm (q) at region 1, band 2, subband 11 (pronounced as “thirteen q one two point one one”).

Genotype–Phenotype

In humans, the percentage of DNA that is the same from person to person is 99.5%, and yet as a species we contain a large degree of variation in how we look and how our bodies function. An individual’s *genotype* is their specific genetic composition, that is, the combination of *alleles*, or variations in genes, that make each person unique. The manifestation of these genes into observable traits (e.g., eye color) is called a *phenotype*. Many genes have a variety of normal alleles associated with them, resulting from *polymorphisms*, or variations in the DNA sequence that do not have an adverse effect. The sum of this normal genetic variation in each person specifies our anatomy and physiology (e.g., height, metabolism). When the alleles of a gene on homologous chromosomes are the same, the genotype is described as being *homozygous*. When the alleles of a gene are different on each chromosome, they are described as *heterozygous*. In men, most genes on the X chromosome do not have a counterpart on the Y chromosome, meaning they are *hemizygous* (having only one copy) for those genes.

Genetic Mutations

Genetic *mutations* occur when the nucleotide sequence of a gene is altered in such a way that it changes the protein output, often affecting the structure and function of an organism. Mutations can result from substitutions, *insertions*, or *deletions* of nucleotide bases, which then alter the normal allele and the associated *wildtype*, or naturally occurring phenotype (these are described in Table 25.1). When the substitution of a single nucleotide occurs but the total number of nucleotides in the sequence remains unchanged it is known as a *point mutation*. In some cases, there is no effect on the protein product and the mutation is considered silent. Alternatively, a point mutation may cause the substitution of a different amino acid, in which case it is called a *missense mutation*, or it may change the sequence to instruct for a premature stop codon, known as a *nonsense mutation*. This latter type of substitution often renders the protein nonfunctional.

When nucleotides are inserted or deleted into a sequence in multiples of three (recall that proteins are

TABLE 25.1

Analogy of Mutations at the Molecular Level

Coding Sequence	Mutation Type
The boy ate one hot dog	Wildtype
The boy ate one <i>not</i> dog	Missense
The boy ate	Nonsense
The boy ate one <i>big</i> hot dog	Insertion
The boy ate ____ hot dog	Deletion
The boy <i>uat</i> eon eho tdo g	Frameshift–insertion
The boy teo neh otd og	Frameshift–deletion
The boy ate <i>ate ate</i> one hot dog	Expansion

coded by groupings of three base pairs) an amino acid(s) may be added or missing, or it may produce an abnormal stop codon. Insertions or deletions in multiples of three only affect the involved codon and subsequent codons will be unaffected. If the insertion or deletion of nucleotides occurs by some multiple other than three, all subsequent codons will be affected, thus shifting the entire remaining sequence, or reading frame. This is known as a *frameshift mutation*. Sometimes, short sequences of DNA are incorrectly repeated within a sequence, known as an *expansion*. See Table 25.1 for an analogy of the common types of mutations that can occur at the molecular level.

Mendelian Inheritance

Mutations that occur at the level of a single gene may follow one of three inheritance patterns: Autosomal dominant, autosomal recessive, or sex linked. These patterns of *Mendelian inheritance* are distinguished from one another by which type of chromosome the mutation occurs on (autosomal or sex chromosome) and by how many mutated alleles are necessary for the affected individual to express the trait (one or two). A thorough family history will help identify the mode of inheritance in many cases and even complex histories can be efficiently and effectively captured using a charting tool called the pedigree. A *pedigree* is the visual representation of a family’s health history and its use in distinguishing heritable conditions has become common practice across medical disciplines.

Pedigrees are created using a common set of symbols to catalog the occurrence and presentation of phenotypes within a group of related individuals. Each person is depicted by a symbol (e.g., circle indicates female and square indicates male), and their genetic relationship to other individuals is traced through connecting lines and across generations. Filling or shading the symbol identifies affected individuals, and each row within the pedigree represents a different generation within the family. The first affected family member to come to medical attention is known as the *proband* and is depicted on the pedigree by an arrow next to their symbol.

For a complete review of current standard nomenclature, including common symbols, definitions, and abbreviations for human pedigrees, see Bennett et al. (2008).

AUTOSOMAL DOMINANT INHERITANCE

In autosomal dominant inheritance, an individual only needs one mutated allele to express the trait. In such cases, an affected child typically will have one affected parent from whom they inherited the mutated gene, and they will have a 50% chance of passing on the mutation to their offspring. Conversely, an unaffected child of a parent with the trait will have no risk for passing on the condition. It is important to remember that the risk of inheritance for any condition does not change based on the number of pregnancies and is calculated in the same way for each pregnancy. *Obligate carriers* within a family are members who have one copy of the gene mutation in question based on the pattern of inheritance. In autosomal dominant inheritance, it is relatively easy to identify the obligate carriers because they most often express the phenotype; any member carrying the dominant gene for hearing loss will have hearing loss (assuming 100% *penetrance*—see next paragraph for a discussion of penetrance). In these cases we see a vertical transmission pattern where every generation has at least one affected individual, and males are equally as likely to express the trait as females. See Figure 25.3 for an example pedigree of a family displaying an autosomal dominant inheritance pattern.

An exception to the common vertical transmission pattern associated with autosomal dominant inheritance occurs in instances when there is a *de novo mutation*, or the first occurrence in the transmission line. In such cases affected individuals will not have an affected parent; however, the risk for recurrence in their offspring remains the same (50%) as someone with an inherited autosomal dominant mutation. Similarly, there are examples of autosomal dominant gene mutations where not every person who has the mutation expresses the trait. This is known as the *penetrance* of a gene, or the percentage of individuals carrying a dominant mutation who actually express the trait. When a dominant mutation has incomplete penetrance, not every obligate carrier will have an associated phenotype. In a similar fashion, an autosomal dominant gene may be completely penetrant, but vary in how the phenotype is expressed among individuals (e.g., varying degrees of hearing loss). This is known as *variable expressivity*. The penetrance and expressivity of a heritable disorder can be described for all patterns of Mendelian inheritance and do not apply just to autosomal dominant traits.

AUTOSOMAL RECESSIVE INHERITANCE

When the inheritance pattern is identified as autosomal recessive it means an individual must have two copies of a mutated gene to express the associated phenotype. Classically, this signifies an affected child with two heterozygous unaffected parents who each have one copy of the mutated

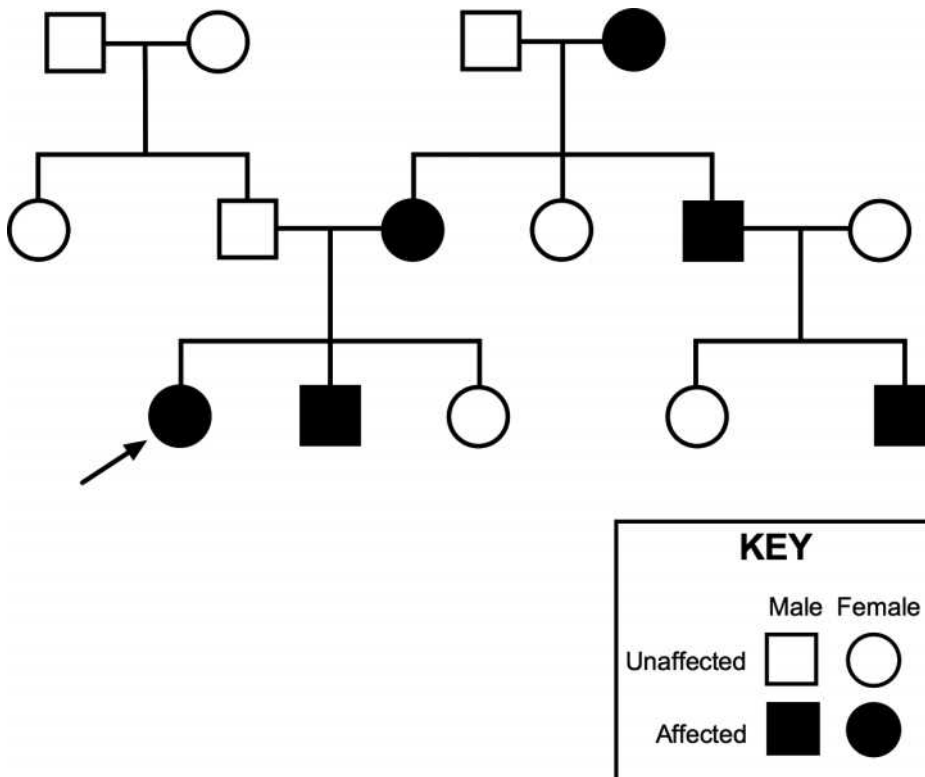

FIGURE 25.3 Three-generation pedigree of a family segregating an autosomal dominant trait. The *arrow* indicates the proband. Note the vertical transmission pattern across generations and father-to-son transmission.

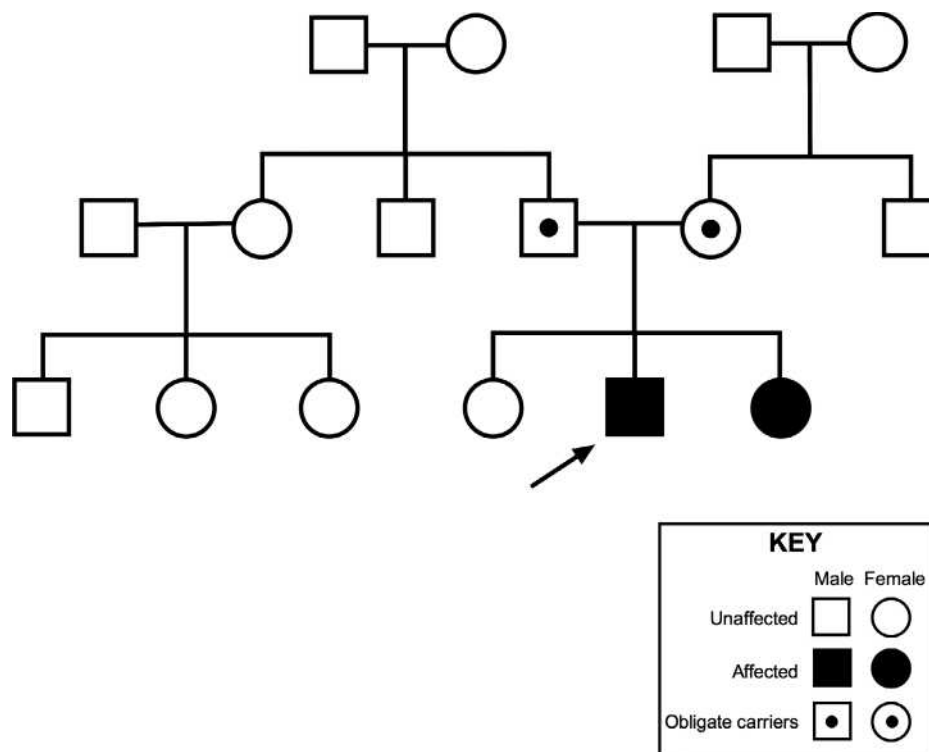

FIGURE 25.4 Three-generation pedigree of a family segregating an autosomal recessive trait. The *arrow* indicates the proband. Note the horizontal transmission pattern and obligate carriers.

allele. There is a 25% chance that the offspring of two heterozygous carriers will acquire a double dose of the mutated gene, one from each parent and, thus, express the trait. There is a 50% chance that each offspring will be a heterozygous carrier, and a 25% chance that the child will inherit no mutated allele. As in autosomal dominant transmission, males and females are equally likely to express the trait, but in the case of autosomal recessive inheritance there can be generations of unaffected individuals and, within a single generation, either a sole affected individual or multiple family members who express the trait. See Figure 25.4 for an example pedigree of a family displaying an autosomal recessive inheritance pattern. The probability of expression for recessive genes increases when parents are related individuals, which is known as *consanguinity*.

SEX-LINKED INHERITANCE

When a genetic mutation occurs on either the X or Y chromosome, the inheritance is considered sex linked. Females pass on one of their X chromosomes to their offspring and males pass on either an X or a Y, which determines the sex of the child. Sex-linked conditions are more likely to involve the X chromosome because it contains many more genes than the Y chromosome. These conditions can be inherited in either a dominant or recessive manner; however, because males are hemizygous for most genes on the X chromosome, the occurrence of X-linked recessive traits is far more common in males than females. In X-linked recessive inheritance, normally there can be no father-to-son transmission of the

mutation, but all female offspring of an affected male will be carriers of the mutated allele. Those carrier females will have a 50% chance of having a daughter who will carry the gene and a 50% chance of having a son who will express the trait. See Figure 25.5 for an example pedigree of a family displaying an X-linked recessive inheritance pattern. In cases of X-linked dominant inheritance, males and females are more equally affected. All female offspring of an affected male will express the trait, and an affected female has a 50% chance of having an affected child of either gender. Y-linked disorders are less common conditions that only occur in males as the result of a mutated gene on the Y chromosome. In such cases, affected males will pass on the trait to their male offspring.

Non-Mendelian Inheritance

Sometimes, the inheritance pattern of a disorder does not follow one of the more common Mendelian patterns. These genetically complex conditions are considered rare currently, but in fact are likely common and simply under-identified. We review several examples of non-Mendelian inheritance here, although the reader should note that this is not a comprehensive list.

MITOCHONDRIAL INHERITANCE

Although the cell nucleus contains the majority of DNA in humans, a small amount is also present outside the nucleus in the mitochondria of the cell. Although nuclear DNA is inherited from both parents, because sperm cells lose their

FIGURE 25.5 Three-generation pedigree of a family segregating an X-linked recessive trait. The *arrow* indicates the proband. Note that there is no father-to-son transmission and that all female offspring of affected males are carriers.

mitochondria during fertilization, mitochondrial DNA (mtDNA) is inherited only from the mother (*matrilineal inheritance*) and passed on to all of her offspring. Consequently, when a mutation occurs in mtDNA, males and females are equally affected. All offspring of an affected female will express the trait, and there can be no transmission between affected males and their offspring. Mitochondrial disorders are often characterized by reduced penetrance, variable expressivity, and the observation of multiple, seemingly unrelated phenotypes that result from a single genetic mutation(s), known as *pleiotropy*.

POLYGENIC INHERITANCE

Polygenic inheritance refers to the cumulative effect of many genes on a phenotype, in contrast to effects from a single gene or pair of genes, known as *monogenic inheritance*. Most traits in humans are inherited in a polygenic fashion, although our understanding of these complex interactions and ability to identify them are just evolving. In the case of *digenic inheritance*, an individual is heterozygous for mutations in two different genes at different loci. In such instances, neither mutation alone would result in an altered phenotype, but the combined effect from the interaction of the independent mutations is deleterious.

MODIFIER GENES

Another complex aspect of heritability involves the influence of genetic background on phenotypic expression. There is growing circumstantial and direct evidence for the existence of *modifier genes*, which are independent genes that alter, or

modify, the expression of traits, such as the onset, progression, and severity of disease. Just as modifiers of the English language can enhance or change the quality or meaning of a sentence, *genetic modifiers* can enhance or inhibit the expression of other autonomous genes. Indeed, much of the phenotypic variability (e.g., expressivity, penetrance, and pleiotropy) observed in single gene (monogenic) disorders may be explained by variations in genetic background. For example, the phenotypic spectrum associated with mutations in the cadherin 23 gene (*CDH23*) ranges from age-related hearing loss, to nonsyndromic prelingual hearing loss, to the occurrence of Usher syndrome (McHugh and Friedman, 2006). The most common effect of modifier genes is an increased risk for disease (e.g., hearing loss) by the interaction of two or more alleles at different loci; in this case, the risk for disease is higher than the risk associated with either allele individually. There is also evidence that some modifier genes exert their influence in a protective fashion by decreasing susceptibility for disease (Nadeau, 2003; Riazuddin et al., 2002). Going forward, the ability to quantify the influence of genetic background on normal and aberrant structure and function will refine our understanding of heritability and susceptibility, clarify fundamental properties of auditory function, and guide future therapeutic designs.

Multifactorial Inheritance

Many clinicians have observed variations in the phenotypic expression of hearing loss between individuals with similar environmental exposures (e.g., noise, pharmacologic intervention). What explains significant ototoxicity documented in one patient given an equivalent dose of the same

cisplatin-based chemotherapy as another patient who exhibits no change at all? Certainly, comorbid factors such as pre-existing hearing loss, age, and renal function, among others, are associated. But these cases also support an underlying genetic influence. Ongoing research in animal models and humans is aimed at delineating the complicated relationship between genes and our environment, known as *multifactorial inheritance*. In multifactorial inheritance individuals have genetic susceptibility for certain diseases or disorders, but do not express the phenotype until they are exposed to a particular environmental trigger. A well-described example of this is a mitochondrial mutation involving an adenine (A) to guanine (G) single nucleotide transition at position 1555 on the 12S *ribosomal RNA* gene (A1555G). Individuals with this mutation have an increased risk for ototoxicity from aminoglycoside exposure. Studies in animal models, mainly mice, have identified several genes associated with increased susceptibility to noise-induced hearing loss, including but not limited to *Ahl1*, which is a gene that is also associated with age-related decline in hearing (e.g., Davis et al., 2001), and several candidate genes in humans (*GRHL2*, *KCNQ4*, *KCNE1*, *CAT*, *PCDH15*, *MYH14*, *HSP70*) have shown promising evidence for a multifactorial interaction with noise (Sliwiska-Kowalska and Pawelczyk, 2013).

Chromosomal Abnormalities

Abnormalities that affect the number or structure of chromosomes result in a loss, gain, or altered location of segments of genetic material. Consequently, multiple body systems may be affected. These are rarely inherited conditions and most often stem from an error in *meiosis* or *mitosis*, processes that take place during cell division. The incidence of chromosomal abnormalities is approximately 1:150 live births, although they account for a significant number of spontaneous abortions, or miscarriages (Carey, 2003).

The normal number of 46, XX or 46, XY chromosomes in females and males, respectively, is known as *euploidy*. When there is an extra copy of a single chromosome (*trisomy*) or when one copy is lost (*monosomy*), it is known as *aneuploidy*. Generally, the gain of genetic material is tolerated more than the loss of a chromosome, and monosomy of any of the autosomal chromosomes is lethal. The most common viable trisomy syndrome is trisomy 21, which causes Down syndrome (e.g., 47, XY +21 for a male with Down syndrome). This extra copy of all or a part of the 21st chromosome accounts for nearly one-third of all infants born with a chromosomal abnormality. Down syndrome is characterized by craniofacial anomalies, varying degrees of intellectual disability, delayed growth, and hearing loss. An abnormality in one of the sex chromosomes occurs in approximately 1:300 live births, and the most common sex chromosome disorder in females is monosomy 45, X, which causes Turner syndrome (described later in this chapter). Excluding trisomy 21 and disorders affecting the sex chromosomes, the incidence of aberrations in number or

structure of all remaining chromosomes occurs in less than 1:1,000 births (Carey, 2003). Occasionally, the entire set of chromosomes is abnormally copied, known as *polyploidy*. An example karyotype for a female with three paired sets of each chromosome (triploidy) would be 69, XXX. Although common in some species, polyploidy is lethal in humans.

It is rare that the loss or gain of an entire chromosome results in a viable fetus. More often, *duplications* or deletions of segments of the chromosome are observed. The term duplication indicates contiguous DNA has been erroneously copied onto the same chromosome resulting in extra genetic material. Similarly, a deletion indicates a region of the chromosome is missing, which often involves the loss of multiple genes. In some cases a portion of a chromosome will break and reverse its order within the same chromosome, known as an *inversion*. Other times, a portion of one chromosome will break and attach to another nonhomologous chromosome, which is known as a *translocation*. Errors in cell division that occur after fertilization has taken place result in an individual with two or more cell lines that contain different genetic information. This is known as *mosaicism*. In many cases, the severity of the phenotype is correlated with the number of abnormal cells present.

Nomenclature

Genes associated with hearing loss have been localized to every autosome and both sex chromosomes. The Human Genome Organization (HUGO) Gene Nomenclature Committee oversees the standardized naming process of genes in humans to ensure that nomenclature is unambiguous and uniform. Gene names are meant to convey the specific character or function of the gene. The standard gene symbol (typically, an abbreviated version of the gene name) for humans is italicized and written in capitalized letters (e.g., *GJB6* is the symbol for the gene “gap junction protein, beta 6, 30 kDa”). The standard nomenclature for loci associated with nonsyndromic hearing loss is DFN (for deafness) followed by a letter that denotes the mode of inheritance: A (autosomal dominant), B (autosomal recessive), X (X-linked), or Y (Y-linked). The number that follows identifies the order in which a locus designation was requested from the nomenclature committee and may reflect when it was mapped or discovered. For example, DFNA1 is the first nonsyndromic autosomal dominant locus for hearing loss that was identified, where DFNX4 is the fourth locus along the X chromosome associated with nonsyndromic hearing loss. Loci for modifier genes for hearing loss are classified as DFNM (Riazuddin et al., 2000).

ROLES OF GENES INVOLVED IN HEREDITARY HEARING LOSS

Identification of genes causing hearing loss has facilitated understanding many different proteins and *ribonucleic acids*

TABLE 25.2

Examples of the Roles of Genes Involved in Hereditary Hearing Loss

Role	Gene	Cytogenetic Locus	Hereditary Hearing Loss
Gene regulation Transcription factor	<i>EYA4</i>	6q23	DFNA10
Fluid homeostasis Gap junctions	<i>GJB2</i>	13q11–q12	DFNB1, DFNA3A, KID [keratosis, ichthyosis, and deafness] syndrome, Vohwinkel syndrome
Ion-channels	<i>KCNQ4</i> <i>KCNQ1</i>	1q34	DFNA2A Jervell and Lange-Nielsen Syndrome
Transporters	<i>SLC26A4</i>	7q31	DFNB4, Pendred syndrome, EVA [enlarged vestibular aqueduct]
Junctional complex and tight junctions Tight barriers	<i>CLDN14</i>	21q22.13	DFNB29
Structural integrity Hair bundle organization	<i>MYO7A</i>	11q13.5	DFNA11, DFNB2, Usher syndrome type 1B
Structural proteins	<i>TECTA</i>	11q23.3	DFNA8/12, DFNB21
Synaptic transmission Synaptic vesicle exocytosis	<i>OTOF</i>	2p23.3	DFNB9

(RNAs) that are necessary for hearing and has also unveiled signaling pathways and protein complexes in the inner ear. Hearing loss genes can be classified by their role in development and function of the ear. These roles include gene regulation, fluid homeostasis, mechanotransduction, and structure (Table 25.2). Regulatory genes primarily function to regulate or transcribe other genes and are important in the development and maturation of the ear. Genes encoding proteins critical for transportation of ions across membranes and fluid homeostasis include those involved in gap junctions, ion-channels, and transporters. Genes contributing to the structural integrity of the inner ear include cytoskeletal proteins, such as the myosins that have an important role in organization of stereocilia and tip-links, and structural proteins that form and organize the tectorial membrane. Additional genes encode proteins important for synaptic transmission between sensory cells and their dendritic connections (Dror and Avraham, 2010; Jones and Jones, 2013).

HEARING LOSS PHENOTYPE

Knowledge of auditory phenotypes observed in hereditary hearing loss is a valuable component of the patient's diagnostic assessment. Familiarity with the presentation and natural history of the hearing loss is essential for etiology-specific counseling, anticipating future hearing-related needs, and establishing a baseline for any current or future interventions. In some cases, the audiologic information alone may help to guide genetic diagnosis.

What we know or understand about the phenotype of some hereditary hearing losses is well defined; however, the

auditory and especially the vestibular phenotypes of many conditions remain incomplete. This is due, in part, to the fact that some conditions are rare and difficult to study. However, it also reflects conclusions derived from limited, at times anecdotal clinical assessments, as well as the current limitations of our diagnostic measures to demonstrate the complex nature of the auditory system.

Use of the term “deafness” by the nonaudiology medical community to describe hereditary hearing loss is vague and often misleading. Observations of self-reported hearing loss or dizziness and cursory screenings (e.g., watch tick or finger-rubbing “tests”) are still found within the method sections of some current papers. The concern raised is that not only do these casual findings fail to adequately characterize auditory function, but they may misrepresent the true course of a disease and delay efforts to advance therapy or identify at-risk populations. There is clearly a role for audiology among these clinical research teams.

A European working group has proposed recommendations for the content and description of audiologic data for nonsyndromic hereditary hearing loss (Mazzoli et al., 2003). This includes specification of hearing loss degree, type, configuration, involved frequencies, laterality, symmetry, estimated age of onset, progression, presence/absence of tinnitus, and assessment of vestibular symptoms and/or function. Within this framework, it is important that the audiologic assessment include testing to specify the type of hearing loss as fully as possible, including (a) differentiation of sensory from neural with tests, such as otoacoustic emissions (OAEs), the auditory brainstem response (ABR), and acoustic reflex measures, and (b) description of middle ear function in addition to 226-Hz

tympanometry using tests such as wideband reflectance and multifrequency tympanometry when there is a conductive component or other evidence of middle ear dysfunction. It is imperative for the audiologist to conduct a comprehensive, consistent, and informative test battery.

NONSYNDROMIC HEARING LOSS

Autosomal Dominant Nonsyndromic Hearing Loss

Nonsyndromic hearing loss inherited as a dominant (DFNA) trait and mapping to one of the 22 autosomal chromosomes (Figure 25.2) is genetically *heterogeneous* with at least 64 loci and more than 25 known genes (Van Camp and Smith, 2013). All autosomal dominant nonsyndromic hearing losses are sensory/neural, with the exception of DFNA23. This gene was reported for a single family, half of whom had a conductive component to their hearing loss, although there was insufficient data to rule out active middle ear disease at the time of the audiometric evaluation (Smith, 2013).

The severity of autosomal dominant nonsyndromic hearing loss is variable, ranging from mild to profound, and in general, it is less severe than that of autosomal recessive nonsyndromic hearing loss. The hearing loss most commonly begins in the high frequencies and progresses to include the mid and eventually the low frequencies. However, there are a variety of configurations which include hearing loss that begins in the low frequencies (e.g., DFNA1 and DFNA6/14/23) or mid frequencies with a “cookie-bite” configuration (e.g., DFNA10). In some cases, the hearing loss can be limited to the high frequencies (e.g., DFNA2).

Onset of the hearing loss is typically postlingual and progressive, beginning in the first or second decade of life; however, there are several loci associated with congenital or prelingual onset, stable, or slowly progressive hearing loss (e.g., DFNA6/14/38). A number of loci are associated with progressive hearing loss that begins during the third decade of life or later (e.g., DFNA9). Fluctuating hearing loss has been observed with four loci (e.g., DFNA9). Hearing loss in persons with DFNA16 has a sudden onset and fluctuations that respond to treatment with steroids (Fukushima et al., 1999).

Vestibular manifestations, ranging from subjective reports to positive findings on tests of vestibular function, have been reported for more than 10 autosomal dominant nonsyndromic loci, although this area of the phenotype in most cases has not been thoroughly explored.

Because of the delayed onset, most people with autosomal dominant nonsyndromic hearing loss will not be identified by newborn hearing screenings, and in many cases not even by early school screenings for hearing loss. In some cases it is difficult to differentiate a late onset autosomal dominant nonsyndromic hearing loss from one caused by environmental factors and aging (e.g., DFNA2B).

DFNA2 (GENES: *KCNQ4* AND *GJB3*; CYTOGENETIC LOCUS: 1q34)

There are two genes, *KCNQ4* and *GJB3*, at the *DFNA2* locus, which are labeled as *DFNA2A* and *DFNA2B*, respectively. Both encode proteins that form channels important for fluid homeostasis. Mutations in *KCNQ4* are one of the more common causes of autosomal dominant nonsyndromic hearing loss.

Hearing loss at the *DFNA2A* locus is typically progressive with postlingual onset in the high frequencies during the first or second decade of life, which may progress to the mid and low frequencies with a sloping configuration. There is phenotypic variability between affected families; some have hearing loss confined to the high-frequency regions, and others have hearing loss spanning the frequency range. Word recognition ability is typically proportionate to the degree of hearing loss. Many experience tinnitus. Although vestibular function is generally normal, there has been at least one report of vestibular hyperactivity on rotary chair testing. Hearing loss associated with *DFNA2B* has a later onset, around the fourth or fifth decade of life, and manifests as a progressive, sloping high-frequency sensory/neural hearing loss (De Leenheer et al., 2002; Smith, 2013).

DFNA6/14/38 (GENE: *WFS1*; CYTOGENETIC LOCUS: 4p16.1)

DFNA6, *DFNA14*, and *DFNA38* are considered mutations in the same gene, *WFS1*. This gene encodes the protein wolframin, which is expressed in many cells in the body including hair cells and other inner ear structures. Its exact function in the ear is unknown, but it is thought to have a role in ion homeostasis within the cochlea.

The hearing phenotype associated with mutations in *WFS1* at the *DFNA6/14/38* locus is one of very few hereditary hearing losses with a low-frequency configuration that progresses slowly. Age of onset is in the first and second decades of life. The hearing loss is typically symmetrical and initially involves 250 and 500 Hz before 10 years of age, making it unlikely that it will be identified on newborn or early school hearing screenings. It gradually progresses to include 1,000 to 2,000 Hz in a low-to-high-frequency progression with puretone thresholds, on average, exceeding 50 dB HL by age 50 years. In the fifth and sixth decades, the audiometric configuration flattens as a concomitant high-frequency hearing loss develops, sometimes with preservation of mid-frequency hearing. Other audiologic characteristics include preserved word recognition ability and absent distortion product OAEs (DPOAEs) commensurate with puretone thresholds. There is frequently nonbothersome tinnitus. Although there are no reports of subjective vestibular complaints, several cases of vestibular hyperactivity are reported in one cohort (Lesperance et al., 2003; Smith, 2013).

Homozygous mutations in *WFS1* can result in Wolfram syndrome, an autosomal recessive disease with a constellation of clinical manifestations including diabetes insipidus, diabetes mellitus, optic atrophy, hearing loss, and neurologic symptoms. Over half of those with Wolfram syndrome experience sensory/neural hearing loss that is typically greater in the high frequencies but with a wide range of severity and configurations. Onset of hearing loss is most often postlingual and in the first decade of life, but cases of congenital and prelingual hearing loss have been reported. Vestibular dysfunction in Wolfram syndrome is possible, but not common (Karzon and Hullar, 2013).

DFNA9 (GENE: *COCH*; CYTOGENETIC Locus: 14q12)

The hearing loss gene at the *DFNA9* locus is *COCH*, which encodes the protein cochlin. *COCH* is expressed in the cochlea and the vestibular labyrinth. Its exact role in the ear is unknown, but it is thought to contribute to structural integrity of the cochlea and susceptibility to inner ear infection (Hildebrand et al., 2009; Smith, 2013).

The phenotype associated with mutations in *COCH* includes both auditory and vestibular dysfunction, and some individuals may have symptoms suggestive of Meniere disease, including hearing loss fluctuations and asymmetry with accompanying episodes of vertigo or imbalance (Smith, 2013). Age of hearing loss onset ranges from the second or third decade for some, to as late as the fifth decade for others, depending on the specific mutation. The hearing impairment typically begins as a moderate-to-severe high-frequency (3,000 Hz and above) hearing loss with progression to a severe-to-profound degree across the entire test frequency range (Hildebrand et al., 2009). Word recognition may be disproportionately reduced relative to puretone thresholds (Bischoff et al., 2005).

Vestibular symptoms occur in most persons with *DFNA9* and include imbalance, especially in the dark, and episodic vertiginous attacks ranging from paroxysmal to several hours in duration without aural fullness. Results of velocity step testing indicate that vestibular dysfunction starts at a younger age and progresses more rapidly than hearing loss; in some cases vestibular *areflexia* (absence of vestibular function) may be an early finding. Endolymphatic hydrops has been observed on histopathology. Several people with *DFNA9*-associated auditory dysfunction have been diagnosed with atypical Meniere disease (Smith, 2013), one with autoimmune inner ear disease, and another with superior semicircular canal dehiscence (Bischoff et al., 2005; Hildebrand et al., 2009).

DFNA10 (GENE: *EYA4*; CYTOGENETIC Locus: 6q23)

Mutations in the *EYA4* gene cause hearing loss at the *DFNA10* locus on chromosome 6q23. *EYA4* is a transcription regula-

tor expressed in the embryonic cochlea that may be involved in inner ear development; its continued role in the cochlea later in life is unknown (Makishima et al., 2007).

Postlingual sensory/neural hearing loss starts during the second to fourth decade of life, often with an initial cookie-bite configuration or with involvement of the middle and high frequencies. There is progression to moderate-to-severe levels across the entire frequency range, with variable expressivity within affected families as the hearing loss progresses. Word recognition scores and acoustic reflex thresholds are typically commensurate with the degree of puretone hearing loss. Vestibular symptoms have been reported for six individuals. Unilateral vestibular hyporeactivity was documented in three of these cases on caloric testing, and benign positional vertigo was observed for one case with a positive Dix Hallpike test (Makishima et al., 2007).

Autosomal Recessive Nonsyndromic Hearing Loss

Autosomal recessive nonsyndromic hearing loss (*DFNB*) is associated with at least 100 known loci and over 40 known genes (Van Camp and Smith, 2013; Figure 25.2). The audiologic phenotype of most autosomal recessive nonsyndromic hearing losses is congenital or prelingual, severe to profound, stable, and sensory/neural. However, several loci are associated with a delayed onset, and although the puretone configuration typically involves all frequencies, a sloping, progressive high-frequency configuration has been reported as well (e.g., *DFNB8/10*). There may be inter- and intrafamilial variability in the audiologic phenotype (e.g., *DFNB1*). Vestibular dysfunction has been reported for approximately 10 loci (e.g., *DFNB8/10*) and auditory neuropathy has been observed for 2 loci (*DFNB9* and *DFNB14*). Some autosomal recessive hearing loss loci are also associated with autosomal dominant hearing loss (e.g., *DFNB1* and *DFNA6*), and some are associated with syndromic forms of hearing loss (e.g., *DFNB12* and Usher syndrome type 1).

Because most autosomal recessive nonsyndromic hearing loss is congenital, it will most often be detected by newborn hearing screenings.

DFNB1 A (GENE: *GJB2*, CYTOGENETIC LOCATION: 13q11–12)

The first locus described for nonsyndromic hearing loss, *DFNB1*, contains the gene *GJB2*, which encodes gap junction beta-2 (also referred to as connexin 26 or CX26), a member of the connexin family of proteins. Connexin proteins assemble to form docking stations between adjacent cells known as gap junctions that allow intercellular flow of small molecules.

GJB2 has particular clinical significance because of the high proportion of hearing loss caused by related mutations at the *DFNB1* locus in many different populations. *Biallelic* (referring to both paired alleles) mutations in

GJB2 account for the majority of moderate-to-profound nonsyndromic recessive hearing loss in some populations. There are over 200 known disease-causing mutations in *GJB2*, some of which are very common. These mutations include 35delG in the United States and Europe, 167delT in Ashkenazi Jewish populations (Morell et al., 1998), and 235delC in Japanese Asians (Smith, 2013). Genetic testing for *GJB2* mutations in newly identified prelingual deafness is a first-line standard of care.

The *DFNB1* hearing loss phenotype associated with *GJB2* mutations is highly variable, even within a family, and ranges from mild to profound in degree, with a congenital onset in approximately 95%. The hearing loss is sensory/neural, typically symmetric with a flat or sloping configuration, and there are no known vestibular manifestations. There is evidence for a genotype–phenotype correlation. For example, biallelic nonsense mutations (premature stop codon) are associated with more severe and earlier onset hearing loss than nontruncating mutations (Snoeckx et al., 2005). Another molecular variation is associated with a milder phenotype characterized by high-frequency hearing loss with delayed onset (Griffith et al., 2000).

DFNB 8/10 (GENE: *TMPRSS3*; CYTOGENETIC LOCATION: 21q22.3)

The causal gene at *DFNB8/10*, *TMPRSS3* codes for the protein transmembrane protease serine 3. The function of *TMPRSS3* in the inner ear is poorly understood, but it likely contributes to normal development and maintenance. The *DFNB8/10* locus is of interest because of the wide variety of phenotypic expressions and a genotype–phenotype correlation. Initial reports were from large, *consanguineous* Pakistani kindred segregating severe-to-profound hearing loss. In this context, *segregation* refers to the separation of phenotypic elements within a population. *DFNB8* hearing loss was postlingual with onset during childhood and *DFNB10* hearing loss was prelingual. These two loci were later found to be on the same gene. Subsequently, eight Dutch families with postlingual onset of progressive, bilateral sensory/neural hearing loss were described. The hearing loss began as a precipitously sloping high-frequency loss, with ensuing progression to the mid and then the low frequencies. Those with homozygosity for the more severe mutations of *TMPRSS3* were more likely to have severe-to-profound hearing loss, and those with two different mutations of the same gene (*compound heterozygote*), including one allele with a less severe mutation, were more likely to have later onset and sharply sloping hearing loss (Weegerink et al., 2011).

DFNB9 (GENE: *OTOF*, CYTOGENETIC LOCATION: 2p23.3)

The *DFNB9* locus is associated with mutations in *OTOF* that encodes for the protein otoferlin, which is believed

to play an important role in synaptic function. The initial phenotypic description of *DFNB9* reported prelingual, severe-to-profound sensory/neural hearing loss and absent ABRs in children in a Lebanese family (Chaïb et al., 1996). Subsequently, mutations in *OTOF* were shown to be the major cause of nonsyndromic recessive auditory neuropathy (Varga et al., 2003). In these latter cases, puretone hearing loss ranged from mild to profound in degree with intact OAEs and abnormal ABRs. Notably, the OAEs were present in young children, but often disappeared with age. It is possible that all persons with *OTOF* mutations have auditory neuropathy, but tests of cochlear function (e.g., OAEs) were not conducted on the early cohorts or at young enough ages.

Another nonsyndromic recessive locus (*DFNB59*, *PJVK*, 2q31.2) is associated with auditory neuropathy in some kindreds but not in others. The corresponding hearing loss can be prelingual, stable, and severe to profound, or it can be progressive (Mujtaba et al., 2012).

DFNB12 (GENE: *CDH23*; CYTOGENETIC LOCATION: 10q22.1)

The *DFNB12* locus is associated with mutations in *CDH23*, which codes for an adhesion protein involved in stereociliary bundle cohesion and tip-link formation. Missense mutations in *CDH23* result in *DFNB12*-related hearing loss, and more severe nonsense mutations result in Usher syndrome (type ID) (Friedman et al., 2011), which is reviewed later in this chapter. Nonsyndromic hearing loss at the *DFNB12* locus is most often congenital or prelingual, but postlingual onset in the first decade has also been reported. The hearing loss can be progressive with the final severity ranging from moderate to profound. Vestibular function is normal (Astuto et al., 2002). The *homolog* of *CDH23* in the mouse, *Cdh23^{ahl}*, is also associated with heritable forms of presbycusis.

X-Linked Nonsyndromic Hearing Loss (*DFNX*)

Five loci are assigned for X-linked hereditary hearing loss (Figure 25.2). There is no unifying pattern of presentation, with the exception that the auditory phenotype is more severe in males than in females. The most common and distinct X-linked hearing loss locus is *DFNX2*, which encodes *POU3F4* (Xq21.1). In males, the hearing loss is congenital and mixed with a conductive component of 30 to 40 dB in the low and mid frequencies and narrowing of the air–bone gap in the high frequencies. The acoustic reflex is frequently present in early stages of the hearing loss, despite air–bone gaps. Over time, there is progression of the sensory component to severe or profound levels. Two anatomic features, dilation of the lateral aspect of the internal auditory canal and enlargement of the vestibule, may contribute to the conductive aspect of the

hearing loss. Attempted stapedectomy has resulted in perilymphatic gushers and subsequent further loss of hearing and vestibular function. This makes it important to consider the possibility of *DFNX2* in males with congenital mixed hearing loss prior to stapedectomy. Female heterozygotes have a similar but milder audiologic phenotype (Cremers et al., 2002; Smith, 2013).

Y-Linked Nonsyndromic Hearing Loss (*DFNY*)

A single locus assigned for Y-linked hearing loss, *DFNY1*, is based on *patrilineal inheritance* of bilateral, symmetrical sensory/neural hearing loss in a nine-generation Chinese family. The degree of hearing loss ranges from mild to severe, and audiometric configurations include sloping, flat, and U-shaped. Age of onset is postlingual and ranges from 5 to 27 years, with a mean of 11.5 years. ABR findings are consistent with a peripheral origin of the hearing loss, and caloric irrigations suggest normal vestibular function in at least a subset of affected individuals. High-resolution CT scans of the temporal bones show no apparent inner ear abnormalities (Wang et al., 2009). Recent evidence suggests that *DFNY1* may be associated with insertion of genetic sequences from chromosome 1 into the Y chromosome rather than mutation of a Y chromosomal gene as the putative cause of hearing loss (Wang et al., 2013).

Deafness Modifier Genes (*DFM*)

The *DFNB26* locus was mapped to chromosome 4q31 in a large, consanguineous Pakistani family. Fifty-three percent of the family members with homozygous *genetic markers* linked to the *DFNB26* region had prelingual, severe-to-profound sensory/neural hearing loss and the other 47% had normal hearing. This led to the discovery of the first deafness modifier locus, *DFNMI*, mapped to a region on chromosome 1q24 (Figure 25.2). All unaffected family members with homozygosity for *DFNB26* had a dominant modifier, *DFNMI*, which suppressed the associated hearing loss (Riazuddin et al., 2000).

Auditory Neuropathy, Autosomal Dominant (*AUNA*)

Currently, there is one known locus for autosomal dominant auditory neuropathy, *AUNA1*, that maps to chromosome 13q21–q24 (Figure 25.2); the causative gene is *DIAPH3* (Schoen et al., 2010). This locus and gene were identified in a four-generation American family of European descent. Age at onset of the auditory symptoms ranged from 7 to 45 years. The puretone hearing loss was symmetrical, worse in the high frequencies, and typically progressed to a profound degree over a 10- to 20-year period. In the younger family members with moderate sensory/neural hearing

loss, the phenotype included absent or grossly abnormal ABRs in the presence of intact DPOAEs, typical of auditory neuropathy. As the puretone hearing loss progressed, there was a loss of DPOAEs, indicating a partial sensory site of lesion, and a loss of the ABR, if it was present to begin with. Some affected family members benefited from cochlear implantation (Kim et al., 2004).

Nonsyndromic Mitochondrial Hearing Loss (*MTRNR1*)

Nonsyndromic sensory/neural hearing loss caused by mutations in mitochondrial genes shows a pattern of matrilineal inheritance. There is considerable heterogeneity in both penetrance and phenotype of the hearing loss. The most common nonsyndromic hearing loss results from A1555G mutation in the ribosomal RNA (*MTRNR1*). This mutation can cause nonsyndromic, congenital, severe-to-profound sensory/neural hearing loss. Additionally, in some families and individual patients with this same mutation, hearing loss occurs only after aminoglycoside exposure (Fischel-Ghodsian, 2003).

Otosclerosis (*OTSC*)

Otosclerosis is a common cause of progressive hearing loss with a prevalence of 0.2% to 1% among white adults. Most audiologists are familiar with the clinical presentation of a mixed hearing loss with air–bone gaps that narrow in the mid frequencies, normal tympanograms, and absent acoustic reflexes. Age of clinical onset ranges from the second to the sixth decade of life or later and penetrance averages about 40% with considerable interfamilial variability. Currently eight loci for clinical otosclerosis (*OTSC*) have been identified and more will likely emerge. No causative genes have been sequenced to date. Each of the known *OTSC* loci segregates as an autosomal dominant trait. Because of the variable penetrance and large range in the age of clinical onset, it is likely that there are modifier genes or environmental factors that impact the expression of hearing loss (Schrauwen et al., 2011).

SYNDROMIC HEARING LOSS

Hundreds of syndromes include hearing and vestibular disorders, and the list is growing. Often, issues of comorbidity and multisensory involvement can affect the diagnostic process and re/habilitation strategies. For example, visual reinforcement audiometry with a visually impaired child will be difficult if not impossible. A child with craniofacial abnormalities may have structural anomalies of the outer ear that limit amplification options. The presence of more than one disability has a multiplying effect in hindering communication and learning that is greater than any single occurring disorder, which underscores the importance of early

diagnosis and intervention for these children. Moreover, in some cases the audiologist may be in the unique position to identify possible syndromic forms of hearing loss and make critical referrals for medical confirmation and multidisciplinary management.

Syndromic hearing loss is classically categorized by its association with other affected systems of the body including the external ear, integumentary system (skin, hair, nails), eye, nervous system, skeletal system, renal system, and other abnormalities. Here, we present several syndromes that represent the range of systems most often associated with hearing loss. Examples of Mendelian inheritance are provided, as well mitochondrial inheritance and chromosomal abnormality. The reader is referred to the resources outlined in Table 25.3 for more expansive and up-to-date information on these and the many other syndromes associated with hearing loss. It is worth noting that although eponyms are routinely used in the naming of syndromes, the current standard is for use of the nonpossessive form (e.g., Usher syndrome instead of Usher's syndrome).

Alport Syndrome

Alport syndrome is characterized by progressive renal disease, ocular anomalies, and sensory/neural hearing loss. It occurs in approximately 1:50,000 live births, and 85% of cases are inherited in an X-linked transmission pattern, because of mutations in the *COL4A5* gene (Xq22). The remaining cases have an autosomal recessive inheritance pattern resulting from biallelic mutations in either *COL4A3* (2q36–q37) or *COL4A4* (2q35–q37). All three of these genes contribute to the production of a protein known as type IV collagen. Type IV collagen is a critical component in the network of proteins that make up basement membrane structures, a thin framework that supports and separates cells in many tissues throughout the body. Type IV collagen appears to be especially critical for the basement membrane structures that are found in the cochlea, as well as the kidney and eye.

The renal disease observed in Alport syndrome is characterized by blood and high levels of protein in the urine (hematuria and proteinuria, respectively), and progressive

renal failure that can result in end-stage renal disease. Eye anomalies include a bulging lens, typically in the anterior direction (*anterior lenticonus*) that is so rarely observed outside of Alport syndrome, it is considered, practically, a *pathognomonic* finding. Additional ocular manifestations, including cataract and retinal flecks, can also occur (Kimberling et al., 2011).

The hearing loss associated with Alport syndrome is most often late onset, occurring in older children or adolescents, but congenital hearing loss has also been reported. It is bilateral and sensory/neural in origin and may be more severe in the higher frequencies. Most males (80% to 90%) and some females (28%) with X-linked transmission will have hearing loss, as will most males and females with an autosomal recessive inheritance pattern. The hearing loss can vary in degree and may be progressive in the first or second decade of onset.

Individuals with Alport syndrome and functionally significant hearing loss can usually benefit from hearing aids. Dysfunction is typically localized to the cochlea, although ABR disturbance has been reported. Vestibular function has not been comprehensively evaluated.

Branchio-oto-renal Syndrome (Melnick–Fraser Syndrome; Branchio-oto Syndrome)

Branchio-oto-renal syndrome (BOR) is one of the more common syndromic conditions associated with hearing loss and inherited in an autosomal dominant transmission pattern. Named for the triad of branchial arch remnants, ear and hearing abnormalities, and renal dysfunction, BOR is estimated to occur in 1:40,000 live births. Approximately 40% of cases are due to a mutation in *EYA1* (8q13.3), but BOR may result from mutations in *SIX1* (14q23.1) and *SIX5* (19q13.32) as well. Not all causative genes have been identified. All three of the known causative genes play important roles in embryologic development and regulate the activity of other genes.

The manifestation of branchial remnants results from disrupted development of the second branchial arch, which contributes to the formation of tissues in the front and sides of the neck. This leads to branchial cleft cysts and fistulas associated with BOR. The renal phenotype may include a variety of kidney abnormalities that affect structure and function and, in severe cases, end-stage renal disease may develop, requiring dialysis or kidney transplant. A variation of BOR without renal dysfunction has also been described, known as branchio-oto syndrome, and can be observed in the same family as someone with BOR (Kochhar et al., 2007).

Hearing loss is the most common phenotypic manifestation of BOR, estimated to occur in more than 70% and as much as 93% of affected individuals (Kochhar et al., 2007). Additional ear-related anomalies include preauricular pits, pinna deformities (e.g., cupped auricle), and stenosis of the

external auditory canal. A less frequent (<20%) manifestation is preauricular tags. In addition to structural anomalies of the outer ear, middle and inner ear anatomy may be compromised (e.g., ossicular fixation, cochlear hypoplasia). The hearing loss can range from mild to profound and may be conductive, sensory/neural, or, most often, mixed. Notably, hearing loss onset is not always congenital and can range from birth to young adulthood and it may be stable or progressive. Vestibular involvement has neither been confirmed nor ruled out as an associated phenotype.

The expressivity of BOR is highly variable, both within and between families, and the signs and symptoms may differ significantly within the same individual between the right and left sides across affected systems. A comprehensive audiologic evaluation in all patients suspected of BOR is necessary, in combination with otologic management. Re/habilitation strategies will vary depending on the type and degree of hearing loss, but some form of amplification and educational accommodation(s) is necessary for many children with BOR. These patients will likely present initially to an otologist and/or audiologist, and early identification of BOR is important to expedite diagnosis and management of the urologic and renal abnormalities and to establish appropriate surveillance of affected individuals.

CHARGE Syndrome

CHARGE syndrome is a multisystem congenital disorder characterized by the co-occurrence of anomalies represented in the mnemonic: *Coloboma*, *Heart* defects, *Atresia of choanae*, *Retarded* growth and development with or without central nervous system involvement, *Genital* hypoplasia, and *Ear* anomalies with or without hearing loss. It occurs in 1:8,500 to 10,000 births and is inherited in an autosomal dominant fashion, although the majority of individuals with CHARGE syndrome represent simplex cases (single affected member of the family). Dominant mutations in *CHD7* (8q12.2) result in CHARGE syndrome, but *SEMA3E* (7q21.11) is also associated. The *CDH7* gene is believed to play an important role in the organization and packaging of DNA into chromosomes.

Clinical diagnosis of CHARGE syndrome is based on the presence of major and minor diagnostic features. Major clinical features are coloboma, atretic or stenotic choanae, cranial nerve involvement (I, VII, VIII, IX/X), and structural anomalies of the auditory system. Minor diagnostic findings include underdeveloped genitals, developmental delay, cleft palate or lip, tracheoesophageal fistulas, growth deficiency, and structural abnormalities in the cardiovascular system. Many of these features present as life-threatening conditions during the neonatal period (Edwards et al., 2002).

Almost all individuals with CHARGE syndrome will present with pinna deformity, which is often asymmetrical, with or without hearing loss. Auricles can be short and wide, possibly protruding, with triangular concha and a missing

helical fold that gives a “snipped off” appearance. Lobes may be absent or small. The external auditory canal is usually unaffected, but middle ear ossicles may be malformed. Temporal bone abnormalities occur in most patients and have been suggested for inclusion as a major diagnostic finding. Mondini dysplasia and underdeveloped or absent semicircular canals are common, and vestibular areflexia has been reported.

At least 80% of individuals with CHARGE syndrome have hearing loss. Mixed hearing loss is most common, and the sensory/neural component is believed to be congenital. The conductive contribution is likely because of either malformation of the ossicles or high rates of chronic/recurrent middle ear disease secondary to craniofacial anomalies, or both. The hearing loss may range from mild to profound, but in the majority of cases it will be sufficiently impaired to affect speech and language development, and it may be progressive.

The multisensory involvement and developmental delay associated with CHARGE syndrome make diagnosing hearing loss and habilitation difficult and often necessitates use of physiological and electrophysiological measures of auditory function. These objective measures can reduce the age at which the loss is diagnostically confirmed and expedite early intervention. Children with CHARGE syndrome can benefit from air- or bone-conducted hearing aids, assistive listening devices, or cochlear implants, depending on the type and severity of the hearing loss and their medical candidacy. Serial audiologic monitoring is warranted throughout the lifetime.

Jervell and Lange-Nielsen Syndrome

Jervell and Lange-Nielsen syndrome (JLNS) is a rare (1.6 to 6:1,000,000) autosomal recessive disorder resulting from mutations in either the *KCNE1* (21q22.12) or *KCNQ1* (11p15.5) genes. It is associated with congenital bilateral profound sensory/neural hearing loss and a heart arrhythmia characterized by a long QT interval. When the electrical activity of the heart is measured during an electrocardiogram (EKG or ECG), the distance between two of the waveforms is known as the QT interval. In JLNS, the QT interval is prolonged, which increases the risk for fainting episodes and, in some cases, sudden death. This aspect of the phenotype is treatable with medication, which underscores the importance of early diagnosis.

The auditory phenotype is uniform. These children present with profound bilateral sensory/neural hearing loss and are audiologic candidates for cochlear implantation. Because of the advent of newborn hearing screening, most children with JLNS will be identified during the neonatal period, prior to recognition of cardiovascular symptoms. Although the syndrome is extremely rare, because of the potential for lethal cardiac events, which have been associated with anesthesia and auditory stimulation, cardiac work-up is recommended in any child with profound

congenital sensory/neural hearing loss, especially in cases of unconfirmed etiology, and prior to surgical intervention. Cochlear implantation is not contraindicated in these patients, necessarily, but special precautions during surgery and activation may be necessary (Siem et al., 2008). There is limited anecdotal evidence in humans for a vestibular phenotype in JLNS, but this is currently poorly described and requires further study to confirm.

KCNE1 and *KCNQ1* regulate the formation and function of potassium channels that control the flow of potassium ions across cell membranes, which is a critical component to normal function in both the heart and inner ear (Schwartz et al., 2006). Heterozygous carriers of mutations in either gene have normal hearing but may have the long QT phenotype (Romano–Ward syndrome). Because hearing loss is detected before the cardiovascular phenotype, the audiologist may be in the position to identify and refer a child with congenital bilateral hearing loss and a history of possible cardiac events.

Mitochondrial Encephalomyopathy (or Myoclonic Epilepsy) with Ragged Red Fibers

Mitochondrial *encephalomyopathy* with ragged red fibers (MERRF) results from mutations in mtDNA and is an exceptionally rare condition, although the exact prevalence is unknown. The majority of cases are associated with mutations in *MT-TK*, which encodes for the production of *transfer RNAs* that help to build functional proteins, produce energy within cells, and process oxygen. The most common mutation is A8334G.

The initial presenting symptom typically observed in MERRF is an involuntary twitching in a muscle or group of muscles, called myoclonus. Epilepsy, ataxia, and muscle weakness follow and may include additional central nervous system symptoms such as dysarthria, neuropathy, and dementia. The onset of symptoms may range from childhood to adulthood and, as such, young children with MERRF almost always reach early developmental milestones. As the phenotype progresses, clumps of mutated mitochondria collect in muscle tissue throughout the body, which can be stained and viewed through a microscope where they appear as red, ragged fibers. Because of *heteroplasmy*, a common condition in mitochondrial disorders in which there are varying percentages of mitochondria containing mutated DNA within a cell, there is variable expressivity in the MERRF phenotype.

Hearing loss associated with mitochondrial encephalopathy disorders may be cochlear or retrocochlear in origin, or both. Absent OAEs with additional retrocochlear findings (prolonged interpeak latencies) on ABR measures have been reported in patients with MERRF (Tsutsumi et al., 2001). Differentiating MERRF from other progressive mitochondrial encephalopathy disorders can be challenging, and MERRF should be considered as a possible etiology

in any patient with myoclonic epilepsy and sensory/neural hearing loss.

Pendred Syndrome (DFNB4)

Pendred syndrome is an autosomal recessive disorder most often resulting from biallelic mutations in *SLC26A4* (7q31). *SLC26A4* codes for production of the protein pendrin, which transports ions across cell membranes in the inner ear, thyroid, and kidneys, as well as other organs in the body. Pendred syndrome is one of the more common syndromic forms of hearing loss, with estimates accounting between 5% and 10% of all early-onset hereditary hearing loss. Pendred syndrome was originally defined as goiter and profound congenital sensory/neural deafness, but it is now known to include variable thyroid and auditory phenotypes.

The most penetrant feature of Pendred syndrome is enlargement of the vestibular aqueduct (EVA), although additional structural anomalies of the bony labyrinth can also occur (e.g., incomplete partition of the cochlea, also known as a “Mondini” cochlea). The hearing loss is often congenital, but can develop during the prelingual and perilingual periods. It is typically bilateral but may not be symmetrical and can be associated with fluctuating or progressive changes in hearing, or both. When hearing loss occurs, progression may be stepwise and head trauma is often reported as a precipitating event. Consequently, patients are encouraged to avoid contact sports or barotrauma (e.g., scuba diving). The configuration of the hearing loss is gradually sloping or flat, but it may also present initially as a high-frequency loss or with sparing of the mid-frequency test region (inverted U). The hearing loss is traditionally described as sensory/neural; however, because EVA is purported to be associated with a third mobile window in the labyrinth, air–bone gaps in the presence of normal tympanometry are often observed (King et al., 2009). In such cases, placement of pressure-equalization tubes to ameliorate suspected conductive hearing loss is not beneficial. Vestibular dysfunction of varying severity is reported in Pendred syndrome, but has not been fully characterized to date.

Diagnosis of Pendred syndrome can be challenging and difficult to differentiate from nonsyndromic forms of EVA, including DFNB4, which is radiologically indistinguishable from Pendred syndrome. The thyroid phenotype has a later onset in childhood or early adulthood and goiter is incompletely penetrant and, thus, not a good diagnostic requirement. Moreover, goiter is common in the population, increasing the potential for possible *phenocopies* (when an environmentally caused trait mimics an inherited one) of Pendred syndrome in patients with severe-to-profound early-onset hearing loss. Even within the same family, there can be large variability in the expression of Pendred syndrome (Madeo et al., 2006).

The audiologist should be aware of the variable auditory phenotype associated with Pendred syndrome beyond

what is classically described, including asymmetries in hearing and even unilateral presentations, milder degrees of loss, air–bone gaps with normal tympanometry, and the risk for sudden or stepwise progressive changes in hearing, all of which can impact intervention and re/habilitation strategies. Some children with Pendred syndrome will pass newborn hearing screenings, and most will be good candidates for hearing aids or cochlear implantation.

Stickler Syndrome

Stickler syndrome is an autosomal dominant connective tissue disorder that affects the eye, ear, development of facial structures, and musculoskeletal system. It occurs in 1:7,500 to 9,000 births and is a clinically and genetically heterogeneous condition. Mutations in one of five causative collagen genes have been identified to date. A mutation in *COL2A1* is found in 80% to 90% of cases. This gene contributes to the production of type II collagen, which adds structure and strength to connective tissues and is found in the inner ear. *COL11A1* mutations occur in 10% to 20% of Stickler syndrome cases, and mutations in the remaining three causative genes are rare. All of the genes associated with Stickler syndrome contribute to the normal production of different types of collagen throughout the body.

Stickler syndrome is associated with a flattened facial profile, which is more pronounced during childhood, because of midface hypoplasia involving the maxilla and nasal bridge. Other craniofacial findings can include underdeveloped jaw and cleft palate. Early onset of osteoarthritis, hypermobile joints, and short stature are associated. Ocular anomalies are most commonly observed with mutations in *COL2A1* and *COL11A1* and include early-onset progressive myopia, retinal abnormalities, cataract, and risk for retinal detachment. A nonocular phenotype is related to mutations in *COL11A2*.

Hearing loss can be observed with all forms of Stickler syndrome, regardless of the underlying genotype. When the causative mutation is *COL2A1* the hearing loss is usually mild, confined to the higher frequencies, and progression of the sensory/neural component appears to be no greater than that associated with typical age-related decline. Mutations in *COL11A2* and *COL11A1* are associated with a more severe degree of hearing loss, affecting a broader frequency range, and the loss may be progressive. Conductive hearing loss is common in children with Stickler syndrome in whom chronic/recurrent otitis media occurs frequently. Many patients with Stickler syndrome will present with hypermobile middle ear systems, which may be related to sequela of chronic/recurrent otitis media or because of reduced amounts of type II collagen in the tympanic membrane (Szymko-Bennet et al., 2001). Vestibular dysfunction has not been reported. Serial audiologic monitoring is recommended for patients with Stickler syndrome, with fitting of amplification for functionally significant hearing loss, as necessary. Educational accommodations for these children, who are

at risk for cosensory loss of vision and hearing, should be emphasized.

Treacher Collins Syndrome

Treacher Collins syndrome is an autosomal dominant disorder marked by underdeveloped bony structures and tissues of the face and surrounding areas. It occurs in approximately 1:50,000 live births and the majority of individuals have a single mutation in *TCOF1* (5q32) encoding the protein treacle, which appears to be vital for normal embryologic development of the face. Causative mutations in *POLR1 C* (6q21.1) and *POLR1D* (13q12.2) have also been identified. Notably, over half of patients with Treacher Collins syndrome represent a de novo mutation.

Dominant clinical features of Treacher Collins syndrome include midface hypoplasia because of underdeveloped zygomatic bones, a small chin and jaw (micrognathia), down-slanting eyes, coloboma of the lower eyelid, and abnormalities in the structures of the external ear, including microtia or severe malformation of the pinnae and atresia of the external auditory canal. In addition, the middle ear cavity and ossicular structures may be underdeveloped or missing, and cleft palate with or without cleft lip can also occur. Inner ear anatomy is typically unaffected.

Approximately 50% of patients with Treacher Collins syndrome have congenital conductive hearing loss. It is usually bilateral and can be severe in degree. Sensory/neural hearing loss is not often reported, but because of the severity and complexity of the external and middle ear anomalies, those born with hearing loss are likely to have some degree of permanent auditory dysfunction. Management often involves a combination of surgeries that are medically necessary (e.g., cleft palate repair) and cosmetic (e.g., construction of an artificial pinna, known as an aural episthesis). Surgical reconstruction cannot be carried out safely during the first few years of life and outcomes rarely restore hearing to within normal limits. Consequently, many patients with Treacher Collins syndrome will be lifelong users of some form of amplification. Traditional hearing aids may not be appropriate, depending on the degree to which the ear anatomy is compromised. Bone conduction hearing aids, either removable or implantable, are essential for many of these children to develop normal speech and language (Marsella et al., 2011). There are no cognitive delays associated with Treacher Collins syndrome; however, because of the *dysmorphic* facial features (i.e., structural defects) and poor speech articulation, persons with Treacher Collins syndrome may be inaccurately stereotyped this way.

Turner Syndrome (Ullrich–Turner Syndrome)

Monosomy 45, X, known as Turner syndrome is a chromosomal disorder resulting from the loss of either an X or Y

chromosome. It is the most common sex chromosome disorder in females (1:2,500 live births), and the characteristic phenotype includes short stature and premature ovarian failure leading to infertility. The majority of fetuses with Turner syndrome spontaneously abort in the first or second trimester because of developmental abnormalities in the cardiovascular and lymphatic systems. Fetuses that survive are phenotypically female and have additional risks beyond heart disease and lymphedema that include urinary system dysfunction, vision loss, autoimmune conditions, and skeletal abnormalities, among other issues related to health and development (Bondy and Turner Syndrome Study Group, 2007).

Hearing loss is present in approximately 50% of females with Turner syndrome, and it is characterized by transient, recurrent middle ear pathology and progressive sensory/neural loss. Pinna deformities such as low set, posteriorly rotated, cupped, and protruding ears and narrow external auditory canals are common. Heightened monitoring for and aggressive treatment of otitis media is recommended, and whether because of active otitis media or sequelae from recurrent disease, middle ear dysfunction remains an issue for many women with Turner syndrome throughout their lifetime.

Sensory/neural hearing loss is present in approximately one-third of those with Turner syndrome and can be greater in degree in the mid frequencies, especially for those with complete monosomy 45, X karyotypes. Women with Turner syndrome are at risk for progressive changes in sensory hearing, particularly in the high frequencies, at an accelerated rate beyond typical age-related decline. Routine audiologic monitoring is warranted throughout the lifetime regardless of prior documentation of normal hearing. Many can benefit from hearing aids.

About one half of patients with Turner syndrome have a total monosomy 45, X karyotype. Alternatively, mosaicism is common (approximately one-third of cases), and the frequency and severity of sensory/neural hearing loss and auricular anomalies is greater in women with a larger percentage of monosomy 45, X cells. Patients with deletions involving the short arm of the X chromosome have a greater degree of conductive hearing loss than patients with deletions affecting only the long arm (45, XdelXq) (King et al., 2007). Many girls with Turner syndrome are not diagnosed until absence of menstruation in the early teenage years. Because of the high rate of middle ear disease and hearing loss, the otologist or audiologist may be the entry point into the healthcare system and early identification may accelerate important medical intervention(s).

Usher Syndrome

Although many syndromes are associated with both vision and hearing loss, the most common of these is Usher syndrome, which occurs in 4 to 5:100,000 births in the United States. Usher syndrome is an autosomal recessive condition

TABLE 25.4

Classical Hearing, Vision, and Vestibular Phenotypes Reported in the Three Subtypes of Usher Syndrome

	Usher Syndrome Type I	Usher Syndrome Type II	Usher Syndrome Type III
Hearing	Congenital profound bilateral hearing loss	Congenital moderate-to-severe bilateral hearing loss	Normal at birth; progressive bilateral loss starting in childhood or teenage years
Vision	Onset of RP prior to age 10	Onset of RP in late childhood or teenage years	Onset of RP in the second to fourth decade, which may vary in severity
Vestibular function	Vestibular areflexia or significant hypofunction	Normal	Varying degrees of dysfunction, from normal to areflexia; may be progressive

RP, retinitis pigmentosa.

that is clinically and genetically heterogeneous and characterized by three distinct subtypes (Table 25.4) based on hearing loss, a progressive loss of vision (*retinitis pigmentosa* (RP)), and varying degrees of vestibular dysfunction. RP manifests initially as difficulty seeing in the dark, followed by a progressive degeneration in the peripheral field of vision and, in end-stage disease, a loss of visual acuity. The prevalence of some types of Usher syndrome is higher among certain ethnic groups (e.g., Ashkenazi Jewish ancestry, Acadian populations in Louisiana) (Friedman et al., 2011).

There are 15 known loci for Usher syndrome and 11 causative genes identified, to date (Figure 25.2). Many of these genes are associated with autosomal recessive forms of nonsyndromic hearing loss and at least one mutant allele has a nonsyndromic dominant transmission (*DFNA11*). The most common mutations reported occur in *MYO7A* (11q13.5) and *CDH23* (10q22.1), both observed with Usher syndrome type I, and *USH2A* (1q41) which is associated with Usher syndrome type II, and which is also related to a nonsyndromic form of RP. The proteins encoded for by each of these genes (usherin, cadherin 23, and myosin VIIA, respectively) are all present in the inner ear and retina and contribute to the development, organization, and maintenance of the hair cells, and in particular the stereociliary bundle.

The manifestation of RP occurs in all three types of Usher syndrome and its presentation is not specific enough as a clinical measure to reliably distinguish phenotypes. Clinical evaluation of hearing and vestibular function is most useful to differentiate the type of Usher syndrome, in the absence of and before obtaining genetic information. All three subtypes are associated with hearing loss, but with variable onset, degree, and progression of the loss.

Children with Usher syndrome type I and type II will not pass a newborn hearing screening based on our current understanding of the onset of the disease. Patients with Usher syndrome type I may identify with the deaf community or benefit from cochlear implantation, or both. Most

patients with Usher syndrome type II will benefit from hearing aids, as will those with Usher syndrome type III when the hearing loss progresses. Any child with congenital severe-to-profound hearing loss for whom the etiology of their loss has not been identified should be evaluated for possible Usher syndrome, especially if the child is a late walker or has delays in motor milestones. As is the case with any congenital or prelingual significant hearing loss, early identification and intervention is critical for language development. In the case of Usher syndrome, knowledge of the etiology and associated outcomes, which includes progressive loss of vision, has important prognostic and counseling implications for managing teams and families, including which communication mode and habilitation strategies are most appropriate. Comprehensive vestibular assessments are warranted for any patient diagnosed with Usher syndrome. Computerized dynamic platform posturography can serve as an especially useful tool, as the complex interaction of somatosensory, visual, and vestibular systems in the maintenance of balance is of concern in these patients for whom one or two of these systems are compromised.

Waardenburg Syndrome

Waardenburg syndrome is a genetically heterogeneous, rare (1:40,000 to 100,000) condition that causes pigmentary anomalies in the skin, hair, and eyes and is associated with sensory/neural hearing loss. There are four subtypes of Waardenburg syndrome, distinguished by their clinical presentation and mode of inheritance. Types I and II are the most common clinical subtypes and have similar phenotypes, but are differentiated by the presence or absence of *dystopia canthorum*, which is observed in type I and not in type II. This lateral displacement of the inner canthus of the eyes gives the appearance of a wide nasal bridge. Type III, also known as Klein–Waardenburg syndrome, has the same presentation as type I with the addition of upper limb

abnormalities (e.g., hypoplasia of limb muscles; contracture of elbows or fingers). Type IV, also known as Waardenburg–Shah syndrome, is similar to type II but includes an intestinal disorder called Hirschsprung disease (Friedman et al., 2003).

Types I, II, and III exhibit an autosomal dominant mode of transmission, but type IV segregates as an autosomal recessive disorder. Eight known Waardenburg syndrome loci and six genes have been identified to date. Waardenburg syndrome types I and III result from mutations in *PAX3* (2q35), which regulates the expression of several genes. Types II and IV are heterogeneous, with causative mutations associated with genetic expression (e.g., *MITE*, 3p14.1-p12.3) and genes involved with the development of pigment-producing cells called melanocytes (e.g., *SOX10*, 22q13). Melanocytes produce melanin that helps promote skin and eye color, but they are also important to the normal development and function of the inner ear, notably in the stria vascularis and vestibular dark cells.

Waardenburg syndrome may account for approximately 2% of congenital hereditary hearing loss. Much of the phenotype is associated with marked inter- and intrafamilial variable expression, including the hearing loss, which can range from normal to profound in degree. It is usually stable, but may be progressive, and can be unilateral or bilateral. Hearing loss appears to be more common in type II than type I, although it is possible some individuals with type II and less severe phenotypes may be diagnostically unrecognized because of the absence of dystopia canthorum. When the hearing loss is not profound, the configuration can reveal a greater loss in the low frequencies, or an inverted U, with sparing of mid-frequency hearing.

Additional phenotypic features of Waardenburg syndrome involve pigmentary anomalies that can include partial or complete *iris heterochromia* (differently colored areas of the same eye, or each eye being a different color) or strikingly blue irises. Distinctive patterns in hair color, often involving a congenital or premature white forelock, are common. Other facial features may include a wide, high nasal root, broad confluent eyebrow, and a square jaw.

Depending on the severity of the auditory phenotype, patients with Waardenburg syndrome may benefit from hearing aids or cochlear implantation. In addition to cochlear dysfunction, dysplasia of the semicircular canals and saccular degeneration have been observed on temporal bone study, and patients may present with vestibular complaints and dysfunction with or without accompanying hearing loss.

GENETIC EVALUATION AND DIAGNOSIS

As the professional who oversees newborn hearing screening programs and conducts confirmatory hearing tests, the audiologist is often the first to inform parents of their

infant's hearing loss and initiate the referral process that begins a multidisciplinary partnership between healthcare professionals and the family. In addition to requisite otolaryngology referrals, a genetic evaluation and counseling should be offered to families of all infants with newly identified hearing loss (AAP and JCIH, 2007). It is appropriate for any person with hearing loss of unknown etiology, regardless of their age, to consider a genetic evaluation. The audiologist who suggests a genetic evaluation should have knowledge of the process and an understanding of the value and limitations of genetic testing.

Benefits and Limitations of Genetics Testing

Genetic testing is conducted for a variety of reasons, including carrier screening to assist in reproductive decisions, prenatal screening to detect the presence of a genetic condition in an embryo or fetus, newborn screening for current disorders (e.g., *biotinidase deficiency* which, if left untreated, may lead to hearing loss), presymptomatic predictive testing for hearing loss and other conditions that occur later in life, predispositional testing for genetic mutations that increase the risk of developing a condition (e.g., the well-known mutations in *BRCA1* or *BRCA2* associated with increased risk for breast or ovarian cancer), and diagnostic testing to determine the etiology of a disease (Arnos, 2003). In some cases, a genetic diagnosis may result in avoidance of expensive and more invasive tests. Establishing an etiologic diagnosis of congenital hearing loss provides answers to parents and may raise additional questions. Knowing the inheritance pattern contributes to understanding recurrence risks. In some cases, hearing loss may be the first manifestation of a syndrome for which critical medical intervention is necessary (e.g., JLNS) or that may have a significant impact on habilitation strategies (e.g., Usher syndrome). A genetic diagnosis may facilitate timely referrals to appropriate specialists and management of associated conditions. Predictive information about hearing loss progression is useful in planning management and making amplification and educational choices. In persons with an increased risk for age-related, noise-induced, or drug-induced hearing loss, a genetic diagnosis may lead to avoidance of environmental causes of hearing loss.

Although genetic testing can be beneficial, there are limitations. Some families may find the process and information emotionally upsetting. Genetic testing will not lead to a diagnosis in all cases; the etiology of congenital hearing loss may remain unknown in as many as 30% to 40% (AAP and JCIH, 2007). Negative findings on genetic testing do not mean that the hearing loss is not hereditary, but may occur when the causative gene or the specific mutation has not been previously identified. Ultimately, the decision to pursue genetic evaluation should be based on an informed family decision.

Diagnostic Evaluation of Hereditary Hearing Loss

A multidisciplinary team comprising audiologists, otolaryngologists, medical geneticists, geneticists, and genetic counselors is necessary for the diagnosis and management of hereditary hearing loss and family support. Guidelines for genetic evaluation to determine the etiology of congenital hearing loss include comprehensive review of (1) the patient's family history of hearing loss and other medical conditions, (2) the patient's medical history and risk factors for hearing loss, and (3) examination of the patient for physical features of a syndrome and other concomitant conditions (Table 25.5) (ACMG, 2002).

Construction of a pedigree based on at least three generations, identification of other medical problems, physical characteristics, or known genetic conditions in the family

TABLE 25.5

Components of a Comprehensive Genetics Evaluation for the Etiologic Diagnosis of Congenital Hearing Loss

Family history
Pedigree [three to four generations], attention to consanguinity, paternity, and hearing status
Ethnicity and country of origin
Inheritance pattern of the hearing loss
Audiometric characteristics of deaf and hearing impaired family members—age of onset, progression, degree, and type
Evidence of vestibular dysfunction
Syndromic versus nonsyndromic features
Visual anomalies
Facial/cervical dysmorphology
Endocrine abnormalities
Cardiac signs or symptoms
Renal abnormalities
Integumentary changes
Patient history—review of risk factors
Intrauterine infections [TORCH]
Prenatal exposure to alcohol or drugs
Postnatal infections [meningitis, varicella, herpes]
Extracorporeal membrane oxygenation [ECMO]
History of hypoxia
Exposure to ototoxic drugs
Prolonged NICU stay
Physical examination
Otologic examination—Ear pits or cysts, pinna, ear canals, tympanic membrane, temporal bone
Craniofacial dysmorphisms
Airway examination
Other dysmorphisms or syndromic manifestations

provides insight regarding the possibility of a syndromic form of hearing loss. Careful inspection and interpretation of family member audiograms and hearing loss history, including age of onset, comorbid conditions, and environmental exposures, assists in assuring that the auditory phenotype is correctly identified.

The medical evaluation begins with a thorough history that reviews risk factors for hearing loss. These include in utero exposures such as maternal infections (cytomegalovirus, herpes, syphilis, and toxoplasmosis) and maternal drug or alcohol use. Neonatal risk factors comprise extracorporeal membrane oxygenation (ECMO), assisted ventilation, exposure to ototoxic medications, hyperbilirubinemia requiring exchange transfusion, neonatal intensive care stay lasting more than 5 days, or culture-positive postnatal infections such as meningitis which is associated with sensory/neural hearing loss (AAP and JCIH, 2007). For older children, a review of speech and language development, including vocal play, gives insight as to the time of hearing loss onset. Vestibular function in young children and toddlers can be indirectly assessed by factors such as age at independent walking, nystagmus, clumsiness, and torticollis. The patient should be examined for ear pits, tags or cysts, defects of the pinna, patency of the ear canals, and status of the tympanic membrane, as well as other craniofacial structural abnormalities.

Additionally, the comprehensive physical examination looks for system-wide features known to be associated with a syndrome that includes hearing loss. Johnston et al. (2010) recommend a comprehensive ophthalmologic evaluation on every child with a confirmed sensory/neural hearing loss to evaluate visual acuity and rule out other ocular disorders. Referrals to other medical specialists, including cardiologists, neurologists, and nephrologists, may be required based on clinical findings. Imaging studies (CT or MRI) of the temporal bone may be indicated for diagnostic purposes (e.g., enlarged vestibular aqueduct) and for assessment of surgical rehabilitative candidacy (e.g., cochlear patency).

It is also suggested that siblings of children identified with hearing loss be evaluated for hearing loss themselves and that this not wait until the etiology of the proband's hearing loss is identified, which may take time and which may never be fully confirmed.

Genetics Professionals

Geneticists and genetic counselors are important members of the multidisciplinary team involved in the diagnosis and management of someone with hereditary hearing loss. Geneticists participate in evaluation, diagnosis, and management of hereditary disorders. Genetic counselors are trained to (1) interpret family and medical histories and assess occurrence and recurrence risk; (2) educate patients and families regarding basic concepts of inheritance, available testing, and resources; and (3) provide

counseling to enable families to make informed decisions (NSGC, 2013). Typically, the family interacts with the genetic counselor to collect and review family medical histories and to ensure that the family understands the benefits and limitations of genetic testing. Additionally, results of genetic testing and the implications of a genetic diagnosis, or lack of a genetic finding, are explained and discussed with the family.

Genetic Testing

In 2002, genetic triage paradigms recommended testing for specific genes if a hearing loss syndrome was suspected. In the case of possible nonsyndromic hearing loss, testing for cytomegalovirus and genetic testing for a *GJB2* mutation served as the starting point (ACMG, 2002) for what amounted to a one-gene-at-a-time methodology. Recent technologies now make the process of identifying causative mutations more efficient, less expensive, and more accurate than ever before, allowing for the screening of thousands of genetic loci at one time. Hearing loss panels for simultaneously sequencing as many as 66 genes known to cause nonsyndromic hearing loss, and genes associated with common hearing loss syndromes such as Usher and Pendred syndromes are currently available at a number of facilities.

FUTURE DIRECTIONS

The proportion of infants with congenital or prelingual heritable hearing loss is expected to increase because of the successful development of vaccines for infectious causes of hearing loss (AAP and JCIH, 2007). In combination with new technologies such as whole *exome* sequencing, where all exons in the genome are examined, we will witness rapid and thorough testing for known hereditary hearing loss genes and the identification of new genes associated with auditory function.

Gene therapy for hearing loss is beginning to receive attention in research laboratories. It is a method that uses genetic material to halt, reverse, or prevent disease by replacing or stopping the function of a mutated gene or inserting a gene. Gene therapy is considered an experimental treatment and is used currently in very limited situations for humans with diseases that have no other cures. The application of gene therapy to treatment of sensory/neural hearing loss is in the early stages of discovery in animal models, but holds promise for eventual use in humans. The potential use of gene therapy in cases of hereditary hearing loss includes (1) delivery of functional copies of the gene to the cochlea to overcome the genetic defect, (2) delivery of genes that will initiate hair cell regeneration, and (3) delivery of genes capable of providing a protective effect on the cells of the organ of Corti and spiral ganglion to minimize the loss of these cells (Chien et al., submitted).

The ability to explore complex polygenic conditions, unravel the interactions between single mutations and their genetic background, and explain the dynamic relationship between genes and the environment is at a critical stage of advancement. Our understanding of all of this in relation to hearing loss is emerging, and future therapies, targeted measures aimed at preventing disease, and routine genetic screening will all be impacted by this new frontier of genetic research. This also means that any number of individuals with hearing loss previously thought to be of unknown origin will be identified as having a hereditary etiology.

ONLINE RESOURCES

Information about hereditary hearing loss continues to expand at a rapid rate. In addition to the information presented in this chapter, it is important for the audiologist to access reliable and up-to-date information regarding hereditary hearing loss. Table 25.3 presents a list of useful websites and a brief description of the website's content.

FOOD FOR THOUGHT

1. How much does the audiologist need to know about genetics? How has the answer to this question changed in recent decades, and how might it continue to evolve in the future?
2. Universal screenings at birth to identify mutations in genes that can affect development and health, including hearing loss, are on the horizon. What are the ethical implications associated with this testing, and will these data reduce or complement the need for universal newborn hearing screenings?
3. How is knowledge of the heritability of a patient's hearing loss incorporated in clinical practice currently, and how might this change in the coming years?

Educational Audiology

Cheryl DeConde Johnson and Carrie Spangler

INTRODUCTION

Audiology services in schools have been clearly defined in the Individuals with Disabilities Education Act (IDEA) since the law was first implemented in 1975. IDEA 2004 (US Department of Education, 2006) contains the most significant changes in policy since the inception of the law. This chapter will address educational audiology services, focusing on the roles and responsibilities as defined in IDEA as well as models for service delivery, caseload guidelines, licensure considerations, participation in the Individual Education Program (IEP) team, program development and evaluation, and ethics and conduct considerations.

EDUCATIONAL AUDIOLOGY SERVICES ACCORDING TO THE INDIVIDUALS WITH DISABILITIES EDUCATION ACT

Audiology is a related educational service under IDEA along with other related services such as speech-language pathology, psychology, and occupational therapy. IDEA is organized into several parts. This chapter will discuss Part B, which pertains to children 3 to 21 years old, and Part C, which pertains to infants and toddlers from birth to age 3 years. Although both sections address hearing loss, they have slightly different definitions (see Appendix 26.1). The definition differences directly impact an audiologist's responsibilities, and so are reviewed here:

- *Agency Responsibility.* Part B is under the education system in all states, whereas Part C responsibility depends on the specified lead agency within each state. Common agencies for Part C are education, health, or human services. Provision of services under Part C depends on several variables including income, the family's insurance, Medicaid and other state insurance programs, state agency services such as those provided through a state school for the deaf, and available services in the family's community. However, under Part C, a family should never be denied services because of inability to pay; ultimately, the community and state lead agency must provide funding for the necessary services.

- *Identification.* Part C specifies the use of appropriate screening techniques as part of identification; Part B does not.
- *Assessment.* Part C includes the assessment of communication functions as determined by the use of audiologic procedures.
- *Habilitation.* Assistive listening device orientation is included as part of habilitation in Part C; it is not mentioned in the Part B audiology definition but is included under the definition of assistive technology.
- *Prevention.* Part C provides for direct provision of services, whereas Part B calls for creation and administration of programs to prevent hearing loss. Direct services include monitoring children at risk of developing late-onset hearing loss.
- *Counseling.* Counseling services are absent in the Part C definition.
- *Amplification.* Part C includes selecting and fitting appropriate devices.

The following sections will discuss each of the areas within these audiology definitions.

IDENTIFICATION

Identification of children with hearing loss suggests several roles for audiologists. Identification does not explicitly mean hearing screening, but screening could be a step in the process toward identification of hearing loss. Resources and regulations in each state generally dictate the level of involvement of the audiologist at this stage. States that have mandated hearing screening of children in schools usually have the associated regulations within health or education agencies that direct those services. Because these procedures apply to all children, basic screening is considered a population-based event that should be completed by nurses, health aides, volunteers, or other individuals designated by the responsible agency, rather than a special education service.

Audiologists, however, do have a significant role in hearing screening programs. They should work with the appropriate state or local agencies to establish screening procedures, referral criteria, and follow-up activities as well as provide training for those individuals who perform the

screening. Screening procedures should be consistent with professional practice guidelines and should include measures that target identification of hearing loss in specific populations of students. For example, acoustic immittance may be part of a screening protocol for young children to identify middle ear problems, whereas the addition of 6,000 and/or 8,000 Hz to a puretone protocol for middle and high school-age students might identify potential noise-induced hearing loss. Audiologists may also assist with establishing databases to ensure that all students are screened and that follow-up is completed.

Children who are very young or unable to respond with traditional puretone screening methods may require special procedures as well as the expertise of an audiologist to conduct the screening. Otoacoustic emissions as a screening procedure have enabled more widespread screening of children who are young and difficult to assess by non-audiologists. With effective training and supervision, audiologists can manage these screening programs, leaving time for follow-up screening, audiologic assessment, and other audiologic activities. The American Academy of Audiology (2011b) provides specific guidance, based on evidence-based practices, for audiologists involved with developing and managing hearing screening programs. Appropriate roles for audiologists in school screening may include the following:

- Facilitate multiagency and community collaboration for hearing identification and referral including programs for early hearing detection and intervention (EHDI).
- Coordinate efforts with nurses, local deaf/hard of hearing services teams, and relevant community resources to implement hearing identification, assessment, and referral procedures that are consistent with professional practice guidelines.
- Manage required preschool, school-age, and Child Find screenings following state and local policies and procedures. Depending on state guidelines, screening may be conducted by trained paraprofessionals or volunteers under the supervision of the school nurse or educational audiologist.
- Provide technical support to the screening team including training; perform screenings for difficult to assess children/students.
- Conduct follow-up activities to ensure that those referred have received the prescribed service.

ASSESSMENT

Audiologic assessment that is focused on communication access in the school environment extends the traditional clinical evaluation. The goal in the educational setting is to not only define the parameters of the hearing loss, including the necessary referrals for diagnosis, treatment,

and hearing instrument fittings, but also determine individual educational implications. To fulfill this objective, audiologic assessment must address classroom listening including classroom acoustics, functional listening, and communication access. Other areas that should be considered are general developmental and educational performance, listening skills, hearing loss adjustment, and self-advocacy. For teens, assessment should include areas that teens need to know to function independently with regard to their hearing loss and communication needs and accommodations. Some of these areas can be addressed broadly through functional skill surveys such as the Functional Skills Screening for Children with Hearing Loss (Appendix 26.2). Assessment should always include information directly from the child whether as a series of questions or through play using a counseling tool such as My World (www.idainstitute.com). Table 26.1 summarizes these individual and environmental assessment areas and recommended procedures.

Hearing Assessment

Audiologic assessment of hearing includes standard measures as well as additional ones that yield a comprehensive profile of a child's auditory abilities. Assessment should include speech recognition tests that address the variety of listening situations encountered in the communication and learning situations such as the ability to understand soft speech and speech in noise. Audiologists should also include measures that provide detailed information regarding speech perception including ones that analyze suprasegmental (e.g., duration, loudness, pitch) and phonetic features of speech, phonemes, words, sentences, and discourse. The added information gained from knowing the auditory perception capabilities of these components assists speech-language pathologists and deaf education teachers in speech and auditory development, planning, and intervention. Otoacoustic emissions are available in most educational audiology settings and should be used when additional information is needed about the integrity of a child's auditory system or used with children who are low functioning or difficult to assess. Assessment should also include testing with the child's personal hearing instruments to assure that they are providing the intended benefit. Educational audiologists and private audiologists should work collaboratively to ensure that the comprehensive assessment covers all areas and duplication is minimized.

Communication Access Assessment

Assessment of communication access provides information on how children are communicating in their classroom and school environments with teachers and peers (normal hearing and deaf or hard of hearing).

TABLE 26.1

Educational Audiology Assessment for Children with Hearing Loss

Individual Measures	Environment Measures
<ol style="list-style-type: none"> 1. Hearing <ul style="list-style-type: none"> • Case history • Otoscopic • Air and bone conduction • Speech reception [unaided/aided] • Acoustic immittance • OAEs [as appropriate] • MCL/UCL [unaided/aided] • Word recognition at soft and average hearing levels and in noise [unaided/aided] • Aided verification procedures for hearing assistance technology [probe microphone] • Aided validation procedures for hearing assistance technology 2. Classroom communication <ul style="list-style-type: none"> • Classroom observation/teacher interview 3. Instruction <ul style="list-style-type: none"> • Classroom observation/teacher interview 4. Administrative support <ul style="list-style-type: none"> • Teacher/administrator interview

OAEs, otoacoustic emissions; MCL, most comfortable loudness; UCL, uncomfortable loudness.

A self-assessment protocol such as the Classroom Participation Questionnaire (Antia et al., 2007) is useful in identifying preferred communication patterns and determining how well the child is able to understand and be understood by peers and teachers. The protocol also includes information about the children’s feelings (positive and negative) regarding their ability to communicate. The audiologist should use this information to make adjustments to hearing assistance technology (HAT) and to serve as a basis for counseling to help students understand and identify strategies they might employ to improve or remediate challenging communication situations. The information may also be informative regarding the appropriateness of placement decisions, particularly components under “special consideration” [34 CFR 300.324(2)(iv)] in the development of the IEP in IDEA.

Classroom Listening Assessment

Assessment of classroom listening skills is an essential component in the evaluation of children with hearing loss. Functional assessments such as the Functional Listening Evaluation (FLE) (Johnson, 2013b); observation tools such as the Early Listening Function (ELF) (Anderson, 2002), the Children’s Home Inventory for Listening Difficulties (CHILD) (Anderson, 2000), the Listening Inventory for Education Revised (LIFE-R) (Anderson et al., 2011), the Children’s Auditory Performance Scale (CHAPS) (Smoski et al., 1998), and the Functional Auditory Performance Indicators (FAPI) (Stredler-Brown and Johnson, 2004); as well as self-assessments such as the student component of the LIFE-R provide critical information about the development of listening and communication skills. These findings support needed

accommodations, document benefits of those accommodations, and identify areas of needed skill development for the IEP.

Hearing Loss Adjustment and Self-advocacy

Classroom performance is often affected by one's level of self-esteem, confidence, and friendships. Including measures in the assessment process, such as English's (2002) Children's Peer Relationship (CPR) Scale (Note: The CPR is a set of discussion points, not a test) and the Self-Assessment of Communication—Adolescents (SAC-A) and Significant Other Assessment of Communication—Adolescents (SOAC-A) by Elkayam and English (2011a, 2011b), identifies levels of self-identification and adjustment to hearing loss and issues associated with lack of adjustment.

The audiologist should also determine how well a student is able to self-advocate for his or her communication needs. The Self-Advocacy Competency Checklist (www.phonak.com) defines self-advocacy development based on what students should know at each level of school (e.g., elementary, middle, high school) (Appendix 26.3).

BULLYING AND HEARING LOSS

Bullying is a growing topic that audiologists should address as part of self-concept and hearing loss adjustment (Squires et al., 2013). Bullying, particularly among school-age children, is a major public health problem both domestically and internationally. Pacer's National Bullying Prevention Center (2012) has reported studies indicating that children with disabilities are two to three times more likely to be bullied than their nondisabled peers.

Bullying is defined as unwanted, aggressive behavior among school-age children that involve a real or perceived power imbalance. The behavior is repeated, or has the potential to be repeated, over time. There are three types of bullying: (1) Verbal bullying (saying or writing mean things); (2) social bullying (sometimes referred to as relational bullying and involves hurting someone's reputation or relationships); and (3) physical bullying (hurting a person's body or possessions) (www.StopBullying.gov).

As practitioners, healthcare professionals should be vigilant for possible signs of victimization or bullying behavior among children and youth, particularly among high-risk youth such as children with disabilities or children who display characteristics of bully-victims. Healthcare professionals should ask children about their experiences with bullying and discuss possible concerns with parents. They should be prepared to make referrals to appropriate mental health professionals within the school or community (Fleming and Towey, 2002).

Identifying possible signs of bullying in children with hearing loss is an important counseling aspect of the role of the audiologist. Although the exact prevalence of bullying in children with hearing loss is unclear, it is at least as preva-

lent as typical children (Bauman and Pero, 2011) and there is evidence that deaf and hard of hearing children may be the most likely victims among the disability groups (Whitney et al., 1994). Professional associations in health care and safety are firm advocates for change whenever evidence suggests that the well-being of children is imminently at risk (www.stopbullying.org). The statistics and prevalence of students with hearing loss being a target are strong evidences that audiologists need to be firm advocates for the well-being of children with hearing loss who are imminently at risk.

Materials to guide audiologists with this issue are available on a website hosted by the American Academy of Audiology (www.audiology.org). A Bullying Decision Tree for Audiologists is a resource that can help audiologists begin the process of incorporating screening techniques into their audiology practice (Squires et al., 2013). The main focus of the website materials is to help audiologists identify the warning signs of bullying, investigate community and school resources, and provide ongoing support. Other tools include Bullying Screening Dialogue: Student Probes and Bullying Screening Dialogue: Parent Probes. These tools have been adapted from the "Roles for Pediatricians in Bullying Prevention and Intervention" (www.stopbullying.gov/resources/files/roles-for-pediatricians-tipsheet.pdf). The dialogue questions can help audiologists prepare themselves for this conversation, start the conversation, respond appropriately if there is a problem, and give proactive help if the child/family does not see a problem at the present time. The tools are intended to be used at frequent intervals to promote preventative practices in all stages of childhood and family life.

If a student is a victim of bullying, audiologists can help direct families to the educational and community resources that are available. Hands & Voices (www.handsandvoices.org) and Pacer's National Bullying Prevention Center (www.pacer.org) websites offer suggestions on how to address bullying specifically for children who have disabilities. Students with disabilities who are eligible for special education under the IDEA will have an Individualized Education Program (IEP). "The IEP can be a helpful tool in a bullying prevention plan. Remember, every child receiving special education is entitled to a free, appropriate public education (FAPE), and bullying can become an obstacle to that education" (www.pacer.org/bullying/resources/students-with-disabilities).

Instruments such as those mentioned in this section often provide counseling opportunities. The audiologist must be prepared in advance to address issues that are identified by the student during the assessment or interview process. Sufficient time should be scheduled during the assessment period or shortly thereafter to give students the opportunity to at least briefly talk about their problems and for the audiologist to begin to skillfully guide them through a problem-solving process. Anytime a student divulges sensitive information, it deserves at least acknowledgment and a response, even if brief. Time for more in-depth counseling can be scheduled once the "door has opened" (English, 2002).

Classroom Acoustics

Assessment includes measuring classroom noise, reverberation, and critical distance (CD) and making recommendations for improvement of the listening environment. Depending on the equipment used by the audiologist and the problems identified, the noise measurements may be sufficient for determining the need for acoustic treatment. The measurements may also be considered a screening that can be used as a basis for referral to an acoustic engineer. The American National Standards Institute/Acoustical Society of America (ANSI/ASA) classroom noise standards (ASA/ANSI S12.60-2010) provide the impetus for making acoustic modifications. These standards specify that, for typical classrooms (under 10,000 cubic feet), unoccupied noise levels should not exceed 35 dBA for the greatest 1-hour average and reverberation time (RT) should be ≤ 0.6 seconds. They further recommend that rooms be readily adaptable to allow reduction of RT to 0.3 seconds for children with special listening needs. Recent emphasis on educational outcomes for all students has highlighted the importance of the learning environment. Furthermore, it has been shown that poor classroom acoustics can also lead to voice fatigue and, subsequently, increased absences by teachers (Allen, 1995).

Classroom acoustics should be evaluated to provide evidence for HAT as well as the type of HAT that will best meet the child's communication needs. Rooms with high reverberation levels may preclude the use of classroom audio distribution systems (CADS also referred to as sound field systems) because sound distribution in highly reverberant areas may exacerbate speech intelligibility problems.

Audiologists in school settings should have a sound level meter (SLM) or smart phone app to conduct immediate screening of classrooms and other spaces. The app should be calibrated against a Type 2 or 3 SLM so that it can be adjusted, or corrections can be made for minor calibration differences. RT can also be measured with an app. If an RT app is not available, an estimated RT can be calculated using known sound absorption coefficients of typical materials used in school construction. CD is the maximum distance between the talker and listener before reflective sound begins to degrade speech transmission. CD is calculated based on room size and RT. Teachers need to know this distance and use this measure to maintain optimal speech communication for students with hearing loss. The American Academy of Audiology (2011a) has created a helpful worksheet for measuring classroom acoustics (see Supplement B).

Classroom Communication, Instruction, and Administrative Support

Interviews and observation provide important information about the appropriateness of the classroom context (e.g.,

general classroom physical environment, communication and instructional styles, the teacher's ability and flexibility in addressing the individual learning styles of students, and classroom management). These variables require careful attention when determining the classroom placement for a child as well as when making a recommendation for HAT. Administrative support is also critical in ensuring that the needs of the students are consistently met. School principals and special education administrators set the tone for their school's acceptance of students with diverse learning needs. Both school administration and teacher

- support for students with disabilities,
- knowledge about hearing loss,
- commitment to making the required accommodations for children with hearing loss,
- willingness to use and support assistive technology,
- willingness to work with specialists, and
- willingness to provide opportunities for individualized attention in the classroom.

Auditory Processing Assessment

Another component of audiologic assessment is the evaluation of central auditory processing abilities, an area of audition that should not be overlooked. The student's ability to understand what the ear hears is essential to the development of communication skills and for learning in school. The school setting is a common environment for identifying children with learning difficulties that may be auditory in nature. Educational audiologists should establish a multidisciplinary process with speech-language pathologists, school psychologists, and learning disabilities specialists to consider children who may have central auditory processing problems. The process should include screening and diagnostic procedures as well as intervention and treatment options. For more information on this topic, the reader is referred to Chapters 27 to 30 of this book.

Assessment Considerations for Eligibility for Services

To be eligible for special education, IDEA requires that there be an adverse impact of the disability on learning. Analysis of the findings must show that, without special education and related services, the child cannot reasonably benefit from a free and appropriate public education (FAPE). Therefore, audiologic assessment must include the procedures required by individual states for eligibility determination. Assessments are required for initial eligibility and re-evaluations which must occur minimally every 3 years. However, all children with hearing loss on IEPs should have annual audiologic assessments to monitor hearing thresholds, speech perception, listening abilities, use and performance of hearing technologies, and the child's functional performance. Even

though auditory sensitivity may be stable, the classroom listening environments change and therefore the accommodations and HAT, if used, need adjustment to assure the child has full communication access. The annual audiologic assessment should be written as a service in the child's IEP.

For children who are not eligible for special education services, the audiologist has a greater role because there is not a teacher of the deaf or other specialist monitoring them. In addition to audiologic assessment, educational performance should also be monitored at least annually to ensure academic level is maintained. This monitoring can be accomplished by the audiologist under a 504 Plan or as part of provisions under IDEA, Early Intervening Services or Response to Intervention (RTI). RTI is a general education program that focuses on high-quality instruction matched to student needs and monitoring of student progress to make decisions regarding educational programming. Audiologists play a critical role in this special education prevention program insuring that accommodations for students with hearing loss are implemented appropriately as part of monitoring student progress. Audiologists should be aware of their options for these programs and procedures according to their state regulations.

Interpretation of test results and recommendations should be detailed in a written report. It is helpful to include background information, test results, implications, and recommendations. A specific section of recommendations for the teacher and other school professionals often helps to highlight the most critical components and accommodations they need to know. Reviewing the report information with the student's teachers provides a forum for discussion as well as an opportunity for reinforcement of the issues, challenges, and necessary accommodations. Teachers appreciate when information is distilled to the essential elements they need to know. Therefore, including a short list of accommodations on a 4 × 6 card can be very helpful. By about third grade, the student should participate in the discussion, gradually taking the lead and developing his or her own list of accommodations. One tool to help a student take the lead is the Personal Profile and Accommodations Letter (PPAL) found within the Guide to Access Planning (GAP) program (www.phonakpro.com/us/b2b/en/pediatric/GAP.html).

AMPLIFICATION

Amplification and services that relate to both personal instruments and HAT are a major responsibility for audiologists in the school setting. IDEA details in its regulations provisions for amplification devices and monitoring the function of personal hearing instruments as well as HAT (Appendix 26.1).

The exclusion for cochlear implants was added in IDEA 2004 to limit the growing demands on schools for cochlear implant programming. IDEA 2004 also strengthened the responsibility of schools to monitor device function. As a

result, schools should always include a monitoring plan that specifies who monitors the device, when it is conducted, the procedures used, and what will happen if a problem is identified. It is recommended that this plan be included in the IEP. See Supplement B of American Academy of Audiology (2011b) for a sample amplification monitoring plan.

HAT that is required for the child to receive FAPE must be designated in the IEP and provided by the school as well as the accompanying services that are indicated. These services begin with a functional assessment in the child's classroom or other "customary" environment. Tools such as functional listening evaluations, observation checklists, and self-assessments provide this essential information. These same tools are also used to validate the effectiveness of recommended devices to assure that they provide the desired benefit. Fitting of HAT should be conducted using professional practice standards including probe microphone measurements (American Academy of Audiology, 2011b) with the specific goal of enhancing audibility of the desired speech signal (usually the teacher's voice), while maintaining access to the discourse of classmates. Educational audiologists must have access to appropriate hardware and software to complete these fittings. Device selection considerations are based on environmental, individual, and technologic factors such as conditions within the learning environment, the age of the student, developmental abilities, device wearability and ease of use, compatibility with other technologies, and potential interference issues. Audiologists must also plan and implement orientation and education programs to assure realistic expectations and to improve the acceptance of, adjustment to, and benefit from HAT as well as from hearing aids and cochlear implants. These programs should include the student, the student's classmates, relevant teachers, and school support staff, as well as the parents when devices are used at home. To summarize, selecting and fitting HAT should include the following steps:

- Determination of candidacy for HAT
- Considerations of device options and device selection
- Fitting and verification procedures
- Orientation and training activities
- Validation procedures
- Monitoring procedures

HABILITATION

Educational audiologists provide a wide range of habilitation services depending on their specific responsibilities in the schools. Regardless of the specific services delivered, the educational audiologist should support and advocate for appropriate intervention methods that address state standards and include

- auditory skill development and listening skill training;
- speech skill development, including phonology, voice, and rhythm;

TABLE 26.2

Audiology Individual Education Program (IEP) Services and Suggestions for Where to Include them in the IEP

Service	Where to Include Service in the IEP
Training students regarding use of their hearing aids, cochlear implants, and hearing assistance technology	<ul style="list-style-type: none"> • IEP goals and objectives—counseling, assistive technology services
Counseling and training for students regarding self-determination and self-advocacy skills	<ul style="list-style-type: none"> • IEP goals and objectives—counseling
Recommending acoustic modifications based on classroom acoustic evaluations that structure or modify the learning environment	<ul style="list-style-type: none"> • Accommodations
Educating and training teachers, other school personnel, and parents, when necessary, about the student's hearing loss, communication access needs, amplification, and classroom and instructional accommodations and modifications	<ul style="list-style-type: none"> • Related services—counseling • Related services—parent counseling and training • Assistive technology needs and services
Monitoring the functioning of hearing aids, cochlear implants, and hearing assistance technology [by who, how often, where, procedures used to monitor, and what will occur when a problem is identified]	<ul style="list-style-type: none"> • Related services • Monitoring plan addendum

- visual communication systems and strategies, including speechreading, manual communication, and cued speech;
- language development (expressive and receptive) of oral, signed, cued, and/or written language, including pragmatic skills;
- selection and use of appropriate instructional materials and media;
- use of assistive technologies, such as those necessary to access television, and telephones, as well as pagers and alerting devices;
- case management and care coordination with family/parent/guardian, school, and medical and community services;
- habilitative and compensatory skill training to reduce academic deficits as related to, but not limited to, reading and writing;
- social skills, self-esteem, and self-advocacy support and training;
- transition skills for self-determination and integration into postsecondary education, employment, and the community;
- the transition between, but not limited to, levels, schools, programs, and agencies; and
- support for a variety of education options for children with hearing loss and other auditory disorders.

To provide input regarding the associated communication and educational implications of the hearing impairment and the needed services, the audiologist must attend all IEP meetings for students with educationally significant hearing loss. Specific habilitation activities that are the

responsibility of the audiologist are identified in Table 26.2, along with suggested ways to document them in the IEP. Since the IEP is the contract that assures services, they must be included in the IEP, along with the frequency with which they are provided and who provides them.

COUNSELING

Counseling services can be provided for the student and the student's family, as well as school staff. Counseling students about their hearing loss provides information, emotional support, and the opportunity to develop self-advocacy skills. Students need to be able to generally describe their hearing loss and understand the necessary accommodations they need in various learning and communication situations. As discussed earlier in the chapter, the Self-Advocacy Checklist (www.phonak.com) suggests a framework for addressing some of these self-advocacy skills, whereas English (2012) provides a curriculum for self-advocacy activities. Audiologists should work with the educational team (school psychologist, speech-language pathologist, educational interpreter, and deaf education teachers as well as the students' classroom teachers) to assure that goals are consistently supported and developing skills are reinforced.

The incidence of emotional disturbance in students with hearing loss is low, about 2% according to the 2010 Gallaudet Annual Survey (Gallaudet Research Institute (GRI), 2010). The GRI also reports that 10% of students participating in its survey received counseling services. Whenever students exhibit significant problems, audiologists should also

refer and defer to the school counselor or school psychologist; preferably, this professional has expertise with children who are deaf and hard of hearing. When providing counseling services, the audiologist should

- assure that parents/guardians receive comprehensive, unbiased information regarding hearing loss, communication options, educational programming, and amplification options, including cochlear implants in cases of severe to profound hearing loss;
- demonstrate sensitivity to cultural diversity and other differences, including those found among individuals and within family/guardian systems and deaf culture; and
- demonstrate reflective listening and effective interpersonal communication skills.

Parent counseling and training is a separate, related service in IDEA. The law specifies that support should be provided to families if it is needed for their children to meet their IEP goals and to receive FAPE. Parents can choose whether or not they desire the support. Unfortunately, this service is underused and can be difficult to implement because of confusion about how to include the service in the IEP, how to provide the service, and how to promote and monitor parent compliance. IDEA states the following:

From the Federal Code of Regulations, Title 34, Section.300.24(c)(8)

- Parent counseling and training means assisting parents in understanding the special needs of their child;
- Providing parents with information about their child's development; and
- Helping parents to acquire the necessary skills that will allow them to support the implementation of their child's IEP or IFSP.

Counseling for school staff is focused on information that teachers and others need to understand the implications of hearing loss and implement appropriate accommodations. Ongoing services should be included in the child's IEP as discussed in the previous section on habilitation.

PREVENTION

Based on the results of the Third National Health and Nutrition Examination Survey (NHANES III), Niskar et al. (2001) estimated that about 12% of children 6 to 19 years old have noise-induced hearing threshold shifts in one or both ears. Shargorodsky et al. (2010) reported data from 1998 to 2006 indicating that the incidence of noise-induced hearing loss among adolescents had increased significantly. In recognition of this evidence, a report called *Healthy People 2020* (US Department of Health and Human Services, 2010) includes the following objectives related to hearing loss prevention in adolescents:

Objective ENT-VSL 6.2. Increase the proportion of adolescents 12 to 19 years who have ever used hearing protec-

tion devices (earplug, earmuffs) when exposed to loud sounds or noise.

Objective ENT-VSL7. Reduce the proportion of adolescents who have elevated hearing thresholds, or audiometric notches, in high frequencies (3, 4, or 6 kHz) in both ears, signifying noise-induced hearing loss.

Prevention of hearing loss, even though required under IDEA, usually receives the least emphasis of all of the audiology services in school audiology practices. Concern in this area is growing based on some of the following issues:

- Schools, as government entities, are exempt from the US Occupational Safety and Health Administration's (OSHA) standards unless there are state OSHA-like requirements. Yet, shop class noise levels have been reported to range from 85 to 115 dB (Langford and West, 1993).
- Noise regulations that do exist in schools apply primarily to classified staff (e.g., grounds, facility, print shop, cooking staff).
- Insurance companies for schools have limited knowledge of noise exposure hazards.
- School hearing screening is not mandated in all states; thus, a mechanism to identify children with potential noise-induced hearing loss is not consistently available; when screening programs do exist, they generally are not designed to identify students with noise-induced hearing loss.

Although there are many resources available that provide hearing loss prevention education (e.g., Dangerous Decibels, www.dangerousdecibels.org; Crank it Down, www.hearingconservation.org; Wise Ears, www.nidcd.nih.gov/health/wise/index.htm), the difficulty lies in coordinating efforts for implementing a systematic hearing loss prevention education program within the curriculum. With the required effort that is necessary to address this area for all students, it is imperative this service be part of a larger agenda shared by health and general education services. Thus, noise-induced hearing loss needs a national focus as a preventable health condition. Given this information, educational audiologists should support such an effort by promoting the following activities (Johnson & Meinke, 2008):

- Noise education activities that are embedded in the school health and science curriculums at multiple grade levels
- Identification of "at-risk" and "dangerous" noise sources
- Mandatory noise safety instruction for classes with potentially hazardous noise exposure, including strategies to minimize noise exposure in those settings
- Mandatory use of hearing protection for all individuals who work in noise-hazard areas
- Mandatory monitoring of hearing levels of classified employees and teachers who work in noise-hazard areas
- Training for school employees in hearing loss prevention, proper use of ear protection, noise control strategies, and interpretation of hearing test results

- School policies to limit decibel levels and exposure time at school-sanctioned events
- Required hearing screening of students that includes protocols targeted to identification of noise-induced hearing loss

MODELS OF SERVICE PROVISION, CASELOADS, AND LICENSURE

Models of Service Provision

There are two primary methods that schools may use to deliver audiology services: (1) Employment directly by the local education agency (LEA) responsible for providing special education and related services or (2) through a contract with an individual, organization, or agency for specified audiology services. The LEA is either the local school district or a consortium established by the state that provides special education services for a group of school districts. These state consortia are usually referred to as Boards of Cooperative Educational Services, Intermediate Units, or Area Education Agencies, and are structured under the respective state department of education to provide special education services.

Although both models can be effective, educational audiologists hired by LEAs usually provide more comprehensive services. As employees of the education agency, educational audiologists are peers of the teachers and other staff and therefore may be more effective working within the system. Their schedules are designed around the school day resulting in more availability and flexibility for meeting student needs and providing teacher support, particularly for students who are not served under special education. Contracted services are often more limited because they are restricted to the specific services that are negotiated. School districts usually prioritize these services to the minimum necessary to provide follow-up to screenings, audiologic assessment, and HAT management. Contracts must assure that services are in compliance with state and federal requirements and that timelines are met. One of the most significant challenges with contracted services is supervision. In these situations, the school administrator providing oversight often has little knowledge of the roles and responsibilities of audiologists, and it is not uncommon for these audiologists to be less familiar with the scope of practice in the schools when they are from private practice or other noneducational settings. For more information about contracting audiology services, see the Educational Audiology Association's Guidelines for Developing Contracts for School-based Audiology Services at www.edaud.org.

Another employment setting that carries unique responsibilities for the educational audiologist is schools for the deaf. In this environment, the audiology role must support the communication systems that are used by the students. Still, it is the audiologist who bears much of the responsibility to assure auditory communication access to those students

who utilize hearing and listening whether as a primary means of communication or to supplement visual systems (e.g., sign language). It often requires a slightly different approach, one that is sensitive to the preferences of the child, his or her family, and the culture of the school.

Caseloads and Workloads

Caseloads for audiologists are recommended at one audiologist for every 10,000 students (American Speech-Language Hearing Association, 2002; Educational Audiology Association, 2009). This ratio assumes a caseload of children with hearing loss and central auditory processing problems based on current prevalence rates. Workload analysis is another factor in determining the number of students served (Figure 26.1). Workload factors that may influence this ratio for a school system include but are not limited to

- the geographic area and travel time, such as within the LEA;
- the number of students with hearing loss served by the LEA:
 - the number of students with additional disabilities,
 - service provision to regional and/or self-contained programs for students who are deaf/hard of hearing,
 - involvement with hearing loss prevention programs and school-age hearing screening programs,
 - role in follow-up diagnostic audiologic assessment of hearing screening program,
 - involvement with RTI,
 - meeting federal, state, and local mandates for the child's IEP,
 - documentation of activities and Medicaid,
- the quantity and diversity of FM and other HAT;
- the quantity of special tests that are performed such as electrophysiological tests, auditory skill development, and auditory processing;
- the amount of in-house equipment calibration, test-check, and maintenance activities that are performed; and
- involvement with local newborn and early childhood screening follow-up, and early intervention.

When direct services to students are provided by the audiologist, the ratio must be further adjusted using caseload guidelines for consultant and itinerant teacher service delivery models. Figure 26.1 illustrates core components of the educational audiologist's workload. More information on workload analysis for audiologists is available from Johnson and Seaton (2012). ASHA also has workload guidelines for SLPS that can serve as a framework for educational audiologists.

Licensure

Audiologists who provide services in the schools must adhere to state licensing requirements. Several states have

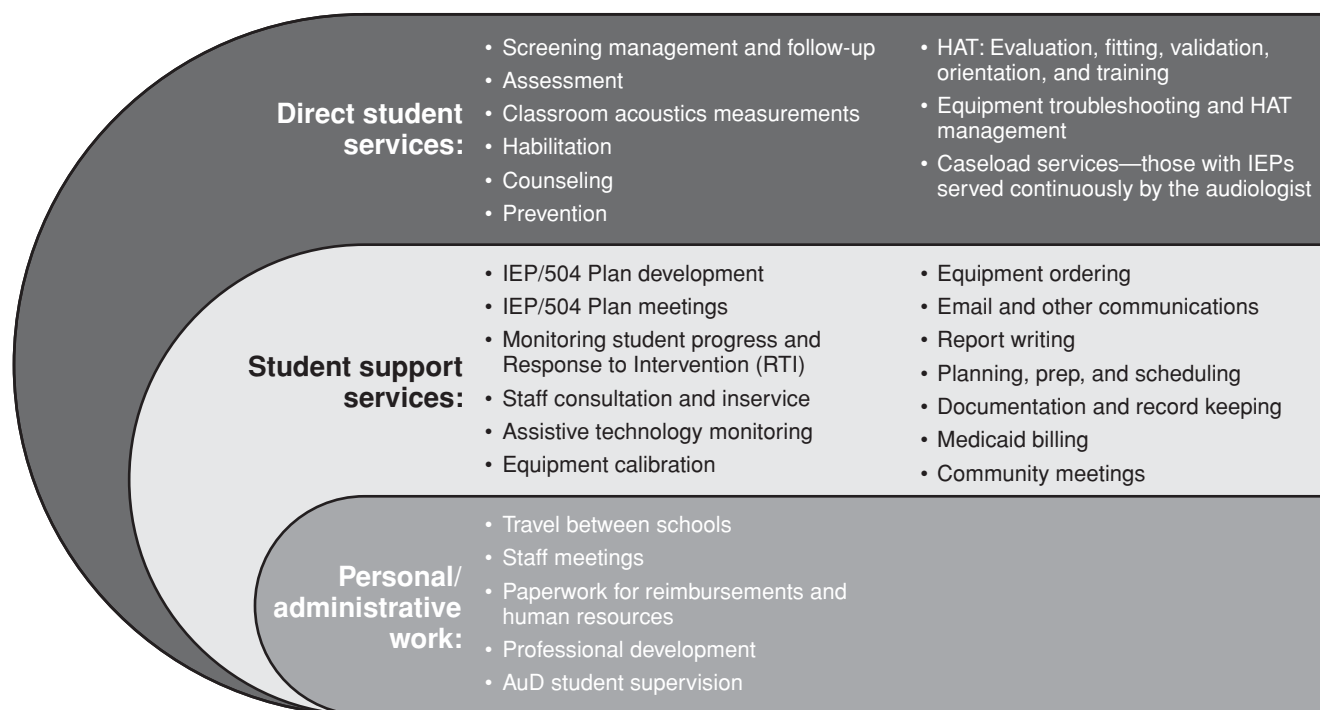

FIGURE 26.1 Workload model of educational audiology responsibilities.

specific certification or licensure for audiologists who are employed in school settings, which is administered through the state department of education. For example, audiology graduate programs in Colorado must demonstrate that their curricula meet knowledge and skill standards and complete a school-based practicum in audiology so that the graduates are eligible to meet the state's Department of Education qualifications in school-based audiology services.

Recognition of advanced specialty practice for pediatric and educational audiologists through the Pediatric Audiology Specialty Certification (PASC) by the American Board of Audiology (ABA) is another opportunity for audiologists to demonstrate and market their expertise. The PASC requires a 2-year postgraduate professional experience including 600 pediatric contact hours and a passing score in the PASC examination. The examination is built on knowledge and skills in seven domain areas: laws and regulations, general knowledge about hearing and hearing loss, child development, screening and assessment procedures, counseling, communication enhancement technology, and habilitation/rehabilitation strategies and educational supports. For more information, see <http://www.americanboardofaudiology.org/specialty/pediatric.html>.

ROLE IN THE INDIVIDUAL EDUCATION PROGRAM TEAM

Special education eligibility and IEP development require input from the educational audiologist to ensure that information about the implications of the child's auditory, listen-

ing, and communication skills are understood. To assist in planning for the learning and communication of children with hearing loss, the audiologist uses data from a variety of sources (e.g., teacher, student, and parent interviews; observations; informal and formal assessments; classroom acoustic evaluations), explains the implications of hearing and listening on the child's ability to communicate and learn, and recommends appropriate HAT.

After a comprehensive profile of a child is developed, the educational audiologist is a resource for planning and implementing evidence-based interventions to increase academic, communication, and social performance. The audiologist's goal as an IEP team member is to collaborate with educators, parents, and other related service professionals to create supportive, communication-accessible learning environments for all students. When children are not eligible for special education, the audiologist should guide the development of an accommodations plan under another educational support system called a Section 504 plan (Johnson and Seaton, 2012) and should serve as the case manager to monitor implementation of the recommendations and the ongoing child's performance trajectories.

PROGRAM DEVELOPMENT AND EVALUATION

An effective educational audiology program undergoes continuous evaluation to determine whether the services continue to meet the needs of the students, staff, and others it serves. Mechanisms for identifying program gaps and

updating technology and services require systematic review and, in turn, help to prioritize future needs. Program components should focus on the impact of audiology services on student outcomes. With teacher evaluation increasingly tied to student performance, educational audiologists need to articulate how the services they provide also impact student performance. Data obtained through program service reviews, workload analysis, and teacher and parent input can be very powerful for affecting change.

ETHICS AND CONDUCT IN EDUCATION SETTINGS

The ethical responsibility for implementing the audiology requirements of IDEA based on the scope of practice discussed in this chapter can be challenging. Given the resource limitations that exist, educational audiologists frequently struggle with doing the right thing. The following questions are just some examples of the ethical dilemmas faced daily by educational audiologists:

- Are you able to evaluate students as often as best practices recommend?
- Are you able to conduct comprehensive assessment procedures that evaluate the functional aspects of hearing ability such as speech in noise, soft speech, speech with and without visual cues, and listening skills?
- Do you have access to current technology for conducting hearing evaluations and providing habilitation?
- Are you able to provide hearing assistive technology to *all* students who would benefit?
- Are you able to recommend the hearing technology that best suits a child's hearing needs?
- Are you able to meet with teachers and staff to discuss the results of each student's audiologic assessment and describe the implications of the loss on hearing and learning?
- Are you able to attend all IEP meetings for students with auditory deficits?
- Are you able to consult or teach students about the effects of noise exposure and requirements for hearing protection?
- Are you able to advocate for appropriate classroom acoustics?

Educational audiologists are often balancing the services they should provide with the resources (mostly time) available to do them. As a result, they often have to make decisions regarding which services should continue and which services need to be eliminated or modified. Reconciling the responsibility for providing “adequate” services versus what is often referred to as “the Cadillac model” can be challenging. Audiologists should be prepared to justify all of their activities under the scope of audiology that is mandated by IDEA to avoid the issue of their administrators perceiving that they are doing more than the law requires.

An ethical question that is often faced is, “How does one balance the necessary audiologic services with what individual school settings allow?” Given the emphasis on accountability that is currently present in the education system, all audiologists should have an ongoing evaluation process for their program that provides data on student numbers, types of services, use of amplification, and student performance, coupled with a plan for addressing unmet needs. Sufficient evidence is needed before a special education director can justify supporting an audiologist's request for additional funds, time, or resources.

Effective audiology support and services are critical to all children and youth with auditory disorders. School-based audiologists have distinct roles and responsibilities to assure that these students are identified and properly assessed and managed so that they have the same opportunity to access their educational program as all students. They are simply children who have an extra communication challenge because of their hearing loss or processing issues; it is the job of the audiologist and the other school team members that support these students to minimize the impact of their impairments. The Educational Audiology Association (www.edaud.org) provides additional information and resources for school-based audiology services.

FOOD FOR THOUGHT

1. Compare the differences in Part B and Part C of IDEA. How do those differences impact the audiologist's responsibilities?
2. Consider the student enrollment (caseload size) for educational audiologists. What factors influence the audiologist's ability to provide compliance-based audiologic services? How might workload factors affect alter the caseload model?
3. How would your services as an educational audiologist shift as the student moves from elementary, middle, and high school?
4. Identify strategies the educational audiologist can use to increase student self-determination of accommodations to improve communication access at school.
5. The numbers of students with hearing loss who are not served by IEPs are increasing. Discuss how the educational audiologist might monitor and support these students.

Central Auditory Processing: A Functional Perspective from Neuroscience

Dennis P. Phillips and Rachel N. Dingle

INTRODUCTION

Generally, reviews of central auditory processing (CAP) take either of two approaches. One details the anatomy and physiology of the central auditory pathway, including such issues as synaptic organization, neurotransmitters, and neural circuits. The second approach is much more functional because it provides descriptions of the perceptual and cognitive processes involved in hearing and what goes wrong in various central disorders. In this chapter, we offer something of a “middle path”: What we are interested in communicating is how the general neural architecture of CAP, as seen in neurophysiological studies, is related to the perceptual architecture that it supports. Those of us interested in functional hearing seek an understanding of CAP that links the properties of neurons (or of neural populations) responding to sounds with our private, mental experiences of those sounds. To be sure, we are a long way from a comprehensive understanding of this relationship. On the other hand, many exciting clues about this relationship are being reported.

The purpose of this chapter is to discuss specific topics that will provide a conceptual framework with which the reader can explore further. This chapter begins with the general anatomy and physiology of the central auditory system, starting with the auditory nerve and then ascending to the auditory cortex. We also provide a perspective on why the descending auditory pathways are so important. Lastly, because sounds inescapably unfold in both time and space, we discuss topics in central processing that emphasize temporal and spatial processing; great advances have been made in relating these neurophysiological and perceptual functions.

THE AUDITORY NERVE

The cochlea communicates with the auditory brainstem via spiral ganglion cells (the axons of which are sometimes called “auditory nerve fibers”). About 90% to 95% of spiral ganglion neurons form synapses with the cochlea’s inner hair cells (IHCs). The form of this afferent organization is

to connect one-to-many, that is, each spiral ganglion cell contacts a single IHC, but each IHC provides input to 20 to 25 auditory nerve fibers. There are no synaptic connections between spiral ganglion cells that serve any given IHC, nor is there significant information transmission between IHCs, with the result that the information transmitted by a given cochlear neuron is largely slave to the activity of the one IHC it innervates.

The cochlea performs a spectral decomposition of the incoming vibrations, such that different basilar membrane loci are forced into oscillation by sounds of different frequencies. This decomposition has the consequence that different IHCs, and thus different auditory nerve fibers, are responsible for transducing sounds of different frequencies and transmitting that information to the central nervous system. In practice, the motion of the basilar membrane at any given site is driven by two factors (Carney, 2012; Harrison, 2012). One is the passive response of the membrane to pressure waves in the cochlear fluids produced by motion of the stapes at the oval window. The second factor is the cochlea’s “active process” or “cochlear amplifier.” The active process can be thought of as an amplification of basilar membrane motion resulting from outer hair cell contractility (hair cell shortening as the membrane moves upward toward scala vestibuli, and hair cell relaxation as the basilar membrane moves downward toward scala tympani). The active process both enhances the sensitivity of the mechanical response and markedly improves its selectivity. The IHCs then passively receive the finely tuned basilar membrane motion and transduce it.

At low frequencies, the IHC membrane response is dominated by an alternating current component; the IHC depolarizes with upward motions of the basilar membrane and hyperpolarizes with downward ones. Because neurotransmitter release by the IHC is tied to membrane depolarization, the oscillating membrane potential affords neurotransmitter release and thus excitation of spiral ganglion cells selectively during upward motion of the basilar membrane. This means that the cochlear nerve spike trains evoked by low-frequency sounds carry information about

the phase of basilar membrane motion, and by extension, the phase of eardrum motion. This synchrony between neural spiking and ear drum motion or sound frequency is termed “phase-locking.” At higher frequencies, the IHC membrane response is increasingly dominated by a direct current (“pedestal”) depolarization response, which results in neurotransmitter release that is more continuous during the stimulus and impedes phase-locking of cochlear neuron action potentials to stimulus phase. To be sure, phase-locking of auditory nerve responses can occur for high-frequency sounds, but it is usually tied to the amplitude envelope of modulated signals and not to individual cycles of the carrier stimulus (see descriptions in Carney, 2012; Phillips et al., 2012b).

The spectral decomposition function of the cochlea is perhaps most clearly revealed in the frequency tuning curves of cochlear neurons (Figure 27.1A). A frequency tuning curve is a plot of the minimum tone amplitude in decibels required to evoke an increase in neural spike rate (above spontaneous levels) as a function of tone frequency. These tuning curves are deep, narrow, V-shaped functions. The tuning curves of high-frequency cells additionally have a high-threshold low-frequency tail. The frequency to which the neuron is most sensitive is called the characteristic frequency (CF) for that neuron. Without the cochlear amplifier, tuning curves are insensitive and broad (Harrison, 2012). Tuning curves for the basilar membrane motion at any given site are strikingly similar to those of cochlear neurons innervating that site. Thus, despite the change in response from up and down motion (basilar membrane) to discharge of action potentials (auditory nerve fiber), there is little change in the frequency tuning information being transmitted.

Another way to examine the frequency selectivity of cochlear neurons is by studying the response area, which is a plot of the spike firing rate as a function of frequency with tone amplitude as the parameter (Figure 27.1B; see also Carney, 2012). At low sound amplitudes, these functions are narrow and peaked. At high amplitudes, the functions are broader and rounder. The difference reflects the influence of the cochlear amplifier (at low sound pressure levels) giving way to passive mechanics (at high sound pressures; see also Plack, 2005). Consider Figure 27.1B. At this neuron’s CF (4.5 kHz), the response is both sensitive (threshold near 20 dB) and grows over a dynamic range of about 40 dB before saturating. In contrast, at low frequencies (e.g., 2 kHz), the threshold is higher (approximately 55 dB) and the dynamic range is only about 25 dB wide. The responses near CF are shaped by the cochlea’s active process, whereas those at high intensities are shaped by passive cochlear mechanics. As we step from responses to low-amplitude sounds to responses to high-amplitude ones, we also step from the active cochlea to the passive one. In the absence of the active process, cochlear neurons are both insensitive and have broad frequency responsiveness (see also Harrison, 2012). The behavioral correlates of this are loss of absolute sensitivity to sound (“hearing loss”), impaired frequency selectivity (because the fine frequency tuning is lost and so the spectral decomposition process is coarser), and possibly loudness recruitment (because neural firing rates go from minimum to maximum over a small amplitude dynamic range).

Figure 27.1 contrasts these two depictions of the frequency selectivity of cochlear nerve fibers. Figure 27.1A presents a tuning curve for an idealized cochlear neuron with a CF near 4.5 kHz. Figure 27.1B presents response area

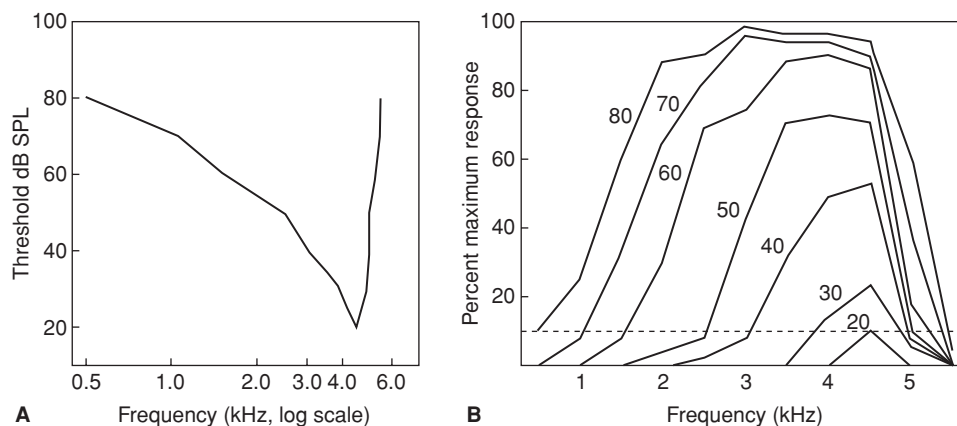

FIGURE 27.1 The frequency selectivity of an idealized cochlear neuron depicted in two ways. **A:** The frequency tuning curve, which is a plot of the minimum tone level required for an excitatory response plotted as a function of tone frequency. These are typically narrow and V-shaped, with a clearly defined characteristic frequency to which the neuron is most sensitive. **B:** Response area data for the same idealized neuron. Here, firing rate is plotted as a function of tone frequency with tone level in dB sound pressure level as the parameter. The tuning curve can be derived from the response area data by defining threshold as 10% of maximum firing rate [dotted line in **B**] and reading off the frequency at which each iso-intensity contour crosses it.

data for the same idealized neuron. The lines are iso-intensity contours, with intensity specified in dB sound pressure level. Note that at low tone amplitudes the effective frequency range is narrow and that as tone level is increased there is a negatively accelerating growth in response rate, and an expansion of the range of effective frequencies, especially toward the low-frequency side. The tuning curve in Figure 27.1A was derived from the response area (Figure 27.1B) by reading off the stimulus frequency at which each iso-intensity contour crossed the 10% maximum response rate (dotted horizontal line in Figure 27.1B).

Cochlear neuron physiology is thus the endpoint of the peripheral spectral decomposition process. It is the job of cochlear neurons to transmit to the brain the presence of stimulus energy within their tuning curves, the amplitude of that energy, and the timing of the stimulus event(s). It is the job of the central auditory system to represent this information (i.e., establish a “neurological picture” of it) and to group together the activity in different frequency channels to define separate auditory sources, their spatial locations, and their timings.

THE CENTRAL AUDITORY PATHWAYS

The Auditory Brainstem

Cochlear neurons send their axons to the cochlear nucleus (Figure 27.2); the axons bifurcate, with one branch going to the anteroventral cochlear nucleus (AVCN) and the other one going to the cells of the posteroventral cochlear nucleus en route to the dorsal cochlear nucleus (DCN). The cochlear nucleus is strictly organized tonotopically. That is to say, the projections from the cochlea to each division of the cochlear nucleus are topographically arrayed, so that information from each cochlear locus is sent to three sheets of neurons in the cochlear nucleus, and within each division, cells in sheets that are spatially next to each other have CFs that are spectrally next to each other. The fact that each division of the cochlear nucleus thus contains a complete representation of the cochlea’s frequency organization permits a parallel processing of different streams of auditory information. As a first example of this, neurons of the AVCN, deriving input from the apical (low-frequency) cochlea, often have a low input resistance; they are, however, innervated by auditory nerve axons via end-bulbs of Held, special synapses that provide a large synaptic current. This matching between input resistance and synaptic current imparts a strong spike-in/spike-out relationship that preserves the time structure of the primary afferent spike train in the AVCN output. This preservation of temporal information becomes important in the medial superior olive (MSO) (a major target of AVCN output), because MSO neurons compare spike times from the two ears to compute sound source location from the relative phases of the stimuli at the two ears (see below). In

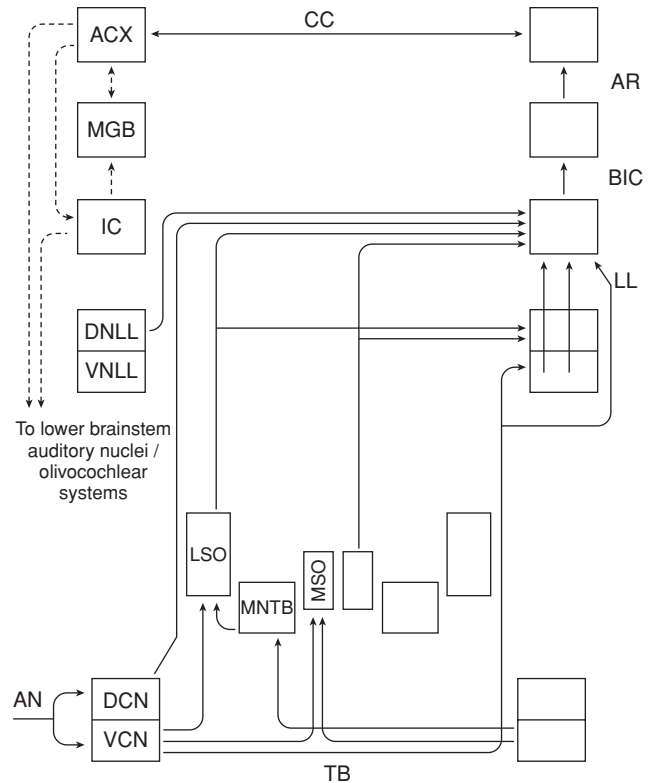

FIGURE 27.2 Schematic diagram illustrating the central auditory pathways. For simplicity, only major structures and pathways directly relevant to this chapter are shown. Ascending [body of illustration] and descending connectivities [left side] are for clarity shown for one side of the auditory forebrain only. Abbreviations: ACX, auditory cortex; AN, auditory nerve; AR, auditory radiations; BIC, brachium of inferior colliculus; CC, corpus callosum; DCN, dorsal cochlear nucleus; DNLL, dorsal nucleus of lateral lemniscus; IC, inferior colliculus; LL, lateral lemniscus; LSO, lateral superior olive; MGB, medial geniculate body; MNTB, medial nucleus of trapezoid body; MSO, medial superior olive; TB, trapezoid body; VCN, ventral cochlear nucleus; VNLL, ventral nucleus of lateral lemniscus.

contrast, the DCN contains circuitry that supports elaborate inhibitory domains in its cells’ frequency-intensity response areas. Many of these cells develop nonmonotonic spike rate-versus-intensity functions and become sensitive to stimulus bandwidth because of inhibitory response areas flanking the excitatory one centered on the CF. The excitatory response areas of these cells can be very small, so that small changes in stimulus spectrum could in principle result in large changes in the populations of neurons activated. These specializations of the DCN likely serve to enhance the central representation of fine spectral detail.

A major target of projections from the ventral cochlear nucleus (VCN) is the superior olivary complex (SOC; Figure 27.2). The SOC contains a number of nuclei and these are also tonotopically organized. The MSO receives bilateral

inputs from the VCN, specifically from neurons that preserve the phase-locked spike timing that was generated in the auditory nerve. This means that MSO neurons can serve as “coincidence detectors” for the timing of spikes from the two sides and in this way compare the phase of low-frequency stimuli at the two ears. Early studies used tonal stimuli (usually CF ones) to examine sensitivity to interaural phase difference (IPD) of neurons rostral to MSO, with the inference being that what was observed in the more rostral nuclei was in part a reflection of processing at the MSO. They showed that the inputs from the two ears are ones phase-locked to basilar membrane motion on each side. In turn, basilar membrane motion is phase-locked to eardrum motion, and the phase relation of sound as it reaches each eardrum is dependent on the azimuthal location of the sound source. The firing rate of MSO cells depends on the temporal coincidence with which spikes from the two ears arrive. This behavior is to be expected of a mechanism that executes a cycle-by-cycle comparison of the phase of the stimulus at the two ears.

More recently, information about neural sensitivity to IPDs has been acquired using noise stimuli (Hancock and Delgutte, 2004; McAlpine et al., 2001). The basic ideas involved in this approach are (a) that central neurons respond to all of the frequencies within their tuning curves and (b) that by using noise stimuli, one obtains a weighted average of responses to IPDs at all of the frequencies to which the neuron is responsive. Plots of firing rate versus IPD obtained in this way are generally called “composite delay functions.” These composite delay functions tend to have a single peak at a “best IPD” and may or may not have lower side-lobes. In guinea pigs (McAlpine et al., 2001), gerbils (Brand et al., 2002), and cats (Hancock and Delgutte, 2004) composite delay functions have at least two features in common. One feature is that the peak of the delay function, when the IPD is expressed in units of phase (as opposed to time), is nearly constant at about 45 degrees (i.e., about 1/8th of a cycle of interaural phase) favoring the contralateral ear, irrespective of a cell’s CF. For animals with small heads, this means that the peak firing rate is evoked by IPDs outside the behaviorally relevant range. The second feature is a correlate of the first, namely that the steep part of the delay function, that is, the portion of the stimulus–response relationship that is most informative about the IPD of the sound, is centered very close to zero delay. That is, small changes in IPD near 0 μ s (or degrees of phase angle) bring about large changes in neural firing rate. The fact that this is true in species with head sizes as different as those of gerbils, guinea pigs, and cats has important implications for the evolution of sound localization mechanisms in mammals (Phillips et al., 2012b).

In principle, the coincidence detection seen in MSO and higher neurons could be based solely on excitatory inputs from the two sides (after Jeffress, 1948). In practice, neural sensitivity to IPDs (and thus, sound source location)

at the MSO and other nuclei typically involves inhibitory inputs—likely mediated through other SOC nuclei. These inhibitory inputs serve at least two functions. One is to increase the extent to which firing rates are modulated by variations in interaural phase. The second is to ensure that the maximum sensitivity to change in IPD is centered over IPDs very close to 0 μ s (Brand et al., 2002). We shall return to this point below in the section specifically on sound localization mechanisms. For now, what is important is that the spike rate-versus-IPD function is most informative for IPDs relatively close to zero, with spike rates commonly at a maximum for IPDs favoring the contralateral ear and at a minimum for those favoring the ipsilateral ear. Behavioral sensitivity to the location of low-frequency sounds is also greatest for source locations near the midline, and so we have a clear neural correlate of behavioral performance (Hancock and Delgutte, 2004; Phillips and Brugge, 1985; Phillips et al., 2012b).

The lateral superior olive (LSO; Figure 27.2) also receives bilateral inputs from the VCN. The ipsilateral input to LSO cells is direct and excitatory. The contralateral input is via the medial nucleus of the trapezoid body and is inhibitory. The strength of each input is intensity dependent. LSO cells thus have firing rates that are sensitive functions of the relative amplitudes of the sound at the two ears. That is, they encode the interaural level difference (ILD) of a sound, and since the ILD is azimuth dependent, the sensitivity to ILD is a code for sound source azimuth (location). In practice, the spike rate-versus-ILD functions are sigmoidal in shape, with the strongest responses for stimuli in which the ILD favors the ipsilateral ear and with the steep portion of the function centered close to zero ILD.

The axonal outputs of the MSO are predominantly uncrossed and projected on the inferior colliculus (IC) directly, or indirectly via the dorsal nucleus of the lateral lemniscus (DNLL). The outputs of the LSO are predominantly crossed and again are projected directly on the IC, or indirectly on the IC via the DNLL. A consequence of this pattern of uncrossed and crossed connectivity is that above the level of the SOC, binaural neurons sensitive to IPDs and ILDs most often tend to be excited maximally by IPDs and ILDs that favor the contralateral ear. By extension, this means that the majority of forebrain auditory neurons sensitive to sound location cues should respond maximally to free-field sound sources in the contralateral auditory hemifield and minimally to sources in the ipsilateral hemifield and have spatial receptive field borders straddling the midline. Because the MSO and LSO outputs have minor crossed and uncrossed outputs, respectively, there should also be exceptions to this generality. As will be seen below, these hypotheses are confirmed empirically.

The convergence of input on the IC has some striking features. An excellent example comes from Semple and Aitkin (1981). They showed that some high-CF cells of the IC had physiologies and afferent connectivities indicating a

convergence of input from the DCN (e.g., nonmonotonic rate-intensity functions for CF tones) and binaural interactions reflecting LSO input. In a different example of hierarchical processing, whereas the responses of MSO cells to IPD stimuli are dominated by the instantaneous IPD of the stimulus, at the IC, neurons become sensitive to the recent history of stimulus IPD (i.e., they become sensitive to change in IPD, and thus simulated auditory motion: Spitzer and Semple, 1998). In yet another example, crossed inhibitory projections from the DNLL to the IC clearly “sharpen” the sensitivity of IC neurons to binaural sound localization cues (see Kidd and Kelly, 1996). What is less clear is whether the resulting sensitivity to localization cues is any better than that seen in the input sources (i.e., whether the “sharpening” is a sharpening per se or simply restores the sensitivity lost when cue-sensitive and cue-insensitive inputs converge.)

The Auditory Forebrain

The ICs project on the ipsilateral thalamic medial geniculate bodies (MGBs; Figure 27.2), which in turn project on the auditory cortex of the same side. The auditory cortex has a complex structural and functional organization (see Rauschecker and Romanski, 2011 for recent review). Particularly, in human beings and primates (probably also in cats), the auditory cortex is divided into “core” and “belt” regions, each of which is made up of a number of separable fields distinguished by their physiology and their afferent and efferent connectivities. Some of these fields are tonotopically organized, typically manifested as strips of cortical tissue containing neurons of comparable CF, and spatially arrayed to span the audible frequency range. Other fields have less obvious tonotopy and contain neurons with broad or irregular frequency tuning. In the tonotopic primary auditory cortex (AI), neurons are usually sharply tuned to frequency, have short response latencies, and have diverse binaural interactions that have been inherited and modified from those initially generated in the auditory brainstem. Studied with complex stimulus paradigms, it is clear that AI neuronal response areas display both a convergence of input within the excitatory response ranges and a development of inhibitory inputs outside those (Phillips and Hall, 1992). Within AI, neurons tend to be segregated into patches according to both their binaural interactions and their intensity coding properties.

Especially in anesthetized animals, responses to tonal or noise stimuli are usually dominated by a frequency-tuned and precisely timed onset component, suggesting that the cortex is especially concerned with the identity and timing of auditory events. Studied with complex sounds, for example, vocalizations, these onset responses can be “mapped” across the cortex, and the spectral content and timing of stimulus events can be quite faithfully represented in the (tonotopic) identities of the neurons contributing to the response and in the timing of those responses (Wang et al., 1995). In this

regard, the precision with which transient responses of AI neurons are timed matches that seen in the cochlear nerve (Phillips and Hall, 1990), indicating that central auditory pathways have preserved this aspect of stimulus timing. In contrast, the temporal coding of stimulus periodicities (e.g., phase-locking to simple tones or to periodic amplitude modulation envelopes) is massively poorer (less than about 100 Hz) than that seen in cochlear neurons (c.f. Eggermont, 1991; Joris and Yin, 1992). This raises interesting questions about the neural coding underlying pitch percepts that typically rely on the existence of periodicities in the stimulus waveform (after Cariani and Delgutte, 1996) if the cortex is unable to support temporal representations of periodicities over the complete pitch range. There have, however, been recent advances that suggest that the neural codes underlying perceived pitch are transformed at the cortex, from temporal ones to rate ones and that the cortex may have dedicated circuits for pitch processing (Patterson et al., 2002; Wang and Walker, 2012).

Still more intriguing is the possibility that parts of the core and belt regions of the auditory cortex differentially participate in “what” and “where” streams of auditory processing (Lomber and Malhotra, 2008; Rauschecker and Romanski, 2011). By this, we mean that one stream of processing is composed of interconnected cortical territories containing a high proportion of neurons sensitive to sound source location, whereas another stream is characterized by a high proportion of neurons sensitive to sound source spectrum. This streaming appears to occur in cats (Lomber and Malhotra, 2008), nonhuman primates (Rauschecker and Romanski, 2011), and humans (Arnott et al., 2004). Most likely, the spatial stream may be involved not only in sound localization per se, but in providing input to multimodal cortical regions involved in spatially directed attention. The other stream may be the auditory corollary of the visual system’s pathways for object identification or recognition.

The auditory cortex is also the source of a highly organized system of descending connections (for review, see Malmierca and Ryugo, 2012). The auditory cortex itself is under modulatory control from “higher” regions, with the result that attentional processes influence the responsivity of cortical regions in imaging studies, and the responsivity and selectivity of individual neurons in the auditory cortex in animal neurophysiological ones (Krumbholz et al., 2007; Lee and Middlebrooks, 2010). Some of these efferent pathways are ultimately involved in the control of middle ear muscle responses and modulation of otoacoustic emissions familiar to audiologists. These descending projections extend as far as the cochlea.

Scharf et al. (1994) studied attention effects in a patient before and after vestibular neurectomy (which necessarily severs descending axons to the cochlea). The listener’s task was to detect low-amplitude tones of a target frequency against a background of noise. Occasionally, tones of nontarget

frequency were presented. Without surgery, correct detection of target tones was high, whereas that of the nontarget tones was low. This is evidence of selective attention in the frequency domain. Following surgery, the listener detected target and nontarget tones at comparable (high) rates, indicating a loss of that attentional control. Especially interesting is the implication that the effect of attention in this instance was a suppression of responses to nontarget tones, rather than any enhancement of the ability to detect tones of the target frequency. Likely, the absolute sensitivity of the cochlea is already as great as it can get, so attentional processes were expressed as an apparent suppression of cochlear output at the nonattended frequencies.

Feedback loops between the cortex and the midbrain and thalamic auditory nuclei have recently taken on special interest (Figure 27.2, left side). One of these loops is the reciprocal one between the cortex and the thalamic nuclei that provide the ascending input. The second is a loop formed by corticofugal projections from the cortex to the IC and the two-step ascending projection from the colliculus through the MGB to the cortex (Malmierca and Ryugo, 2012). These circuits enable the cortex to modulate or refine its own inputs so that inputs of the greatest behavioral significance receive an elaborated cortical representation (Suga, 2012). In what may be a prescient case of this phenomenon, Suga et al. (1987) reported that the “resting” frequency of mustached bat echo-location calls varied between individuals and that the tonotopic cortical maps of frequency were “personalized” to the individuals’ resting frequencies. This is important in bats that often hunt in groups, because the bats need to be able to differentiate their own calls (and echoes driven by them) from those of other members of the group.

There is an arguably far more general importance of these circuits. As might be inferred from the preceding paragraph, these circuits may mediate forebrain auditory plasticity. That is, they may be a mechanism for optimizing the cortical representation of behaviorally relevant signals. This is one mechanism that may contribute to auditory learning. In Suga’s terms, the cortex is able to self-select the afferent inputs of interest for cortical elaboration. In primates, temporally correlated activation of peripheral inputs drives cortical receptive field organization in the somatosensory system, and there is some evidence that in the auditory system, too, the behavioral relevance of stimuli enhances their cortical representation (Recanzone et al., 1993; see also Suga, 2012). Behavioral relevance might be construed as a plasticizing agent effected by the nucleus basalis of the basal forebrain on cortical synaptic connectivity (Weinberger, 2003). That is, the cholinergic (and possibly other) inputs serve as modulators or enablers of synaptic development at the affected neural loci. The following section details temporal synchrony and/or temporal coordination of the relevant inputs are critical to the development of the new synaptic connectivity.

THE IMPORTANCE OF NEURAL SYNCHRONY

Stimulus Representation

All sounds unfold over time. The fashion in which they do so is described by their time waveforms that specify the spectral and temporal content of the sounds. For simple tones of relatively low frequency, cochlear neurons and some of their direct and indirect central connections are able to synchronize (“phase-lock”) action potentials to individual cycles of the stimulus (see above), so that the time structure of the stimulus is largely preserved in the temporal cadence of spike trains emerging from the cochlea. This property extends to more complex sounds, including speech, such that both glottal pulse rates and spectral elements of vowels have clear temporal representations in the central auditory system (Aiken and Picton, 2008). A case can be made that all sounds evoking clear pitch percepts have periodicities in the phase-locking range, whether they are at the level of the fine time structure or the amplitude envelope of the signal (Cariani and Delgutte, 1996).

Precisely how the nervous system extracts the pitch from the spike trains is unclear, but may involve an autocorrelation process in which the spike train is delayed and then compared to the original train (see Plack, 2005). The peak in the autocorrelation function will occur when the delay matches the periodicity in the spike trains, and thus the periodicity in the stimulus. Consider the case of rippled noise: A wideband noise is delayed and added to itself; this process is iterated repetitively and results in a noisy stimulus that evokes a pitch inversely related to the iterated delay (Patterson et al., 2002). If one were to perform an autocorrelation of the instantaneous amplitudes of the two waveforms themselves, then the peak of the function would occur at the iterated delay.

If the stimulus regularity is long enough in period, then the sound fails to evoke a clear pitch percept (Phillips et al., 2012a). This occurs for intervals longer than about 30 to 40 ms. Under these circumstances, discrimination of differences in periodicity still likely relies on synchrony of neural responses to stimulus event times, but the perceptual operation becomes one of the discrimination of the rhythm or relative timing of individuated stimulus events (Phillips et al., 2012a).

Somewhat analogous cases can be made for transient stimulus events. Auditory temporal gap detection will serve as a useful illustration (see Phillips, 2012 for review). The classical stimulus design in gap detection studies presents the listener with two streams of otherwise identical sound in which one stream has a silent period (“gap”) inserted at some point in its duration. The task of the listener is to identify which stream of sound (“standard,” “target”) contains the gap. This two-interval, two-alternative forced choice is embedded in an adaptive, threshold-tracking staircase

designed to measure the shortest detectible gap. This general stimulus paradigm has been termed “within-channel” gap detection, because the operation required to detect the silent period ultimately reduces to the detection of a discontinuity of activity within the frequency channels carrying information about the presence of the gap. Gap thresholds decrease with increases in stimulus bandwidth. Gap thresholds for pairs of noise bands are lower than those for single ones, largely irrespective of the bands’ frequency separation. Both of these findings might be explained by the fact that the more frequency channels that carry information about the presence of the gap, the greater is the efficiency with which the perceptual recovery of the gap is executed because more information is available. In turn, however, this process requires that the cochlear nerve (and central auditory system) time the stimulus continuity with great precision, because it is the temporal correlation/coherence of those event detections that is the neural database for the perceptual recovery of the gap.

A different form of the gap detection measurement is the one in which the sound following the silent period is different from the sound that precedes it (between-channel gap detection: See Phillips, 2012). Gap detection thresholds in this paradigm may be up to an order of magnitude (or more) greater than those seen in within-channel paradigms and may asymptote if the frequency disparity between leading and trailing sounds is sufficiently large. For widely frequency-spaced gap markers, the operation required to detect the silent period presumably involves a relative timing of the offset of activity in the neural/perceptual channel representing the leading marker and the onset of activity in the channel representing the trailing one (Phillips, 2012); in conditions of frequency overlap/proximity between the gap markers, other operations may contribute (again, see Phillips, 2012 for a detailed review). We shall return to the relative timing point later. For now, what is important is that efficient performance of the between-channel gap detection task requires a precise neural timing of the offset of the leading marker and the onset of the trailing one. The salience of that neural code depends on the synchrony of neural discharges to those stimulus events.

Neural Synchrony at the Synaptic Level

The preceding section emphasized the need of the auditory system to be able to synchronize neural action potentials with stimulus event times. A second expression of neural synchrony is in the ability of central neurons to synchronize their activity with each other. To explore this issue in principle, let us use the example of the role of glutamate receptors in the development of new synaptic strengths. The point here is to understand how it is that neurons alter the strengths of their synaptic connections (or for that matter,

establish new connections), because alteration of connectivity strengths is a major expression of neural plasticity, quite likely including that involved in auditory learning (recalling the seminal work of Hebb, 1949). For a more detailed coverage of this topic, the reader is referred to almost any modern textbook of cellular or systems neuroscience (Bear et al., 2007).

Glutamate neurotransmitter receptors come in a number of forms, two of which are the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor and the *N*-methyl-D-aspartate (NMDA) receptor. These frequently coexist in the postsynaptic membranes in receipt of glutamatergic input. AMPA receptors are ionotropic, meaning that binding of arriving (presynaptically released) glutamate opens the channel protein pore to admit sodium ions into the postsynaptic cell, and thus induce a modest depolarization (because sodium ions are positively charged and bring that charge with them). NMDA receptors in their resting state have their ion channel pore occluded by a magnesium ion. Binding of arriving glutamate is relatively ineffective in opening the pore, but postsynaptic depolarization (mediated by AMPA receptors) displaces the magnesium plug and permits major inflow of both sodium and calcium ions—each of which is positively charged and thus effect significant postsynaptic depolarization. We therefore say that NMDA receptors are “voltage gated.” The important feature here is that effective function of the synapse requires a coordination of presynaptic activity (release of glutamate) and postsynaptic activity (depolarization mediated by AMPA receptors) for the synapse to “work.” The further important consequence of this is that the inflow of calcium ions through the NMDA receptors initiates a sequence of intracellular events that can result in the recruitment of new, preassembled AMPA receptors to the postsynaptic site. This has the consequence that presynaptic release of glutamate becomes more efficient at inducing postsynaptic depolarization, voltage-gating of the NMDA receptors, further depolarization, and potentially recruitment of still further AMPA receptors and stabilization of the synapse. This is likely a mechanism contributing to the so-called “long-term synaptic potentiation.” In contrast, failure of this mechanism, perhaps because of poor presynaptic input or its coordination, can result in failure to maintain the synapse (“long-term synaptic depression”).

Now consider the case of competing glutamatergic inputs to the same postsynaptic neuron. If one of the inputs is strong and has a strict temporal organization, whereas the other is weak and/or temporally sporadic, then the former input is more likely to stabilize or strengthen its connection, whereas the latter is likely to weaken its connectivity. Consider now the situation of a peripheral noise- (or other-) induced peripheral hearing loss at one or both ears. The effective inputs retain or expand their connectivity, whereas the impaired inputs lose theirs. This is neural plasticity, and it is no surprise that cochlear regions adjacent to the damage

expand their cortical representation at the cost of representation of the cochlear regions deprived of significant output. By the same token, if the behavioral importance of one input supersedes that of another (likely mediated by a modulation of synaptic plasticity exerted by the cholinergic nucleus basalis), then the behaviorally relevant input is selectively strengthened. This may be a neurophysiological underpinning of auditory learning. Again, the important points are that pre- and postsynaptic responses must be coordinated and that the rate and temporal properties of competitive inputs determine their relative developments of strength of connectivity.

These and other mechanisms (e.g., feed-forward inhibition: Eggermont and Roberts, 2004) may be at work in any reorganization of neural frequency-intensity response areas and in the reorganization of topographic cortical maps when there is a selective activation or a selective deactivation of afferent inputs. As mentioned above, this kind of selective modulation of inputs might occur after restricted cochlear hearing loss (Robertson and Irvine, 1989) and in auditory learning (Weinberger, 1997). It is also seen in studies using rearing in experimental acoustic environments that themselves produce no peripheral hearing loss (Norena et al., 2006; Pienkowski and Eggermont, 2010).

We can construe the thalamic input to the cortex as having a direct component that excites the target neurons. But it may also have a direct or indirect feed-forward (“lateral”) inhibitory component (Eggermont and Roberts, 2004) that serves to suppress activity in adjacent neurons representing off-stimulus frequencies (e.g., through contribution to the development of so-called lateral inhibitory inputs to their response areas: Phillips and Hall, 1992). The frequency-restricted loss of afferent input not only deprives a focal cortical region of stimulus signal, but releases adjacent cortical regions from feed-forward inhibition. These are conditions that may permit the expansion of the (adjacent) functional inputs to deafferented recipient zones, resulting in changed neural response areas and distortions to tonotopic organization. A focal enhancement of afferent input, whether deriving from a cortical or thalamic source, is capable of expanding the cortical representation of the inputs that are selectively stimulated, and perhaps of suppressing the representation of adjacent inputs. In both cases, there will be changes in neural synchrony deriving from the changes in the efficiency of shared afferent inputs. As Eggermont (2007) remarks, temporally correlated neural activity may be the driving force for changes in the organization of both the properties of individual cortical neurons and the topographic organization of cortical fields. Precisely what functional deficits or advantages accrue from the neural changes described above is unclear, but this issue should be a major focus of future research. From the clinical standpoint, these data make clear that rearing conditions that do not induce peripheral hearing loss can nevertheless induce changes in central functional connectivity. This raises important issues

for how we conceptualize central auditory processing disorder (CAPD).

Synchrony of Activity between Geographically Remote Brain Regions

There are good grounds to support the view that there is no (conscious) perception without attention. Thus, it becomes inescapable that forebrain neural circuits involved in attentional/cognitive processing need to be temporally coordinated with those involved in strictly sensory/perceptual processing to generate fully elaborated, conscious percepts of the relevant stimulus. For the audiologist, this point penetrates even the most basic, elemental levels of auditory examination. We have already seen this phenomenology in the work of Scharf and his colleagues (above). Clinically, the issue is important because to interpret poor hearing performance, one often needs to separate out sensory processing issues and attentional–cognitive ones. This may be particularly relevant in cases of CAPD (cf. Bellis, 2007; Moore et al., 2010) and in aging in which one might anticipate some attentional or cognitive deficits.

To be sure, one can assess auditory performance and attentional/cognitive state independently and try to infer from those measurements the source of poor hearing performance. Another approach is to employ preattentive electrophysiological measures, for example, the mismatch negativity response (MMN), to isolate strictly sensory function. A new question is whether one can objectively quantify the temporal coordination (“synchrony”) between geographically remote brain regions that are required to execute the task at hand.

This brings us to advanced brain imaging methods. Magnetoencephalography provides a high spatial resolution and high temporal resolution of brain activity in which the temporal relations of activity in geographically remote brain regions can be assessed (Ross et al., 2010). Diffusion tensor imaging provides measures of the structural status of white matter pathways, and this may change with as little as 2 hours of task training (Sagi et al., 2012). Most recently, methods have been developed to measure white matter functional activation during task performance (Mazerolle et al., 2010). Certainly, all of these methods are still being refined and some of them can be expensive to employ because of scan-time fees. The point, however, is that these methods may prove to be immensely valuable in measuring the degree to which impairments in hearing performance reflect, or are associated with, impairments in the coordination of geographically separated brain regions mediating different (sensory, attentional, cognitive) contributions to task performance.

The importance of this point comes home if we consider the processes thought to contribute to performance in within- and between-channel gap detection tasks. In the

former case, the task of the listener is to detect the singular “glitch” or “hiccup” in the target stimulus. In the latter, it is currently assumed that a relative timing process is involved, that is, the listener may have to consciously execute a temporal ordering process (offset of the leading marker, onset of the trailing one, detection of a silent period between them). In this regard, differentially poor performance on the between-channel task may be helpful diagnostically (Phillips et al., 2010), but it fails to specify the level at which the deficit occurs (sensory coding, attentional processing). This is a nontrivial point because the between-channel version of the gap detection task is the more cognitively/attentionally demanding.

Behavioral Evidence

There are many diagnoses or specifiable disease processes that are capable of disrupting neural synchrony at one or more of the levels described above. These include multiple sclerosis, CAPD, auditory neuropathy (Starr et al., 1996), and aging (Pichora-Fuller et al., 2007). Let us consider the latter two.

Auditory neuropathy is now a relatively well-understood condition (c.f. Starr et al., 1996; Zeng et al., 2005). It involves pathology of the IHC-afferent fiber synapse and/or pathology of the cochlear nerve (and possibly more central neurons). Its hallmark features are (a) intact otoacoustic emissions, (b) severely impaired auditory brainstem response, and (c) deficits in speech perception more severe than would be expected on the basis of absolute sensitivity to sound (e.g., puretone average). The intact otoacoustic emissions are a sign that the cochlea’s “active process” (and therefore the spectral decomposition function of the cochlea) is likely normal. The poor brainstem response speaks to impaired neural synchrony—at the level of neurons synchronizing their spike times with stimulus event times and/or at the level of the spike times of neurons responding to the same stimuli not being synchronous enough to support a measurable response at the scalp. The speech perception deficit, which is often particularly severe in noisy settings, is what one might expect in the face of impaired neural timing available to encode both the fine time structure of the speech signal and the timing of the phonetically important elements.

The conceptualization of auditory neuropathy as a case of neural dys-synchrony is bolstered by recent studies that have explored the electrophysiological and perceptual responses that depend on precise neural timing. Zeng et al. (2005) showed that neuropathy patients had impaired perceptual discrimination of stimuli encoded temporally (e.g., interaural time differences, pitch of low-frequency tones), but not of stimuli neurally represented by a rate/place code (e.g., ILDs, pitch of high-frequency tones). Kraus et al. (2000) provided a particularly thorough evaluation of an auditory neuropathy patient with normal audiograms and speech reception thresholds in quiet. As expected, they

found that the patient’s speech discrimination in quiet was very good, but significantly impaired (compared to controls) if the stimuli were presented against a noise masker. Analytical studies with a /ba/-/wa/ stimulus continuum (in which the independent variable was the duration of the formant transitions) revealed a normal just noticeable difference for transition duration. In contrast, studies with a /da/-/ga/ continuum (in which the independent variable was the starting frequency of the third formant transition) revealed an abnormally high just noticeable difference. The authors concluded that the patient had “difficulty discriminating stimuli that differ spectrally at stimulus onset and are characterized by rapid spectro-temporal changes throughout the formant transition” (p. 36). Interestingly, when the patient was studied for MMN responses to /ba/-/wa/ and /da/-/ga/ contrasts, responses were normal for the former, but absent for the latter (Kraus et al., 2000). Because the MMN is a pre-attentive response, this result suggests that the patient’s difficulty was at a sensory representation level rather than at an attentional or cognitive one (although those may also have existed).

The recent literature on auditory processing in aging offers another intriguing hypothesis on the role of neural synchrony. Miranda and Pichora-Fuller (2002) showed that temporally “jittering” the low-frequency (<1.2 kHz) content of speech stimuli produced a perceptual deficit of “rollover” (reduced speech discrimination at high stimulus levels) in young, normal-hearing listeners mimicking that seen in aged listeners. This effect cannot be due to a spectral distortion caused by the jitter, because spectral smearing in the absence of jitter was without effect on word identification (Pichora-Fuller et al., 2007). The authors make the assertion that temporal jitter introduced to the stimulus provides a model or “simulation” of aging (Pichora-Fuller et al., 2007), that is, that the aging brain is prone to jittered neural timing.

SPATIAL HEARING

Sound localization is computational. In the visual and somatic sensory systems, there is a direct mapping of stimulus location onto the nervous system. It takes the form of neurons with spatially adjacent receptive field locations being spatially adjacent in the brain. This forms a topographic “map” of the world (e.g., skin surface, visual field) in which there is a “place code” for stimulus location, that is, stimulus location is specified by which neurons in the map are active. There is no such mapping of source location in the auditory periphery. Instead, central processes compute source location from location cue information that is present at the ear(s). The cue information comes in two forms: Monaural and binaural. Monaural cues are most helpful in determining sound source elevation and for making front/back discriminations. Binaural cues are important for localization in the azimuthal plane.

Monaural cues are made up of directionally dependent spectral filtering of a sound wave by the outer ear; reflection and absorption by the pinnae and the conchae result in specific changes in the amplitudes and frequencies within a sound, which are described by the “head-related transfer function” (HRTF). The characteristic modifications in a sound’s waveform resulting from the HRTF change with the sound source position and so can serve as a cue for location. However, the use of these cues requires a listener to be familiar with the sound’s spectrum and able to associate a particular filter with the correct location. This ability to compare a sound against pre-existing neural templates is probably partially learned and partially a result of innately making certain assumptions about a sound (such as that natural sounds will not contain the prominent peaks or notches caused by outer ear filtering; Middlebrooks, 1992) or about how characteristic filtering will change as sound (or as your head) moves. This HRTF filtering is unique for each individual, and damage to the outer ear can disrupt these location cues for a time until internal templates are relearned. Experiments in which ear molds have been used to alter the shape of participants’ pinnae have shown that their abilities to use monaural cues is dramatically diminished at first, but returns to normal over a course of about 6 weeks (Hofman et al., 1998). Critically, participants in this experiment lost their ability to localize sound in the vertical plane while maintaining their ability to discriminate sound position along the azimuth, confirming that binaural cues are insufficient for vertical localization. On the other hand, whereas binaural cues are normally dominant for horizontal sound localization, some unilaterally deaf listeners can learn, in the absence of binaural information, to quite effectively use monaural cues for horizontal sound localization (Slattery and Middlebrooks, 1994).

Binaural cues are associated with the azimuthal position of a sound source, especially for sources within about 45 degrees of the midline. ILDs arise for frequencies with wavelengths shorter than head diameter because of the sound-shadowing effect of the head on signal level at the ear further from the source; for humans, ILDs are useful above about 1,500 Hz. For low frequencies, the extra travel time of the sound to the further ear imposes an interaural time (phase) difference (IPD) that is best resolvable by the nervous system below about 750 Hz. The computation involved in both cases is, thus, a comparison of the signals at the two ears.

There are countless descriptions of the fashions in which neurons of the central auditory system encode ILDs and IPDs. The broad picture is twofold. Because cochlear output is frequency specific and intensity dependent, it is possible for the auditory nervous system (esp. LSO, see above) to compare the signal levels at the two ears. Second, because low-frequency cochlear output is phase-locked to basilar membrane (and thus eardrum) motion, it is possible for central neurons (esp. MSO, see above) to compare the relative phases of those signals at the two ears.

For many years, the Jeffress (1948) model of a place code for sound localization has been highly influential in conceptualizing the “architecture” of sound localization mechanisms. It was offered initially for the encoding of interaural time differences and was predicated on the assumption that by means of a set of neural “delay lines,” binaural neurons would develop a preferred interaural delay and that in principle, neurons could be spatially arrayed according to their preferred delays. This model played out exquisitely in barn owls in which it was shown that midbrain neurons had narrow ranges of preferred IPDs (which determined the azimuthal range of free-field receptive fields) and ILDs (which in owls specify the elevations of receptive fields) and were spatially arrayed to form a neurophysiological “map” of contralateral auditory space (see Konishi, 1993).

The model does not, however, appear to hold up in mammals (McAlpine et al., 2001; Phillips, 2008). For central neurons sensitive to ILDs, most are broadly tuned to disparities favoring the contralateral ear, although there are smaller populations tuned to disparities close to zero ILD or broadly tuned to ILDs favoring the ipsilateral ear. These data are matched by free-field observations in animal neurophysiology: Most spatially sensitive high-frequency neurons have receptive fields that are broadly tuned to contralateral azimuths, with medial borders near the midline, although there are smaller populations of cells with ipsilaterally or centrally (midline) located receptive fields (Lee and Middlebrooks, 2010; Stecker et al., 2005). For IPDs of noise stimuli, firing rates are broadly tuned to disparities favoring the left or right auditory hemifields (McAlpine et al., 2001). There is less evidence for a distinct population of neurons tuned to zero IPD, and there is a startling absence of data on the free-field receptive fields of low-frequency neurons (Dingle et al., 2013).

The neurophysiological data from animals have a striking parallel in data from human psychophysics. Using selective adaptation paradigms, it has been revealed that human perceptual channels for ILD-based azimuths are broadly tuned to left or right auditory hemifields or to midline locations and at both low and high frequencies (Dingle et al., 2012; Phillips and Hall, 2005). For IPDs, there is strong evidence for left and right auditory hemifields at both low and high frequencies, and modest evidence for a midline channel at low frequencies (Dingle et al., 2010, 2013). The current account, then, is that the neural code for source azimuth resides in the relative activation of two or three neural-perceptual channels, because those relative rates of activity uniquely specify sound source azimuth (after Phillips and Hall, 2005; Stecker et al., 2005). This model is reminiscent of that for color vision in which the relative activation of blue, green, and red cone systems enables the discrimination of a million colors. The existence of left and right azimuthal channels was predicted in an early auditory temporal gap detection study and the midline channel had been suspected

FIGURE 27.3 The three-channel model of sound localization mechanisms in mammals. **Upper diagram** shows the rate of activity aroused in each channel as a function of the azimuth of a sound source. L, M, and R refer to the left, midline, and right channels, respectively. **Middle panels** show the location of a sound source in relation to a listener's head. **Lower panels** show the relative activation of each channel evoked by the source locations depicted in the **middle row**. Note that each stimulus location is associated with a unique pattern of relative activation of the three channels.

to exist (see Phillips, 2008); for IPDs, the model has recently received independent support from human brain imaging studies (Salminen et al., 2010).

The functioning of the three-channel model is illustrated schematically in Figure 27.3. The upper part shows the activation of left (L), midline (M), and right (R) channels as a function of sound source location (in degrees of azimuth). The middle row of images depicts selected sound source locations relative to the listener's head, and the bottom row of histograms shows the relative activation of the three channels for each source location depicted in the middle row. The important point to be gleaned from this illustration is that each sound source azimuthal location is represented by a unique distribution of activity across the three channels. How far the "skirts" of the channels' tuning extend is not known with certainty. However, note that small changes in source azimuth will bring about the greatest changes in the distribution of channel activity for locations relatively close to the midline. This is where behavioral spatial acuity is at its greatest. It reflects two related factors. One is that disparity size versus azimuth functions are steepest near the midline, especially for ILDs. The second is that neural spike rate versus disparity size functions are steepest for disparities close to zero (Phillips and Brugge, 1985). Restated, the neural code for disparity size is most unambiguous over disparity sizes which themselves most precisely specify source azimuth. It is thus no surprise that spatial acuity is greatest around the midline.

CONCLUSION

Sounds unfold over time. We are used to the notion that the auditory system is able to encode the spectral identity of sounds, but it is becoming increasingly apparent that sound source identity and location can reside as much in the temporal properties of the stimuli at the ears as in the spectral ones. This is obvious in cases such as temporal ordering and sound localization, but it penetrates down to the generation of pitch percepts and temporal regularity, and neural timing clearly plays an important role in the coordination of responses involved in the generation of central representations of sounds, auditory plasticity, and sound detection and discrimination. Methods are available for the behavioral, electrophysiological, and brain imaging measurements of these temporal processes. With the understanding that "temporal processing" has become an umbrella term with a wide capture, it behooves us to dissect out these processes and to use the resultant data to define, or redefine, disorders of CAP.

FOOD FOR THOUGHT

1. Consider the following two assertions. (A), If you practice auditory temporal processing intensively and in a structured way, then you will improve your auditory temporal processing skills. (B), If you practice auditory temporal processing intensively and in a structured way, then neuroplasticity will kick in and you will improve your auditory temporal processing skills. Which of those two assertions carries more weight with you, and why? If you substituted "caber tossing" or "cake baking" for "auditory temporal processing," would your answer change?
2. It is argued that in mammals, the perceived location of a sound in the azimuthal plane depends on the relative outputs of two or three perceptual channels, each of which is rather broadly tuned to source location. In the case of two-channel systems, this is sometimes termed "opponent processing." How many instances of opponent processing can you find in other sensory or cognitive systems? That is, how common is the implementation of this strategy in the brain?
3. Suppose that an otherwise normal person was born with the following abnormality: their left cochlea projects upon the right cochlear nucleus, and their right cochlea projects upon the left cochlear nucleus. What would be the consequences of this abnormality for that person's hearing?

ACKNOWLEDGMENTS

The preparation of this chapter, and some of the research described herein, was supported by grants from NSERC of Canada and the Killam Trust to DPP. RND was supported by an NSERC postgraduate scholarship. Many thanks are due to Susan E. Hall for her input at all stages of this work.

Auditory Pathway Representations of Speech Sounds in Humans

Daniel A. Abrams and Nina Kraus

INTRODUCTION

An essential function of the human auditory system is the neural encoding of speech sounds. The ability of the brain to translate the acoustic events in the speech signal into meaningful linguistic constructs relies in part on the way the central nervous system represents the acoustic structure of speech. Consequently, an understanding of how the nervous system accomplishes this task would provide important insights into the basis of language function and auditory-based cognition.

One of the challenges faced by researchers is that speech is a complex acoustic signal that is rich in both spectral and temporal features. In everyday listening situations, the abundance of acoustical cues in the speech signal provides enormous perceptual benefits to listeners. For example, listeners are able to shift their attention between different acoustical cues when perceiving speech from different talkers to compensate for the built-in variations in the acoustical properties (Nusbaum and Morin, 1992). This form of “listener flexibility” reflects a critical aspect of speech perception: The listener makes use of whatever spectral or temporal cues are available to help decode the incoming speech signal.

There are two basic approaches that researchers have adopted for conducting experiments on speech perception and the underlying physiology. One approach uses “simple” acoustic stimuli, such as tones and clicks, as a means to control for the complexity of the speech signal. Whereas simple stimuli enable researchers to reduce the acoustics of speech to its most basic elements, the auditory system is nonlinear (Sachs and Young, 1979) and, therefore, responses to simple stimuli generally do not accurately predict responses to actual speech sounds. A second approach uses speech and speech-like stimuli (Song et al., 2006; Cunningham et al., 2002; Skoe and Kraus, 2010). There are many advantages to this approach. First, these stimuli have greater face validity for understanding speech processing. Second, a complete description of how the nonlinear auditory system responds to speech can only be obtained by using speech stimuli. Third, long-term exposure to speech sounds and their use

linguistically produces plastic changes in the auditory pathways that may alter neural representation of speech in a manner that cannot be predicted by simple stimuli. Fourth, when speech stimuli are chosen carefully, the acoustic properties of the signal can still be well controlled.

This chapter is organized into five sections, with each section describing what is currently known about how the brain represents a particular acoustic feature present in speech (see Table 28.1). These acoustic features of speech were chosen because they have essential roles in normal speech perception. Each section contains a description of the acoustical feature, an explanation of its importance in speech perception, followed by a review and assessment of the data for that acoustic feature.

An exciting aspect of brain function is the remarkable capacity of the brain to modify its functional properties following training. In the auditory domain, a growing body of research has shown that targeted training and remediation programs can provide substantial speech perception benefit to a number of populations, including both normal listeners and clinical populations with impaired auditory function. Given the prevalence of hearing deficits in industrialized societies and an aging population in most Western countries, targeted auditory training to maintain and improve speech perception, particularly in the presence of background noise, represents an important strategy for sustaining speech-based communication and cognitive skills (Lin et al., 2013). Importantly, behavioral improvements that result from training originate in changes in brain function, and it is of great interest to the field of auditory research to understand what aspects of brain function change in response to auditory-based training. These findings are of theoretical interest: Many auditory training paradigms constitute relatively complex tasks, exposing the listener to a host of acoustical features and tapping into a range of sensory and cognitive skills; therefore, an understanding of the specific brain changes that accompany training-based improvement provides a window on the particular acoustical features that are most important for improvement on the trained tasks. Thus, a final goal of this chapter is to highlight exciting recent research describing

TABLE 28.1

Acoustic Features of Speech and their Representations in the Central Auditory System

Major Sections: Acoustic Features in Speech	Feature's Role in the Speech Signal	Brainstem Measure	Cortical Measure
1. Formant structure	Ubiquitous in vowels, approximants, and nasals; essential for vowel perception	Frequency-following response	N100m source location; STS activity (fMRI)
2. Periodicity	Temporal cue for the fundamental frequency and low formant frequencies (50–500 Hz)	Frequency-following response	N100m source location and amplitude; nonprimary auditory cortex activity patterns (fMRI)
3. Frequency transitions	Consonant identification; signal the presence of diphthongs and glides; linguistic pitch	Frequency-following response	Left versus right STG activity (fMRI)
4. Acoustic onsets	Phoneme identification	ABR onset complex	N100m source location; N100 latency
5. Speech envelope	Syllable and low-frequency (<50 Hz) patterns in speech	N/A	N100m phase-locking

changes in auditory brain function following speech and auditory training, with a focus on therapeutic training paradigms designed to improve speech perception in both clinical populations and normal hearing listeners.

An important consideration is that the acoustical features described in this chapter are not mutually exclusive. For example, one section of this chapter describes the neural encoding of “periodicity,” which refers to acoustical events that occur at regular time intervals. Many features in the speech signal are periodic; however, describing all of these simultaneously occurring periodic features would be experimentally unwieldy. For simplicity, and to show how these features were investigated, some related acoustical features will be discussed in separate sections. Throughout the chapter we have tried to identify when there is overlap among the acoustical features.

THE SIGNAL: BASIC SPEECH ACOUSTICS

The speech signal can be described according to a number of basic physical attributes (Johnson, 1997). An understanding of these characteristics is essential to any discussion of how the auditory system encodes speech. The linguistic roles of these acoustic features are described separately within each section of the chapter.

Fundamental Frequency

The fundamental frequency component of speech results from the periodic beating of the vocal folds. In Figure 28.1A, the frequency content of the naturally produced speech sentence “The Young Boy Left Home” is plotted as a function

of time: Greater amounts of energy at a given frequency are represented with dark lines whereas smaller amounts of energy are depicted in white. The fundamental frequency can be seen as the horizontal band of energy in Figure 28.1A that is closest to the *x*-axis (i.e., lowest in frequency). The fundamental frequency is labeled F0 and provides the perceived pitch of an individual’s voice.

Harmonic Structure

An acoustical feature that is related to the fundamental frequency of speech is known as the harmonic structure. Speech harmonics, which are integer multiples of the fundamental frequency, are present in ongoing speech. The harmonic structure of speech is displayed in Figure 28.1A, as the regularly spaced horizontal bands of energy that are seen throughout the sentence.

Formant Structure

Another essential acoustical feature of speech is the formant structure which describes a series of discrete peaks in the frequency spectrum of speech that are the result of an interaction between the frequency of the vocal-fold vibrations and the speaker’s vocal tract resonance. The frequency of these peaks, as well as the relative frequency between peaks, varies for different speech sounds. The formant structure of speech depends on the harmonic structure of speech. Harmonic structure is represented by integer multiples of the fundamental frequency, and formants are harmonics that are close to a resonant frequency of the vocal tract. In Figure 28.1, the formant structure of speech is represented by the series of horizontal, and occasionally diagonal, lines that

FIGURE 28.1 Spectrogram for the naturally produced speech sentence “The young boy left home.” **(A)** The complete sentence; **(B)** the word “left” is enlarged to illustrate the frequency structure: The fundamental frequency (F0) and formants (F1–F3) are represented in the spectrogram by *broad dark lines* of energy.

are darker than their neighbors that run through most of the speech utterance. The word “left” has been enlarged in Figure 28.1B to better illustrate this phenomenon. The broad and dark patches seen in this figure represent the peaks in the frequency spectrum of speech that are the result of an interaction between the frequency of vibration of the vocal folds and the resonances of a speaker’s vocal tract. The frequency of these peaks, as well as the relative frequency between peaks, varies for different speech sounds within the sentence. The lowest frequency formant is known as the first formant and is notated F1, whereas subsequent formants are notated F2, F3, and so on. The frequencies of F1 and F2 in particular are important for vowel identity.

THE MEASURES OF BRAIN ACTIVITY

We begin by describing the neurophysiological measures that have been used to probe auditory responses to speech and speech-like stimuli (comprehensive descriptions of these measures can be found elsewhere: Hall, 1992 as well as in chapters in this book). Historically, the basic research on the neurophysiology of speech perception has borrowed a number of clinical tools to assess auditory system function.

Brainstem Responses

The auditory brainstem response (ABR) consists of small voltages originating from neural activity in auditory structures in the brainstem in response to sound. Although these responses do not pinpoint the specific origin of auditory activity among the auditory brainstem nuclei, the great

strength of ABRs (and auditory potentials in general) is that they precisely reflect the time-course of neural activity at the microsecond level. The ABR is typically measured with a single active electrode referenced to the earlobe or nose. Clinical evaluations using the ABR typically use brief acoustic stimuli, such as clicks and tones, to elicit brainstem activity. The ABR is unique among the AEPs because of the remarkable reliability of this response, both within and across subjects. In the clinic, the ABR is used to assess the integrity of the auditory periphery and lower brainstem (Hall, 1992). The response consists of a number of peaks, with wave V being the most clinically reliable. Deviations on the order of microseconds are deemed “abnormal” in the clinic and are associated with some form of peripheral hearing damage or with retrocochlear pathologies. Research using the ABR to probe acoustic processing of speech utilizes similar recording procedures, but different acoustic stimuli.

Cortical Responses

CORTICAL-EVOKED POTENTIALS AND FIELDS

Cortical-evoked responses are used as a research tool to probe auditory function in normal and clinical populations. Cortical-evoked potentials are small voltages originating from neural activity auditory cortical structures in response to sound. These potentials are typically measured with multiple electrodes, often referenced to a “common reference,” which is the average response measured across all electrodes. Cortical-evoked “fields” are the magnetic counterpart to cortical-evoked potentials; however, instead of measuring voltage across the scalp, magnetic fields produced by brain activity are measured.

Electroencephalography (EEG) is the technique by which evoked potentials are measured and magnetoencephalography (MEG) is the technique by which evoked fields are measured. Similar to the ABR, the strength of assessing cortical-evoked potentials and fields is that they provide detailed information about the time-course of activation and how sound is encoded by temporal response properties of large populations of auditory neurons, though this technique is limited in its spatial resolution. Because of large inter- and intrasubject variability in cortical responses, these measures are not generally used clinically. Results from these two cortical methodologies are generally compatible, despite some differences in the neural generators that contribute to each of these responses. Studies using both EEG and MEG are described interchangeably throughout this chapter despite the subtle differences between the measures. The nomenclature of waveform peaks is similar for EEG and MEG: Typically, an N or P, depicting a negative or positive deflection, followed by a number indicating the approximate latency of the peak. Finally, the letter “m” follows the latency for MEG results. For example, N100 and N100m are the labels for a negative deflection at 100 ms as measured by EEG and MEG, respectively.

FUNCTIONAL IMAGING

Functional imaging of the auditory system is another often-used technique to quantify auditory activity in the brain. The technology that is used to measure these responses, as well as the results they yield, is considerably different from the previously described techniques. The primary difference is that functional imaging is an indirect measure of neural activity, that is, instead of measuring voltages or fields resulting from activity in auditory neurons, functional imaging measures hemodynamics, a term used to describe changes in metabolism as a result of changes in brain activity. The data produced by these measures is a three-dimensional map of activity within the brain as a result of a given stimulus. The strong correlation between actual neural activity and blood flow to the same areas of the brain (Smith et al., 2002) has made functional imaging a valuable investigative tool to measure auditory activity in the brain. The two methods of functional imaging described here are functional magnetic resonance imaging (fMRI) and positron emission tomography (PET). The difference between these two techniques is that fMRI measures natural levels of oxygen in the brain, as oxygen is consumed by neurons when they become active. PET, however, requires the injection of a radioactive isotope into a subject. The isotope emits positrons, which can be detected by a scanner, as it circulates in the subject’s bloodstream. Increases in neural activity draw more blood, and consequently more of the radioactive isotope, to a given region of the brain. The main advantage that functional imaging offers relative to evoked potentials and evoked fields is that it provides extremely accurate and

precise spatial information regarding the origin of neural activity in the brain. A disadvantage is the poor resolution in the temporal domain: Neural activity is often integrated over the course of seconds, which is considered extremely slow given that speech tokens are as brief as 30 ms. Although recent work using functional imaging has begun describing activity in subcortical regions, the work described here will cover only studies of temporal cortex.

ACOUSTIC FEATURES OF SPEECH

Periodicity

DEFINITION AND ROLE IN THE PERCEPTION OF SPEECH

Periodicity refers to regular temporal fluctuations in the speech signal between 50 to 500 Hz (Rosen, 1992). Important aspects of the speech signal that contain periodic acoustic information include the fundamental frequency and all components of the formant structure (note that encoding of the formant structure of speech is covered in a later section). The acoustic information provided by periodicity conveys both phonetic information as well as prosodic cues, such as intonation and stress, in the speech signal. As stated in Rosen’s paper, this category of temporal information represents both the periodic features in speech and the distinction between periodic and aperiodic portions of the signal, which fluctuate at much faster rates.

This section will review studies describing the neural representation of relatively stationary periodic components in the speech signal, most notably the fundamental frequency. An understanding of the mechanism for encoding a simple periodic feature of the speech signal, the F0, will facilitate descriptions of complex periodic features of the speech signal, such as the formant structure and frequency modulations.

PHYSIOLOGICAL REPRESENTATION OF PERIODICITY IN THE HUMAN BRAIN

Auditory Brainstem

The short-latency frequency-following response (FFR) is an electrophysiological measure of phase-locked neural activity originating from brainstem nuclei that represents responses to periodic acoustic stimuli up to approximately 1,000 Hz (Smith et al., 1975; Stillman et al., 1978). Based on the frequency range that can be measured with the FFR, a representation of the fundamental frequency can be measured using this methodology (Krishnan et al., 2004; Russo et al., 2004; Skoe and Kraus, 2010), as well as the F1 in some instances (encoding of F1 is discussed in detail in the Formant Structure section).

A number of studies have shown that F0 is represented within the brainstem response (i.e., FFR) according to a

FIGURE 28.2 Acoustic waveform of the synthesized speech stimulus /da/ [above] and grand average auditory brainstem responses to /da/ [below]. The stimulus has been moved forward in time to the latency of onset responses [peak V] to enable direct comparisons with brainstem responses. Peaks V and A reflect the onset of the speech sound and peak O reflects stimulus offset. Peaks D, E, and F represent a phase-locked representation to the fundamental frequency of the speech stimulus, and the peaks between D, E, and F occur at the F1 frequency.

series of peaks that are temporally spaced corresponding to the wavelength of the fundamental frequency. An example of F0 representation in the FFR can be seen in Figure 28.2, which shows the waveform of the speech stimulus /da/ (top), an experimental stimulus that has been studied in great detail, as well as the brainstem response to this speech sound (bottom). A cursory inspection of this figure shows that the primary periodic features of the speech waveform provided by the F0 are clearly represented in negative-going peaks D, E, and F of the FFR brainstem response. Importantly, it has been shown that the FFR is highly sensitive to F0 frequency; this aspect of the brainstem response accurately “tracks” modulations in frequency (Krishnan et al., 2004), a topic which is discussed in depth in the Frequency Transitions section of this chapter.

A hypothesis regarding the brainstem’s encoding of different aspects of the speech signal has been proposed (Kraus and Nicol, 2005). Specifically, it is proposed that the source (referring to vocal-fold vibration) and filter aspects (vocal musculature in the production of speech) of a speech signal show dissociation in their acoustical representation in the auditory brainstem. The source portion of the brainstem’s response to speech is the representation of the F0, whereas the filter refers to all other features, including speech onset, offset, and the representation of formant frequencies. For example, it has been demonstrated that brainstem responses are correlated within source and filter classes but are not correlated between classes (Russo et al., 2004). Moreover, in a study of children with language-learning disabilities, whose behavioral deficits may be attributable to central auditory processing disorders, it has been shown

that source representation in the auditory brainstem is normal whereas filter class representation is impaired (Banai et al., 2009; Hornickel et al., 2012a; King et al., 2002). The converse, impairments in brainstem encoding of source (F0) but not filter components, is a characteristic of individuals with poor hearing in noise (Anderson et al., 2011). These data suggest that the acoustical representations of source and filter aspects of a given speech signal are differentially processed and provide evidence for neural specialization at the level of the brainstem.

Cortex

Neurons in the auditory cortex respond robustly with time-locked responses to slow rates of stimulation ($< \sim 25$ Hz) and generally do not phase-lock to frequencies greater than approximately 100 Hz (Creutzfeldt et al., 1980). Therefore, cortical phase-locking to the fundamental frequency of speech, which is near or greater than 100 Hz, is poor, and it is generally thought that the brainstem’s phase-locked representation of F0 is transformed at the level of cortex to a more abstract representation. For example, it has been shown that cortical neurons produce sustained, nonsynchronized discharges throughout a high-frequency (> 50 Hz) stimulus (Lu et al., 2001), which is a more abstract representation of the stimulus frequency compared to time-locked neural activation.

An important aspect of F0 perception is that listeners native to a particular language are able to perceive a given speech sound as invariant regardless of the speaker’s F0, which varies considerably among men (F0 ~ 100 Hz), women (F0 ~ 200 Hz), and children (F0 up to 400 Hz). For

example, the speech sound “dog” is categorized by a listener to mean the exact same thing regardless of whether an adult or a child produces the vocalization, even though there is a considerable difference in the F0 of the adult’s and child’s vocalizations. To address how auditory cortical responses reflect relatively large variations in F0 between listeners, N100m cortical responses were measured with MEG for a set of Finnish vowel and vowel-like stimuli that varied in F0 while keeping all other formant information (F1–F4) constant (Makela et al., 2002). Results indicated that N100m responses were extremely similar in spatial activation pattern and amplitude for all vowel and vowel-like stimuli, irrespective of the F0. This is a particularly intriguing finding given that N100m responses differed when 100-, 200-, and 400-Hz puretone stimuli were presented to the same subjects in a control condition. The similarity of the speech-evoked brain responses, which were independent of the F0 frequency, suggests that variances in F0 may be filtered out of the neural representation by the time it reaches the cortex. The authors suggest that the insensitivity of cortical responses to variations in the F0 may facilitate the semantic categorization of the speech sound. In other words, since F0 does not provide essential acoustic information relevant to the semantic meaning of the speech sound, it may be that the cortex does not respond to this aspect of the stimulus in favor of other acoustic features that are essential for decoding word meaning.

Electrophysiological Changes due to Training

The brain’s representation of periodicity has been shown to be malleable following auditory-based training. The goal of one study was to train the perception of speech in the presence of background noise, an environmental sound source which negatively impacts speech perception in normal individuals and has even more severe perceptual consequences in individuals with hearing impairments. In this study, a group of 28 normal hearing young adults were trained on a commercially available computer program entitled “Listening and Communication Enhancement” (LACE) (Sweetow and Sabes, 2006), which trains listeners on a number of auditory tasks including comprehension of degraded speech, auditory mnemonic and cognitive skills, and communication strategies (Song et al., 2012). After 4 weeks of training, participants showed improvements in measures of speech perception in noise as measured by LACE as well as independent measures of speech perception in noise, including the Hearing in Noise Test (Nilsson et al., 1994) and the Quick Speech in Noise Test (Killion et al., 2004). An age-matched group of normal hearing, untrained listeners showed no improvements in speech in noise perception.

Neural correlates of these behavioral improvements were explored by measuring ABRs to a synthetic /da/ stimulus in both quiet and in the presence of background noise. Results showed that behavioral improvements in trained listeners were accompanied by enhanced brainstem repre-

sentation of periodicity, as measured by the spectral magnitude of the F0 and the second harmonic (H2), in responses measured in the presence of background noise. An important consideration is the breadth of auditory and cognitive skills trained by LACE and the specificity of these brainstem results. The LACE program broadly trains speech perception in noise, and consequently the brainstem representation of any number of acoustical features in speech could have shown training-related effects. Nevertheless, only the F0 and H2 features of the brainstem response were enhanced following LACE training. The interpretation of this result is that the brain’s coding of periodicity is a particularly critical element for the perception of speech in noise. On the surface, this may be surprising: The fundamental frequency is not always necessary for speech comprehension. For example, the fundamental frequency is systematically filtered out of all telephone signals. Nevertheless, these results strongly suggest that in challenging listening conditions, including the perception of speech in noise, periodic features may provide important acoustical benefit to the listener as reflected by the sharpening of this feature in the brainstem response to speech in noise.

In summary, periodicity of the fundamental frequency is robustly represented in the FFR of the ABR. Moreover, the representation of the fundamental frequency is normal in children with learning disabilities (LDs) despite the abnormal representations of speech-sound onset and first formant frequency. Yet, its role appears to be essential in hearing speech in noise. This disparity in the learning disabled auditory system provides evidence that different features of speech sounds may be served by different neural mechanisms and/or populations. In the cortex, MEG results show that cortical responses are relatively insensitive to changes in the fundamental frequency of speech sounds, suggesting that differing F0s between speakers are filtered out by the time the signal reaches the level of auditory cortex. Results from speech in noise training indicate that improvements in speech perception in noise result in systematic enhancement of periodic aspects of the speech signal, including the F0 and H2 components.

Formant Structure

ROLE IN THE PERCEPTION OF SPEECH

Formant structure describes a series of discrete peaks in the frequency spectrum of speech that are the result of an interaction between the frequency of vibration of the vocal folds and the resonances within a speaker’s vocal tract (see Introduction for a more complete acoustical description of the formant structure). The formant structure is a dominant acoustic feature of sonorants, a class of speech sounds that includes vowels, approximants (e.g., /l/ and /r/), and nasals. The formant structure has a special role in the perception of vowels in that formant frequencies, particularly

the relationship between F1 and F2 are the primary phonetic determinants of vowels. For example, the essential acoustic difference between /u/ and /i/ is a positive shift in F2 frequency (Peterson and Barney, 1952). Because of the special role of formants for vowel perception, much of the research regarding the formant structure of speech uses vowel stimuli.

PHYSIOLOGICAL REPRESENTATION OF FORMANT STRUCTURE IN THE HUMAN BRAIN

Auditory Brainstem

The question of how the human auditory brainstem represents important components of the formant structure was addressed in a study by Krishnan (2002). In this study, brainstem responses (FFRs) to three steady-state vowels were measured and the spectral content of the responses was compared to that of the vowel stimuli. All three of the stimuli had approximately the same fundamental frequency; however, the first two formant frequencies were different in each of the vowel stimuli. Results indicate that at higher stimulus intensities the brainstem FFR accurately represents F1 and F2; however, the representation of F1 was greater than for F2. The author indicates the similarity between this finding and a similar result in a classic study of vowel representation in the auditory nerve of anesthetized cats (Sachs and Young, 1979) which also demonstrated a predominant representation of F1. These data provide evidence that phase-locking serves as a mechanism for encoding critical components of the formant structure not only in the auditory nerve, but also in the auditory brainstem.

Auditory Cortex

A number of studies have described the representation of formant structure in the human cortex as a means of investigating whether a cortical map of phonemes, termed the “phonemotopic” map, exists in the human brain. Specifically, researchers want to know if the phonemotopic map is independent of the tonotopic map, or alternatively whether phonemes are more simply represented according to their frequency content along the tonotopic gradient in auditory cortex. To this end, investigators have measured cortical responses to vowel stimuli, a class of speech sounds that differ acoustically from one another according to the distribution of F1–F2 formant frequencies. Vowel stimuli also offer the advantage of exhibiting no temporal structure beyond the periodicity of the formants.

The method that has been used to investigate the relationship between the tonotopic map in human auditory cortex and the representation of formant structure has been to compare cortical source locations for tones and specific speech sounds with similar frequency components. For example, in one study (Diesch and Luce, 1997) N100m source location was measured in response to separately presented 600- and 2,100-Hz puretones as well as a two-tone

composite signal comprising the component puretones (i.e., simultaneous presentation of the 600- and 2,100-Hz puretones). These responses were compared to isolated formants, defined as the first and second formant frequencies of a vowel stimulus, complete with their harmonic structure, separated from the rest of the frequency components of the stimulus (i.e., F0, higher formant frequencies). These isolated formants had the same frequency as the tonal stimuli (i.e., 600 and 2,100 Hz). Finally, a two-formant composite signal, which constituted a vowel, was also presented. Results indicated that the N100m source in response to the vowel stimulus was different in location from that predicted by both the puretone responses and the superposition of responses to the component single formant stimuli. These data indicate that formant structure is spatially represented in human cortex differently than the linear sum of responses to the component formant stimuli and suggest that formant structure has a different representation relative to the tonotopic map. The authors of this work hypothesize that the different spatial representation of the vowel stimuli reflects the additional acoustic components of the vowel stimuli, including the harmonic and formant structures. The authors of this work refrain from a potentially more intriguing conclusion, that is, does the spatial representation of the vowel stimuli in some way reflect the behavioral experience of the subjects with these speech sounds? For example, it is possible that a larger, or different, population of cortical neurons is recruited for sounds that are familiar, or have significant ecologic importance, relative to the population recruited for puretones or single formant frequencies and that the source location for the vowels reflects this phenomenon.

Additional studies have attempted to better describe the acoustic representation of vowels in the human brain. In one study, Obleser et al. (2003) addressed the neurophysiology underlying a classic study of speech acoustics in which it was shown that the distinction of vowels is largely carried by the frequency relationship of F1 and F2 (Peterson and Barney, 1952). To this end, cortical source locations were measured in response to German vowels that naturally differ in F1–F2 relationships. Results indicated that the location of the N100m source reflects the relationship of the F1–F2 formant frequencies. This finding was replicated in a second study using 450 natural speech exemplars of three Russian vowels; again, the spectral distance between F1 and F2 was reflected in the dipole location of N100m responses (Shestakova et al., 2004).

Although these studies provide evidence that the cortex represents the formant structure of vowels in a manner that is (a) unrelated to the tonotopic map and (b) organized according to the perceptually essential formant frequencies, these findings require a number of caveats. First, the source locations described in these studies represent the center of gravity, as a single point in three-dimensional space in the cortex, of the neural contributors to a given N100m response (Näätänen and Picton, 1987). Second, approximately six

neural regions contribute to the N100 and therefore it represents a highly complex neural response. Consequently, the N100 described in these studies of phonemotopic maps should not be viewed as an exact representation of well-described, and highly localized, auditory maps in animal models (Schreiner, 1998). This is particularly relevant given that the clear tonotopic gradient in auditory cortex is no longer apparent when puretone stimuli are presented above 50 dB SPL (Schreiner, 1998), such as the levels used in the MEG experiments described in this section. In addition, it has not yet been definitively shown that the neural representations of phonemes described in these studies truly constitute a phonemotopic map. The presence of a phonemotopic map suggests behavioral relevance of phoneme stimuli beyond their acoustic attributes. None of the studies described here have tested if cortical responses to the F1–F2 components for nonnative vowel sounds show similar sensitivity as native phonemes. Despite these limitations, these studies provide consistent evidence that a perceptually critical aspect of the formant structure of vowels, the F1–F2 relationship, is represented in a spatial map in auditory cortex as early as ~100 ms poststimulus onset.

Another line of evidence has used functional imaging to show the particular regions of the temporal cortex that are sensitive to the formant structure of speech sounds relative to other natural and vocally generated sounds, that is, laughs and coughs (Belin et al., 2000). Cortical responses to natural vocal stimuli were compared to vocal stimuli in which the formant structure of speech was replaced by white noise and scrambled vocal sounds. All stimuli were matched for overall RMS energy. In both of these experimental conditions, the original amplitude envelope of the speech signal modulated the altered spectral information. Results from this experiment indicated that all stimuli activated regions along the superior temporal sulcus (STS), a cortical region consisting of unimodal auditory and multimodal areas that is hypothesized to be a critical speech-processing center subsequent to more rudimentary acoustic processing in structures of the superior temporal plane. However, responses to the natural vocal stimuli were significantly larger and more widespread throughout the STS, particularly in the right hemisphere, than for the spectrally manipulated vocal stimuli. These data indicate that the formant structure of speech deeply affects activity patterns in the STS, a speech-selective region of temporal cortex, even when the temporal components of the signals are held constant. In addition, these data suggest a right-hemisphere bias for processing the formant structure, which supports the more general hypothesis that the right hemisphere is dominant for resolving spectral components in acoustic signals (Zatorre et al., 2002).

An interesting consideration is how cortical asymmetries in response to the acoustic features of speech relate to well-established cerebral asymmetries for higher-order language processing, such as phonemic and semantic processing (Geschwind and Galaburda, 1985), which are strongly

lateralized to the left hemisphere. Although a direct link between these forms of asymmetry has not been established, a plausible scenario is that the acoustic-level asymmetries precede, and serve as the input to, phonemic and semantic processing in left-hemisphere language regions. If this is the case, it remains to be seen what physiological advantage a right-hemisphere preference for formant structure processing (Belin et al., 2000) might offer given that phonemic and semantic processing of speech stimuli takes place in the opposite hemisphere, thereby requiring transmission through the corpus callosum. Future studies investigating acoustic-level asymmetries and their interface with higher-order language asymmetries would provide essential information regarding the functional neuroanatomy of speech perception.

Electrophysiological Changes due to Training

Musical training can enhance the brainstem's representation of formant frequencies, and this enhancement is related to important aspects of speech perception. For example, it was recently shown that adult musicians have greater differentiation of brainstem responses for consonant–vowel stimuli that vary according to F2 frequency (Parbery-Clark et al., 2012; Strait et al., in press). Specifically, musicians showed more pronounced brainstem timing differences in response to /da/, /ga/, and /ba/ stimuli compared to nonmusicians, and brainstem differentiation of these stimuli correlated with standardized measures of speech perception in noise. This finding is important for a number of reasons. First, it shows that musicians' goal-directed attention to spectrotemporal features in music promotes neural differentiation of subtle variants in formant structure in speech as well as perceptual benefits for speech in noise. This result is also significant with regard to efficacy of therapy: Whereas many forms of auditory perceptual training fail to generalize to untrained stimuli (Burk and Humes, 2008; Halliday et al., 2012), results from the music literature have consistently shown that musical training generalizes to speech perception tasks in children (Moreno et al., 2009; Thompson et al., 2004) and adults (Schon et al., 2004; Thompson et al., 2004) as well as the neural encoding of speech (Moreno et al., 2009; Schon et al., 2004; Strait and Kraus, 2014). Importantly, results from the Parbery-Clark study show that musical training influences the neural differentiation of subtle formant frequency characteristics, which is fundamental to the identification and discrimination of phoneme contrasts (Peterson and Barney, 1952).

In summary, the brainstem encodes lower formant frequencies, which are critical to vowel perception, with phase-locked responses. Moreover, the representation of these formants is enhanced following long-term musical training, and the strength of these representations is correlated with perceptual benefit for speech in noise. Converging evidence indicates that the cortex encodes a perceptually essential aspect of the formant structure of speech. Specifically, the F1–F2 relationship is spatially mapped in the cortex at ~100 ms poststimulus onset as measured by N100m source

location. In addition, functional imaging data provide evidence that the STS, a nonprimary auditory region of temporal cortex, is more responsive to speech stimuli that contain formant structure than speech in which the formant structure has been replaced with other sounds. Together, these results suggest that both primary and associative regions of temporal cortex are sensitive to aspects of the formant structure that are essential for normal perception.

Frequency Transitions

ACOUSTIC DESCRIPTION AND ROLE IN THE PERCEPTION OF SPEECH

Frequency transitions of the fundamental and formant frequencies are ubiquitous in ongoing speech. In English, modulation of the fundamental frequency typically does not provide segmental cues; rather it provides suprasegmental cues such as the intent (e.g., question or statement) and emotional state of the speaker. In other languages, such as Mandarin and Thai, modulations to the fundamental frequency provide phonetic cues. Formant transitions on the other hand are critical for speech perception of English in that they serve as a cue for consonant identification and signal the presence of diphthongs and glides (Lehiste and Peterson, 1961). Formant transitions have also been shown to play a role in vowel identification (Nearey and Assmann, 1986). The movements of formant frequencies can be distilled to three basic forms that occur during an ongoing sequence of phonemes (taken from Lehiste and Peterson, 1961): (a) The movement of a formant from the initiation of the consonant until the beginning of the vowel in a consonant–vowel combination, (b) the movement of a formant from one vowel to another vowel (i.e., in a diphthong), and (c) formant movement from a vowel until vowel termination for a vowel–consonant combination. The frequency modulations that occur during formant transitions can occur at relatively fast rates (~40 ms) while spanning large frequency ranges (>2,000 Hz in F2 transitions).

PHYSIOLOGICAL REPRESENTATION OF FREQUENCY TRANSITIONS IN THE HUMAN BRAIN

Auditory Brainstem

The FFR is able to “track,” or follow, frequency changes in speech. This phenomenon was demonstrated in a study of FFR tracking of the fundamental frequency (F0) in Mandarin speech sounds (Krishnan et al., 2004). In this study, FFR to four different tonal permutations of the Mandarin word “yi” was measured in a group of native Mandarin speakers. Specifically, synthetic stimuli consisted of “yi” pronounced with (1) a flat F0 contour, (2) a rising F0 contour, (3) a falling F0 contour, and (4) a concave F0 contour that fell then rose in frequency. In Mandarin, which is a “tonal”

language, these four stimuli are different words: The F0 contour provides the only acoustic cue to differentiate them. Results indicated that the FFR represented the fundamental frequency modulations for all of the stimulus conditions irrespective of the form of the frequency contour. These data indicate that the FFR represents phase-locked activity in the brainstem for rapidly changing frequency components in speech, an essential acoustical cue for consonant identification.

A similar methodology was used in another study by Krishnan and colleagues to investigate the role of language experience on auditory brainstem encoding of pitch (Krishnan et al., 2005). FFRs to the “yi” stimuli described above were measured in native Mandarin speakers as well as native speakers of American English, to whom the pitch alterations bear no linguistic value. Results from this study indicate greater FFR pitch strength and pitch tracking in the Chinese subjects compared to the native English speakers across all four of the Mandarin tones. The FFR of the Chinese subjects also indicated increased harmonic representation of the fundamental frequency (i.e., larger neural representation of the harmonic content of the F0) compared to the English speakers. These data indicate that responses from the auditory brainstem reflect the behavioral experience of a listener by enhancing the neural representation of linguistically relevant acoustic features.

An hypothesis proposed by Ahissar and Hochstein (2004) may explain how experience engenders plasticity at low levels of sensory systems. Their “reverse hierarchy” theory proposes that when a naïve subject attempts to perform a perceptual task, the performance on that task is governed by the “top” of a sensory hierarchy. As this “top” level of the system masters performance of the task, over time, lower levels of the system are modified and refined to provide more precise encoding of sensory information. This can be thought of as efferent pathway-mediated tuning of afferent sensory input. Although the reverse hierarchy theory does not explicitly discuss plasticity of the brainstem, this theory could account for the findings of Krishnan. Specifically, because of the importance of extracting lexical information present in pitch contours, native Mandarin speakers are “experts” at encoding this acoustic feature, which is accomplished, at least in part, by extreme precision and robustness of sensory encoding in low levels of the auditory system such as the brainstem. Native English speakers, who are not required to extract lexical meaning from pitch contours, are relative novices at this form of pitch tracking, and consequently their brainstems have not required this level of modification.

An interesting question that was addressed in a subsequent study is whether native Mandarin speakers are better than English speakers at pitch tracking the F0 exclusively for familiar speech sounds or whether Mandarin speakers’ superior performance would extend to all periodic acoustic signals, including nonnative speech sounds (Xu et al., 2006). Results show that a lifetime of experience using F0 to extract

linguistic meaning specifically affects auditory responses to familiar speech sounds and does not generalize to all periodic acoustic signals. However, data from the Kraus Lab suggests that another form of long-term auditory experience, musicianship, contributes to enhanced neural encoding of speech sounds in the auditory brainstem relative to nonmusicians (Wong et al., 2007). This finding provides evidence that expertise associated with one type of acoustic signal (i.e., music) can provide a general augmentation of the auditory system that is manifested in brain responses to another type of acoustic signal (i.e., speech) and indicates that auditory experience can modify basic sensory encoding.

Auditory Cortex

Similar to Krishnan's work involving the brainstem, multiple studies have investigated cortical processing of F0 pitch contours and its relationship to language experience. The most convincing of these studies is that by Wong et al. (2004). In this study, native Mandarin and native English speakers underwent PET scanning during passive listening and while performing a pitch discrimination task. Stimuli consisted of (a) Mandarin speech sounds that contained modulations of the fundamental frequency that signal lexical meaning and (b) English speech sounds which also contained modulations to the fundamental frequency; however, F0 modulations never provide lexical information in English. Imaging results indicated that native Mandarin speakers showed significant activation of the left anterior insular cortex, adjacent to Broca's area, only when discriminating Mandarin speech sounds; the homologous right anterior insula was activated when this group discriminated English speech sounds, as well as when native English speakers discriminated both Mandarin and English speech sounds. These data suggest that the left anterior insula is involved in auditory processing of modulations to the fundamental frequency only when those modulations are associated with lexical processing. Moreover, these data suggest that the neural processing of acoustic signals is context dependent and is not solely based on the acoustical attributes of the stimuli.

In addition to studies of the neural representation of F0 modulations, a number of studies have also addressed the cortical representation of formant frequency modulation in humans. As it is known that neurons in auditory cortex do not phase-lock to frequencies greater than approximately 100 Hz (Creutzfeldt et al., 1980), and the formant structure of speech consists of frequencies almost exclusively above 100 Hz, the cortical representation of frequency modulation as measured by evoked potentials is abstract (i.e., not represented with time-locked responses) relative to those described for the auditory brainstem. One cortical mechanism that has received considerable attention for the processing of rapid formant modulations is that of asymmetric processing in the left-hemisphere auditory cortex. A more general hypothesis proposes that left-hemisphere auditory cortex is specialized for all forms of rapid acoustic stimuli

and serves as an early acoustic analysis stage at the level of the cortex. A significant piece of evidence in support of this hypothesis was provided in a study of cortical activation patterns for rapid and slow formant frequency modulations (Belin et al., 1998). In this study, nonspeech sounds containing temporal and spectral characteristics similar to speech sounds were presented to listeners as they were PET scanned. Nonspeech sounds were used so that any cortical asymmetry could not be associated with well-known asymmetries for language processing. Results indicated that the left STG and primary auditory cortex showed greater activation than the right STG for rapid (40 ms) formant frequency transitions but not for slow (200 ms) transitions. In addition, a left-hemisphere region of prefrontal cortex was asymmetrically activated for the rapid formant transition, which was corroborated in a separate fMRI study that used nearly identical acoustic stimuli (Temple et al., 2000). These data suggest that left-hemisphere auditory regions preferentially process rapid formant modulations present in ongoing speech.

In summary, modulations in the fundamental frequency of speech are faithfully encoded in the FFR. Moreover, these brainstem responses appear to be shaped by linguistic experience, a remarkable finding that indicates that cognitive processes (e.g., language) influence basic sensory processing. In the cortex, a mechanism for encoding frequency modulation is the specialization of left-hemisphere auditory regions, and results indicate that rapid frequency changes in speech-like stimuli preferentially activate the left hemisphere relative to slower frequency changes. In addition, the anterior insular cortex is activated for the processing of F0 modulations: The left-hemisphere insula is specifically activated when F0 modulations provide lexical information to a native speaker, whereas the right-hemisphere insula is activated when F0 modulations do not provide lexical information. These cortical findings would appear to be contradictory: The former indicates asymmetric activation by left-hemisphere structures is based on physical parameters of the speech signal, irrespective of linguistic content, whereas the latter suggests that linguistic context is essential for left-asymmetric insular processing of F0 modulations. However, Wong et al. (2004) stated that these results can be reconciled if the insular activity shown in their study occurs after the "acoustically specialized" cortical activity described by Belin et al. (1998) and Temple et al. (2000). If this were true, it would indicate two independent levels of cortical asymmetry: One based on the acoustic attributes of the signal and one based on the linguistic relevance to the listener. This hypothesis needs to be tested in future studies.

Electrophysiological Changes due to Training

There is ample evidence that multiple forms of auditory therapy and training have enhancing effects on the neural representation of frequency transitions in speech, including transitions of the fundamental and formant frequencies. Consistent with neural enhancement of formant structure

discussed previously, musical training also strengthens brainstem representations of frequency transitions, including representations of both the fundamental and formant frequencies. As discussed previously, one study showed that adult musicians have enhanced brainstem representations in response to tonal permutations of the Mandarin word “mi,” which are characterized by contours to the fundamental frequency (Wong et al., 2007). It is hypothesized that this neural benefit is the result of years of attention to pitch variations in musical stimuli, and again it is significant that this neural advantage generalizes from the music domain to speech. In another study, it was shown that musical training also enhances brainstem representations of formant transitions in speech. For example, young children (3 to 5 years of age) with at least a year of musical training showed earlier brainstem responses to the formant transition portion of a consonant–vowel stimulus compared to age-matched listeners, with the greatest effects of musicianship being evident in the presence of background noise (Strait et al., 2013). Studies examining other forms of auditory training have also shown strengthening of brainstem responses to formant transitions in speech. In one study, two groups of older adults (mean age = 62 years) participated in different training paradigms matched for time and computer use: One group was trained on an adaptive computer-based auditory training program that combined bottom-up perceptual discrimination exercises with top-down cognitive demands whereas an active control group was trained on a general educational stimulation program (Anderson et al., 2013). Results for the auditory training group showed improved resiliency of speech-evoked brainstem responses in background noise, and this resiliency was most pronounced for the formant transition period of the consonant–vowel stimulus. This neural effect in the auditory training group was accompanied by significant improvement in a number of auditory behavioral and cognitive measures, including speech in noise, auditory memory, and processing speed. Importantly, the active control group failed to show improvements on both the neural and behavioral measures. A third study examined brainstem plasticity for yet another type of auditory therapy, in this case the use of assistive listening devices for use by children with reading impairments in the classroom (Hornickel et al., 2012b). The theoretical basis for providing these listening devices to this population is that children with reading impairments have impaired speech perception in noise relative to age-matched children (Bradlow et al., 2003). Importantly, assistive listening devices provide substantial improvements with regard to the signal-to-noise ratio of the teacher voice relative to classroom background noise. Results from this study showed that after using assistive listening devices for one academic year, children with reading impairments showed greater consistency of brainstem responses in the formant transition period of a consonant–vowel stimulus. These children also showed behavioral improvements on standardized measures of phonologic processing and reading ability. A control

group, composed of reading-impaired children who did not use assistive listening devices, failed to show improvements in either of these neural or behavioral measures.

Taken together, results from these studies show that the neural representation of frequency transitions in speech is highly malleable in response to very different kinds of auditory training, including musical training, adaptive auditory-based computer programs, and the use of assistive listening devices. This suggests that therapies that sharpen “top-down” brain mechanisms, such as goal-directed attention to auditory stimuli, and “bottom-up” signals, as provided by assistive listening devices, can focus and improve the efficiency of neural mechanisms serving the tracking of frequency modulations. Moreover, the relative abundance of studies showing training effects for neural responses of frequency transitions further suggests that the brain’s representation of this acoustical feature is particularly plastic, reflecting a critical auditory mechanism underlying rapid improvement in important auditory skill acquisition.

Acoustic Onsets

ACOUSTIC DESCRIPTION AND ROLE IN THE PERCEPTION OF SPEECH

Acoustic onsets are defined here as the spectral and temporal features present at the beginning (the initial ~40 ms) of speech sounds. Although the acoustics of phonemes are only slightly altered based on their location in a word (i.e., beginning, middle, or end of a word), an emphasis has been put on acoustic onsets in the neurophysiological literature. Consequently, acoustic onsets are discussed here separately, despite some overlap with acoustic features (e.g., frequency transitions) discussed previously.

Onset acoustics of speech sounds vary considerably in both their spectral and temporal attributes. In some cases, the spectral features of the onset are essential for perception (e.g., the onset frequency of F2 for discriminating /da/ vs. /ga/), whereas in other cases temporal attributes of onsets are the critical feature for perception. A frequently studied acoustic phenomenon associated with the latter is that of the voice onset time (VOT), which is present in stop consonants. The VOT is defined as the duration of time between the release of a stop consonant by speech articulators and the beginning of vocal-fold vibration. The duration of the VOT is the primary acoustic cue that enables differentiation between consonants that are otherwise extremely similar (e.g., /da/ vs. /ta/, /ba/ vs. /pa/, /ga/ vs. /ka/).

PHYSIOLOGICAL REPRESENTATION OF ACOUSTIC ONSETS IN THE HUMAN BRAIN

Auditory Brainstem

The brainstem response to speech-sound onsets has been studied extensively (Banai et al., 2005; Russo et al., 2004;

Wible et al., 2004). The first components of the speech-evoked ABR reflect the onset of the stimulus (Figure 28.2). Speech onset is represented in the brainstem response at approximately 7 ms in the form of two peaks, positive peak V and negative peak A.

Findings from a number of studies have demonstrated that the brainstem's response to acoustic transients is closely linked to auditory perception and to language function, including literacy. These studies have investigated brainstem responses to speech in normal children and children with language-based LDs, a population that has consistently demonstrated perceptual deficits in auditory tasks using both simple (Tallal and Piercy, 1973; Wright et al., 1997) and complex (Kraus et al., 1996; Tallal and Piercy, 1975) acoustic stimuli. A general hypothesis proposes a causal link between basic auditory perceptual deficits in LDs and higher-level language skills, such as reading and phonologic tasks (Tallal et al., 1993), although this relationship has been debated (Mody et al., 1997). In support of a hypothesis linking basic auditory function and language skills, studies of the auditory brainstem indicate a fundamental deficiency in the synchrony of auditory neurons in the brainstem for a significant proportion of language-disabled subjects.

The brainstem's response to acoustic transients in speech is an important neural indicator for distinguishing LD from typically developing (control) subjects. A number of studies have provided compelling evidence that the representation of speech onset is abnormal in a significant proportion of subjects with LD (Banai et al., 2009). For example, brainstem responses to the speech syllable /da/ were measured for a group of 33 normal children and 54 children with LD, and a "normal range" was established from the results of the normal subjects (King et al., 2002). Results indicated that 20 LD subjects (37%) showed abnormally late responses to onset peak A. Another study showed a significant difference between normal and LD subjects based on another measure of the brainstem's representation of acoustic transients (Wible et al., 2004). Specifically, it was shown that the slope between onset peaks V and A to the /da/ syllable was significantly smaller in subjects with LD compared to normal subjects. The authors of this study indicate that diminished V/A slope demonstrated by LDs is a measure of abnormal synchrony to the onset transients of the stimulus and could be the result of abnormal neural conduction by brainstem generators. In another study (Banai et al., 2005), LD subjects with abnormal brainstem timing for acoustic transients were more likely to have a more severe form of LD, manifested in poorer scores on measures of literacy, compared to LD subjects with normal brainstem responses. In yet another study, it was shown that the timing of children's brainstem onset responses to speech sounds correlated with standardized measures of reading and phonologic abilities across a wide range of reading abilities (Banai et al., 2009).

Taken together, these data suggest that the brainstem responses to acoustic transients can differentiate not only a

subpopulation of LDs from normal subjects, but also within the LD population in terms of the severity of the disability. Findings from the brainstem measures also indicate a link between sensory encoding and cognitive processes such as literacy. An important question is whether the link between sensory encoding and cognition is a causal one, and if so, whether brainstem deficits are responsible for cortical deficits (or vice versa). Alternatively, these two abnormalities may be merely coincident. Nevertheless, the consistent findings of brainstem abnormalities in a sizable proportion of the LD population have led to the incorporation of this experimental paradigm into the clinical evaluation of LD and central auditory processing disorders.

Auditory Cortex

Cortical encoding of spectral features of speech-sound onsets has been reported in the literature (Obleser et al., 2006) and indicates that a spectral contrast at speech onset, resulting from consonant place of articulation (i.e., front produced consonant /d/ or /t/ vs. back produced consonant /g/ or /k/), is mapped along the anterior–posterior axis in auditory cortex as measured by N100m source location. This is significant because it indicates that phonemes differentially activate regions of auditory cortex according to their spectral characteristics at speech onset. It was also shown that the discrete mapping of consonants according to onset acoustics is effectively erased when the speech stimuli are manipulated to become unintelligible despite keeping the spectral complexity of the stimuli largely the same. This stimulus manipulation was accomplished by altering the spectral distribution of the stimuli. The authors argue that this latter finding indicates that the cortex is spatially mapping only those sounds that are intelligible to listeners. These data provide important evidence that cortical spatial representations may serve as an important mechanism for the encoding of spectral characteristics in speech-sound onsets. In addition to differences in spatial representations for place of articulation contrasts, cortical responses also showed latency differences for these contrasts. Specifically, it was shown that front consonants, which have higher frequency onsets, elicited earlier N100m responses than back consonants. This finding is consistent with near-field recordings measured from animal models indicating earlier response latencies for speech onsets with higher frequency formants (McGee et al., 1996).

Cortical responses to temporal features of speech-sound onsets have also been reported in the literature, many of which have utilized VOT contrasts as stimuli. These studies were performed by measuring obligatory evoked potentials (N100 responses) to continua of consonant–vowel speech sounds that varied gradually according to VOT (Sharma and Dorman, 1999, 2000; Sharma et al., 2000). Additionally, perception of these phonetic contrasts was also measured using the same continua as a means of addressing whether cortical responses reflected categorical perception of the phonemes.

Neurophysiological results indicated that for both /ba-/pa/ and /ga-/ka/ phonetic contrasts, one large negative peak was evident at approximately 100 ms in the response waveform for stimulus VOTs < 40 ms. A second negative peak in the response waveform emerged for stimulus VOTs of 40 ms, and this second peak occurred approximately 40 ms after the first peak and was thought to represent the onset of voicing in the stimulus. Moreover, as the VOT of the stimulus increased in duration, the lag between the second peak relative to the first increased proportionally, resulting in a strong correlation between VOT and the interpeak latency of the two peaks ($r = -0.80$). The onset of double peaks in cortical responses with a VOT of 40 ms is consistent with neurophysiological responses measured directly from the auditory cortex of humans (Steinschneider et al., 1999), and an important consideration is that the onset of the double peak occurred at 40 ms for both /ba-/pa/ and /ga-/ka/ phonetic contrasts. In contrast, behavioral results require different VOTs to distinguish the /ba-/pa/ and /ga-/ka/ phonetic contrasts. Specifically, a VOT of ~40 ms was required for listeners to correctly identify /pa/ from /ba/, whereas a VOT of ~60 ms was required for correct identification of /ga/ from /ka/. Taken together, these data indicate that cortical responses reflect the actual VOT irrespective of the categorical perception of the phonetic contrasts.

Brainstem–Cortex Relationships

In addition to linking precise brainstem timing of acoustic transients to linguistic function, it has also been shown that abnormal encoding of acoustic transients in the brainstem is related to abnormal auditory responses measured at the level of cortex. In addition to their imprecise representation of sounds at the auditory brainstem, a significant proportion of LDs have also consistently demonstrated abnormal representations of simple and complex acoustic stimuli at the level of the auditory cortex. Three studies have linked abnormal neural synchrony for acoustic transients at the auditory brainstem to abnormal representations of sounds in the cortex. In one study, it was shown that a brainstem measure of the encoding of acoustic transients, the duration of time between onset peaks V and A, was positively correlated to auditory cortex's susceptibility to background noise in both normal and LD subjects (Wible et al., 2005). Specifically, the longer the duration between onset peaks V and A, the more degraded the cortical responses became in the presence of background noise. In another study, it was shown that individuals with abnormal brainstem timing to acoustic transients were more likely to indicate reduced cortical sensitivity to acoustic change, as measured by the mismatch negativity (MMN) response (Banai et al., 2005). Finally, a third study showed that brainstem timing for speech-sound onset and offset predicts the degree of cortical asymmetry for speech sounds measured across a group of children with a wide range of reading skills (Abrams et al., 2006). Results from these studies indicate that abnormal

encoding of acoustic onsets at the brainstem may be a critical marker for systemic auditory deficits manifested at multiple levels of the auditory system, including the cortex.

In summary, evidence from examining the ABR indicates that acoustic transients are encoded in a relatively simple fashion in the brainstem, yet they represent a complex phenomenon that is related to linguistic ability and cortical function. In the cortex, results indicate that spectral contrasts of speech onsets are mapped along the anterior–posterior axis in the auditory cortex, whereas temporal attributes of speech onsets, as manifested by the VOT, are precisely encoded with double-peaked N100 responses.

Electrophysiological Changes due to Training

A survey of the brainstem and cortical literatures indicates that there is relatively scant evidence that the brain's representation of acoustic onsets is malleable following auditory-based training and therapy, and the primary evidence for plasticity of this feature is from a study of very young children. This study, which was previously described in the Formant Transition section, showed that a year or more of musical training in young children (3 to 5 years of age) resulted in decreased brainstem onset latencies in response to a consonant–vowel stimulus (Strait et al., 2013). Sound onsets are considered to be particularly rudimentary sound features, and the fact that the brainstem's response to acoustical onsets does not appear to be plastic following training (except in very young children) strongly suggests that this neural feature is established early in development and remains largely static irrespective of the experience of the individual. However, subcortical encoding of acoustic onsets does undergo substantial developmental changes across the lifespan, irrespective of training (Anderson et al., 2012; Skoe et al., in press).

The Speech Envelope

DEFINITION AND ROLE IN THE PERCEPTION OF SPEECH

The speech envelope refers to temporal fluctuations in the speech signal under 50 Hz. The dominant frequency of the speech envelope is at ~4 Hz, which reflects the average syllabic rate of speech (Steeneken and Houtgast, 1980). Envelope frequencies in normal speech are generally below 8 Hz (Houtgast and Steeneken, 1985), and the perceptually essential frequencies of the speech envelope are between 4 and 16 Hz (Drullman et al., 1994), although frequencies above 16 Hz contribute slightly to speech recognition (Shannon et al., 1995). The speech envelope provides phonetic and prosodic cues to the duration of speech segments, manner of articulation, the presence (or absence) of voicing, syllabication, and stress. The perceptual significance of the speech envelope has been investigated using a number of methodologies (Drullman et al., 1994; Shannon

et al., 1995) and, taken together, these data indicate that the speech envelope is both necessary and sufficient for normal speech recognition.

PHYSIOLOGICAL REPRESENTATION OF THE SPEECH ENVELOPE IN AUDITORY CORTEX

Only a few studies have investigated how the human brain represents the slow temporal information of the speech envelope. It should be noted that the representation of the speech envelope in humans has only been studied at the level of the cortex, since measuring ABRs typically involves filtering out the neurophysiological activity below ~100 Hz (Hall, 1992). Since speech envelope frequencies are between 2 and 50 Hz, any linear representation of speech envelope timing in brainstem responses is removed with brainstem filtering.

In one EEG study, responses from the auditory cortex to conversational, clearly enunciated, and time-compressed (i.e., rapid) speech sentences were measured in children (Abrams et al., 2008). Results indicate that human cortex synchronizes its response to the contours of the speech envelope across all three speech conditions and that responses measured from right-hemisphere auditory cortex showed consistently greater phase-locking and response magnitude compared to left-hemisphere responses. An MEG study showed similar results; however, in this study, it was shown that these neurophysiological measures of speech envelope phase-locking correlated with subjects' ability to perceive the speech sentences: As speech sentences become more difficult to perceive, the ability of the cortex to phase-lock to the speech sentence was more impaired (Ahissar et al., 2001). These results are in concert with results from the animal literature, which show that neurons of primary auditory cortex represent the temporal envelope of complex acoustic stimuli (i.e., animal communication calls) by phase-locking to this temporal feature of the stimulus (Wang et al., 1995).

A second line of inquiry into the cortical representation of speech envelope cues was described previously in this chapter in the discussion of cortical responses to VOT (Sharma and Dorman, 1999, 2000; Sharma et al., 2000). Acoustically, VOT is a slow temporal cue in speech (40 to 60 ms; 17 to 25 Hz) that falls within the range of speech envelope frequencies. Briefly, neurophysiological results indicated that for both /ba/-/pa/ and /ga/-/ka/ phonetic contrasts, cortical N100 responses precisely represented the acoustic attributes of the VOT. In addition, it was shown that neural responses were independent of the categorical perception of these phonetic contrasts (see the Acoustic Onsets section for a more detailed description of this study).

On the surface, it may appear that the findings from these experiments contradict one another since cortical phase-locking to the speech envelope correlates with perception in one study (Ahissar et al., 2001) whereas phase-locking fails to correlate with perception in the other study

(Sharma and Dorman, 1999, 2000; Sharma et al., 2000). These data are not, however, in contradiction to one another. In both cases, an a priori requirement for perception is phase-locking to the speech envelope; there is no evidence for perception in the absence of accurate phase-locking to the temporal envelope in either study. The primary difference between the studies is that despite phase-locking to the temporal envelope in the /ka/ stimulus condition at a VOT of ~40 ms, reliable perception of /ka/ occurs at ~60 ms. This suggests that accurate phase-locking is required for perception; however, perception cannot be predicted by phase-locking alone. Presumably, in the case of the /ka/ VOT stimulus, there is another processing stage that uses the phase-locked temporal information in conjunction with additional auditory-linguistic information (e.g., repeated exposure to /ka/ stimuli with 60 ms VOT) as a means to form phonetic category boundaries. The question of if and how category boundaries are established irrespective of auditory phase-locking requires additional investigation.

CONCLUSIONS

Speech is a highly complex signal composed of a variety of acoustic features, all of which are important for normal speech perception. Normal perception of these acoustic features certainly relies on their neural encoding, which has been the subject of this review. An obvious conclusion from these studies is that the central auditory system is a remarkable machine, able to simultaneously process the multiple acoustic cues of ongoing speech to decode a linguistic message. Furthermore, how the human brain is innately and dynamically programmed to utilize any number of these acoustic cues for the purpose of language, given the appropriate degree and type of stimulus exposure, further underscores the magnificence of this system.

The primary goals of this chapter are to describe our current understanding of neural representation of speech as well as training-related changes to these representations. By exploring these two topics concurrently it is argued that we have provided complementary perspectives on auditory function: The initial descriptions of brainstem and cortical representations of these speech features are thought to reflect “bottom-up” function of the auditory system with minimal consideration for the dynamic interactions provided by top-down connections in the auditory system (Xiao and Suga, 2002); in contrast, the descriptions of training-related changes to these representations provide information regarding how “top-down” cognitive and brain mechanisms sharpen these auditory representations (reviewed in Kraus and Chandrasekaran, 2010). Evidence accumulated across studies provides a complicated, but compelling, account of the malleability of these auditory responses. Results show that brainstem representations of speech can be affected and sharpened by multiple forms of auditory-based experiences, from long-term musical experiences to relatively short-term

auditory-cognitive training paradigms. Importantly, the relative plasticity of these different speech features appears to fall on a continuum: Acoustic onsets, which are largely static following all forms of auditory training, occupy one end of this continuum, whereas neural representations of formant transitions occupy the other end of this continuum, showing enhanced response properties following multiple training paradigms measured in a wide range of subject populations. Consistent with the animal literature (Recanzone et al., 1993), it is plausible that the relative plasticity of these features reflects the behavioral demands of each form of training, and a prediction of this hypothesis is that relatively static neural representations do not significantly contribute to the improvement on these tasks whereas more dynamic neural representations are important for improved performance.

To garner a greater understanding of how the central auditory system processes speech, it is important to consider subcortical and cortical auditory regions as reciprocally interactive. Indeed, auditory processing reflects an interaction of sensory, cognitive, and reward systems. Across the acoustic features described in this review, the brainstem appears to represent discrete acoustic events: The fundamental frequency and its modulation are represented with highly synchronized activity as reflected by the FFR; speech-sound onset is represented with highly predictable neural activation patterns that vary within fractions of milliseconds. Alternatively, the cortex appears to transform many of these acoustic cues, resulting in more complex representations of acoustic features of speech. For example, many of the cortical findings described here are based on the spatial representation of acoustic features (i.e., the relationship between F1 and F2 required for vowel identification; the differentiation of speech transients; the encoding of periodicity). Because cortical neurons are not able to phase-lock to high-frequency events, it is tempting to propose that cortex has found an alternative method for encoding these features based on the activity of spatially distributed neural populations. The extent to which these acoustic features are truly represented via a spatial organization in cortex is a future challenge that will be likely achieved using high-resolution imaging technologies in concert with EEG and MEG technologies.

FOOD FOR THOUGHT

Here, we have described what is currently known about brain representations of key elements of speech that are necessary for normal speech perception. Our review covers information garnered from multiple research methodologies, including brainstem- and cortical-evoked responses using EEG, which provide crucial information regarding the neural timing in response to specific speech features, as well as fMRI research, which provides complementary information regarding “where” in the brain this activity occurs. Furthermore, we have described the relative plasticity of these

brain responses as a result of specific behavioral experiences, with an emphasis on musical training. The following are important questions for future research that will enable us to further understand the brain basis of speech perception as well as associated plasticity and impairments.

1. Both the auditory brainstem and cortical regions are highly sensitive to elements of speech structure. An important question is what is the relationship between the integrity of brainstem representations of speech structure and cortical regions beyond auditory cortex that are known to be critical for structural processing of speech? For example, the posterior temporal sulcus is considered “voice-selective cortex” (Belin et al., 2000) and has been proposed to be a critical gateway which enables speech information to access other brain networks that serve semantic, reward, and mnemonic processes (Belin et al., 2011). A better understanding of how lower levels of the auditory hierarchy (i.e., the auditory brainstem) impact voice selectivity in the posterior temporal sulcus would provide important information regarding the function of this extensive network.
2. While humans are drawn to the sounds of speech, it is seldom considered a “rewarding” stimulus. Perhaps for this reason little research has been conducted to study the brain networks that are used for pleasurable speech. For example, what parts of the auditory hierarchy are differentially activated in response to pleasurable compared to neutral speech? Would these pleasurable speech sounds provide altered neural responses across the entire auditory hierarchy, or alternatively would only specific regions of the brain show effects of pleasure?
3. Research described in this chapter has convincingly shown that speech in noise perception is greatly improved through musical training (Parbery-Clark et al., 2012; Song et al., 2012). An exciting question is what are the particular neural mechanisms that enable this effect of musicianship? What aspects of musical training facilitate these behavioral advantages, and how might we harness this information to train individuals of all ages to become better listeners in noisy environments?

Central Auditory Processing Evaluation: A Test Battery Approach

Kim L. Tillery

INTRODUCTION

Audiologists routinely administer peripheral hearing assessments and a growing number also administer central auditory processing (CAP) tests. It seems logical that audiologists should consider to assist individuals with difficulty in “hearing” the auditory message, whether it is because of a peripheral dysfunction, central dysfunction, or both. After all, the hearing system is complex and we should be able to assess the integrity of the entire hearing system to better serve those who struggle in communication, language, and learning functions. It appears that the educational training dealing with central auditory processing disorder (CAPD) in clinical doctorate of audiology (Au.D.) programs has increased the awareness of CAPD in audiologists and in the importance of the test battery approach in forming a comprehensive understanding.

BACKGROUND

CAPD was first officially described in 1992 by the American Speech-Language-Hearing Association (ASHA). The general definition described CAPD as having difficulty in retrieving, transforming, analyzing, organizing, and storing information from audible acoustic signals (ASHA, 1992). This simple definition was later expanded when ASHA initiated a task force to discuss and derive the first professional consensus of several issues involving central auditory processing disorders (CAPDs) (ASHA, 1995, 1996). The issues included a definition, basic auditory science, assessment, clinical application, and developmental and acquired communication problems. CAPD was defined as involving deficits in localization, lateralization, auditory discrimination, pattern recognition skills, temporal processing, and performance decrements with competing or degraded auditory signals.

The consensus provided recommendations for determining the presence of CAPD and its functional deficits, emphasizing a team approach and the delineation of developmental or acquired CAPD deficits. Management approaches were focused on enhancing processing skills by

increasing the language knowledge base and improving processing speed. Intervention goals were to bridge linguistic and cognitive perception (within the realm of the speech pathologist) and the acoustic properties of speech (within the realm of the audiologist), thus enabling the client with a CAPD to function better with a minimum of behavioral deficits. The consensus document encouraged collaborative efforts between clinicians and researchers to improve our understanding of CAPD.

ASHA provided an updated technical report on CAPD in 2005. This report recognized the previously accepted ASHA definition and detailed a number of additional topics, including a review of basic science advances, audiometric assessment, developmental and acquired communication problems associated with CAPD, and the use of diagnostic information to indicate specific interventions. Although the Bruton Conference (Jerger and Musiek, 2000) suggested removing the word “central” from the title of this disorder, the ASHA (2005) report did not take a stand on the preferred title but rather indicated that both were acceptable. They recommended that the word “central” remain in the title, as (central) auditory processing disorder or CAPD, because most of the tests administered for CAPD diagnosis involve the central auditory nervous system (CANS), which is reiterated in the American Academy of Audiology (AAA) 2010 guidelines.

A second clarification provided in the ASHA (2005) Technical Report addressed the “modality-specific” approach to diagnosing CAPD (Cacace and McFarland, 2005; Jerger and Musiek, 2000). This approach, initiated by one group of researchers over the last decade (Cacace and McFarland, 2005; McFarland and Cacace, 1995, 1997), hinges on whether a CAPD evaluation should be purely auditory or might include other sensory and supramodal systems, such as language (Katz and Tillery, 2005; Musiek et al., 2005). The ASHA (2005) report provides substantial research and reasoning that a diagnostic criterion to rule out all other perceptual factors is not consistent with brain organization and central nervous system (CNS) processing and that assessment of multimodality function is not within

the scope of one professional discipline. In addition, the report stated that influences of maturational delays, extent of neurobiologic disorders, social and environmental factors, and neurologic disorders or diseases most certainly can impact different individuals with the same auditory deficit in different ways. It was concluded that CAPD involves a neural processing deficit of auditory stimuli that may “coexist with, but *is not the result of*, dysfunction in other modalities” (ASHA, 2005, p 3). Thus, CAPD is described as a distinct clinical entity that relates to complex skills including speech, reading, and other functions.

Five years later, the AAA (2010) guidelines elaborated on the potential influence of poor motivation, fatigue, or attention issues as sources that might cause a decreased test performance toward the end of the 45- to 60-minute test battery. The guidelines stress the need to use more than one test, in particular, to be conscious that sensitivity may be raised when increasing the number of tests whereas specificity may be reduced. The audiologist must be aware that the more tests that are used the more likely it is to have errors because of attention or fatigue. The purpose of an evaluation is to (1) identify strengths and weaknesses in the auditory system and (2) differentiate normal versus abnormal performance.

Successive position statements support the importance of diagnosis and treatment of children and adults. This was echoed most recently by the 2012 Canadian Guidelines on CAPD which incorporates the British Society of Audiology Position Statement (2011) and the International Classification of Functioning, Disability, and Health (ICF) of the World Health Organization (WHO, 2001). The latter ensures two main principles to be considered. First, the focus should involve assessment and intervention in meeting the needs of the individual and family. Second, the end result should consider clinical, social, vocational, educational, and community needs. In other words, is there community support for remediation and how do the processing deficits influence one’s life? Secondly, there should be a consideration of clinical, social, vocational, educational, and community needs. Further consideration should include developmental CAPD over time, acquired CAPD, and secondary CAPDs (i.e., peripheral hearing impairment or transient hearing issues because of otitis media or progressive presbycusis). Although all position papers show agreement on many of the whys and why not issues in proper diagnosis and intervention, the Canadian Guidelines offer more thorough information on the above models than the previous position statements.

Various authors have described the severity and variety of functional behavioral limitations caused by CAPD and coexisting disorders (Chermak et al., 1999; Keller, 1992, 1998; Keller and Tillery, 2002, 2014). Questionnaires can be useful for indicating the types of functional limitations present and assisting in appropriate referrals (Moore et al., 2013; Tillery, 1998). Given the associated language, communication, and

learning difficulties frequently associated with CAPD, a multidisciplinary approach can lead to more accurate diagnoses, thereby enhancing effective treatment and management plans (Keller and Tillery, 2002, 2014). Although a team approach is recommended to determine the problems associated with the client’s communication skills (Keller and Tillery, 2014), it is the audiologist who administers tests to determine the integrity of the CANS (AAA, 2010; ASHA, 1995, 2005; Canadian Guidelines, 2012).

CENTRAL AUDITORY PROCESSING TEST BATTERY APPROACH

As early as 1954, Mykelbust suggested that children with language disorders may have an auditory deficit beyond peripheral hearing and that the clinician should assess for such possibilities (Mykelbust, 1954). This early suggestion came when there were no audiologic tests to determine auditory functioning beyond the peripheral system. Today, there are quite a few central tests, and the test battery approach continues to be well recognized for CAP assessment (Domitz and Schow, 2000; Rawool, 2013).

The intent of CAP evaluations is to assess the CANS system at different levels. The efficacy of any test is determined by examining how it compares with different assessment tools (AAA, 2010; ASHA, 2005). Such comparisons may indicate that two or three auditory processing tests provide the same conclusions as six or seven other tests (AAA, 2010; Musiek and Lamb, 1994).

CAP tests have been in use for decades. The reader is referred to the following for a review of these tests: Bellis (2003), Katz (1994), Rawool (2013), and Weihing et al. (2013). Table 29.1 lists the CAP tests with their targeted processes and CANS sensitivity.

In addition to tests and test batteries that provide insights into CANS system issues, we now recognize that such an approach can help us to determine the possible underlying auditory mechanisms. For example, Schow et al. (2000) analyzed various central tests in comparison to the ASHA (1996) processes listed and determined the following measurable auditory behaviors: (1) Auditory pattern temporal ordering (APTO), (2) monaural separation/closure (MSC), (3) binaural separation (BS), and (4) binaural integration (BI). In addition, these authors suggested that CAPD testing can also evaluate auditory discrimination, localization/lateralization, and temporal tasks (resolution, masking, and integration). Table 29.2 provides definitions of these measurable auditory behaviors with associated CAP tests. The Schow et al. (2000) study is an example that illustrates the selection of tests, in this case based on auditory behaviors that should be assessed according to ASHA (1995, 2005); however, as discussed in the following sections, researchers have developed test batteries based on various conceptualizations of what they sought to examine.

TABLE 29.1

Summary of Central Auditory Processing Tests with Targeted Process and Central Auditory Nervous System Sensitivity to Specific Sites

	Monaural	Targeted Processes	Sensitive To:
Low-Pass Filtered Speech Tests			
Band-Pass Filtered	X	Auditory closure	Brainstem/cortical lesions
Compressed Speech	X	Auditory closure	Primary auditory cortex
Speech Recognition in Noise	X	Auditory closure	Brainstem to cortex
Dichotic Speech Tests			
Staggered Spondaic Word		Binaural integration	Brainstem/cortical/corpus callosum
Dichotic Digits		Binaural integration	Brainstem/cortical/corpus callosum
Synthetic Sentence Identification w/Contra Competing Message		Binaural separation	Cortical vs. brainstem
Competing Sentences		Binaural separation	Language processing
Dichotic Sentence Identification		Binaural integration	Brainstem/cortical
Dichotic Rhyme		Binaural integration	Interhemispheric
Dichotic Consonant Vowels		Binaural integration	Cortical
Temporal Patterning Tests			
Pitch Pattern Sequence [PPS]	X	Temporal ordering Linguistic labeling	Cerebral hemisphere lesions Interhemispheric transfer
Duration Patterns	X	Temporal ordering Linguistic labeling Duration discrimination	Cerebral hemisphere lesions Interhemispheric transfer
Random Gap Detection Test		Temporal resolution	Left temporal/cortical
Gaps-in-Noise	X	Temporal resolution	Interhemispheric transfer
Frequency Pattern [FP]	X	Temporal ordering Linguistic labeling Frequency discrimination	Cerebral hemisphere lesions
Other Tests			
Binaural Fusion		Binaural integration	Low brainstem
Masking Level Difference		Binaural interaction	Low brainstem
Rapid Alternating Speech		Binaural interaction	?Low or high brainstem

CENTRAL AUDITORY PROCESSING TEST BATTERY MODELS

Some CAP models that have been in use for the past several years or longer will be discussed below. Some were developed to determine the underlying auditory difficulties that relate to communicative and academic deficits (Bellis and Ferre, 1999; Katz and Smith, 1991), others tended to emphasize a medical framework (Jerger and Musiek, 2000), whereas others are based on the intertwining of cognitive, language, and auditory processes (Medwetsky, 2011).

These models incorporate different tests depending on the desired outcome of the applied construct. Three of the four models deliver subtypes or profiles that describe the CAPD, rather than pointing to a general CANS diagnosis. These models provide more information about an individual's

functional limitations and, in turn, suggest effective treatment opportunities. Regardless of the underlying construct, all of these models rely on CANS tests being administered in a manner that controls for fatigue and attention since these can affect test performance (AAA, 2010; Moore et al., 2013; Tillery, 2013; Tillery et al., 2000).

Minimal Test Battery

Jerger and Musiek (2000) discussed a possible test battery that would include both behavioral and electrophysiological testing. The authors suggested this battery as a minimum:

- Immittance audiometry (tympanometry and acoustic reflex threshold testing) to ascertain the status of the middle ear as well as auditory neuropathy differential diagnosis
- Otoacoustic emissions to diagnose inner ear problems

TABLE 29.2

Measurable Auditory Processing Behavioral Processes Recommended by Schow et al. (2000) and Adopted by the Bellis/Ferre Model

Process	Measurable Auditory Processing Performance	Types of Tests	Bellis/Ferre Profiles
Auditory pattern/temporal ordering (APTO)	Auditory discrimination of frequency or duration/order and sequencing/temporal processes/interhemispheric integration	1. Frequency pattern tests 2. Duration pattern tests 3. Pitch Pattern Sequence Test	Prosodic deficit
Monaural separation/closure (MSC)	Performance with degraded signals	1. Filtered or time-compressed speech 2. Ipsilateral competing signals	Auditory decoding deficit
Binaural integration (BI)	Ability to properly respond to all competing signals directed to both ears	Dichotic tests	Integration deficit
Binaural separation (BS)	Ability to attend to stimulus in one ear while ignoring the stimulus in the other ear	Competing sentences	Integration deficit
Sound localization/lateralization	Ability to describe location of stimuli in relation to position of one's head	Brainstem-level binaural interaction tests (masking level difference [MLD])	Integration deficit
Auditory discrimination	Ability to describe when two stimuli are different	1. Difference limens for frequency/duration/intensity or speech stimuli 2. Speech-sound or word discrimination tests	Auditory decoding deficit
Temporal resolution Temporal masking Temporal integration	Discrimination of speech and nonspeech, prosodic elements of speech, localization/lateralization	Need for research in developing more tests; possibly random gap detection/forward and backward masking	Auditory decoding deficit

- Auditory brainstem and middle latency evoked responses to assess brainstem and cortical level integrity
- Puretone audiometry to evaluate the integrity of the peripheral hearing system
- Performance-intensity functions for word recognition ability
- A dichotic task consisting of dichotic words, dichotic digits, or dichotic sentences (assessing the communication between hemispheres)
- Duration pattern and a temporal gap detection test to assess temporal processing aspects of CAPD

The authors further state that the above tests recommended in the minimal test battery (MTB) are a “reasonable compromise” (Jerger and Musiek, 2000, p 472) of tests until research can provide analogous measures in the visual modality and neuroimaging results can be applied to the clinical utility of CAPD testing. Note that this

model does not describe specific processing-related difficulties, but rather the goal is to ascertain whether CAPD is present.

Concerns were voiced about the MTB stating that a pure medical (diagnostic) model, as described in the Jerger and Musiek (2000) paper, would not delineate the CAP problems (Katz et al., 2002). Katz and colleagues pointed out that the tests lacked national CAP norms (at that time) and most had limited clinical use with the target population. In addition, the MTB did not address the educational concerns of children.

Bellis/Ferre Model

Initially, this model was called CATfiles (the CAT acronym stands for “categories” of CAPD) (Ferre, 1992). This was

later developed into a broader expansion of profiles (Bellis, 1999; Bellis and Ferre, 1999) with even further published changes (Bellis, 2002; Ferre, 2002), based on the Schow et al. (2000) criteria (Bellis, 2002). The current Bellis/Ferre CAPD subprofiles include three primary deficits—auditory decoding, prosodic, and integration—with secondary subprofiles that include associative deficit and organization-output deficit. The profiles are based on a conceptualization of the underlying neurophysiology in the CANS for encoding the auditory signal with the goal of identifying dysfunction in the left hemisphere, right hemisphere, and interhemispheric pathways. Bellis (2003) suggests that by examining the pattern of results across auditory processing functions, cognition, language, and learning, one can glean the underlying CAPD difficulties/profile.

The Bellis/Ferre profiles may be seen in isolation or together, with Bellis (2002) cautioning that one profile is typically primary in nature; however, another profile can be present because of possible overlap in the adjacent cortical structures. Electrophysiological tests are not used in the Bellis/Ferre model. Table 29.2 outlines this model, whereas the reader is referred to Bellis (2003) and Chapter 30 for an in-depth review of these profiles and for therapies. Following are descriptions of the various Bellis/Ferre CAPD subprofiles.

AUDITORY DECODING DEFICIT

According to Bellis (2003, p 291), auditory decoding deficit is possibly “the only true CAPD.” This subprofile involves weak phonemic representations, poor discrimination and blending of sounds, and an inability to remember the learned phonemes. Determination of this profile is based on weaker right ear versus left ear test performance on low-redundancy speech and speech-in-noise tests (Bellis, 1996). Bellis (2002) describes the additional components of weak reading, vocabulary, and spelling skills, as well as concomitant behaviors such as auditory fatigue, and performance being improved with good visual perceptual skills. Site-of-lesion and electrophysiological research has suggested the primary auditory cortex within the left hemisphere as the probable site of dysfunction (Bellis, 1996). A later report (Bellis, 2002) found this deficit to be associated with diminished right ear/both ear performance on the Dichotic Digits Test (Musiek, 1983) (labeled a BI weakness) and the Competing Sentence Test (Willeford and Burleigh, 1985) (labeled a BS weakness).

PROSODIC DEFICIT

Prosodic deficit is characterized by (1) difficulty in perceiving and recognizing nonverbal information, such as tonal patterns; (2) weak left ear test performance on dichotic tests showing weak BI and BS abilities; and (3) good speech-in-noise ability because of intact decoding ability (Bellis, 2002).

Associated problems include weak singing ability (such as poor replication of melodies), poor social communication skills (i.e., difficulty understanding body language, facial gestures), flat voicing patterns, and diminished ability on visual-spatial tasks. Academic concerns involve weakness in mathematics, reading, sequencing, and spelling and poor sight-word abilities.

INTEGRATION DEFICIT

Integration deficit is characterized as a struggle involving interhemispheric skills, such as drawing, understanding dictation, dancing, and multimodal tasking (Bellis, 1996). Integration deficits may be the result of an immature corpus callosum or other structures related to the transfer of interhemispheric information. Auditory test results observed for this profile include weak left ear results on dichotic tasks and poor nonverbal test performance scores. Bellis (2002) further elaborates that BI and BS deficits are also often seen with this profile of CAPD, with weak sound localization abilities.

SECONDARY PROFILES

Auditory Associative Deficit

The secondary profile known as an auditory associative deficit was observed in the original work of Bellis and Ferre (1999) as a CAPD profile, but it more recently has been classified as a secondary profile of CAPD (Ferre, 2002). This deficit consists of an inability to use rules of language with acoustic information, with the most severe cases replicating receptive childhood aphasia (Bellis, 1996). Performance on speech-sound discrimination tasks is normal; however, weak word recognition and dichotic test findings are observed bilaterally. Receptive language struggles are seen in vocabulary, semantics, and syntax. Inefficient communication between primary and associative cortical regions may be the causal aspect of this category (Bellis, 1996) and realized as significant auditory–language-processing difficulties (Ferre, 2002). The individual exhibits functional communication deficits when there is no specific-language impairment (Ferre, 2010).

Output-Organization Deficit

Another secondary profile is the output-organization deficit, which involves an inability to properly sequence, plan, and organize information (Bellis, 1996). Test performance requiring one simple response (e.g., monaural low-redundancy tests) will be good, whereas performance on tests with multiple components, such as those required on dichotic, frequency, or duration pattern tests, will be poor because of the use of complex stimuli (Bellis, 1996). Individuals with this type of deficit exhibit fine motor difficulties as well as sequencing and sound-blending errors. Reading comprehension is generally good for those who exhibit only this subprofile. At

the time this subprofile was proposed, the site of dysfunction for this category was not known, although an efferent (motor planning) hypothesis was proposed because of the weak skills observed on motoric tasks seen with this type of CAPD (Bellis, 1996).

Buffalo Model

This model, first reported in the early 1990s, consists of four CAPD subtypes (Katz, 1992; Katz and Smith, 1991). The Buffalo Model comprises of three tests, in which the Staggered Spondaic Word (SSW) test (Katz, 1962, 1968) is the center of the battery; the other two tests include the Phonemic Synthesis (PS) (Katz and Harmon, 1982) and Speech-in-Noise (Mueller et al., 1987) tests. This test battery provides 34 quantitative and qualitative indicators. Quantitative indicators are the number of errors seen in each of the three tests, whereas qualitative indicators refer to inter/intratest comparisons and the behavioral struggles seen during testing. Test results are compared to independent parent–teacher assessments (Katz and Zalweski, 2013) to determine if the test results relate to the same concerns of the family and school. The combination of the test performance indicators and academic and social behaviors (particular clusterings of each being associated with cortical anatomic sites) results in four CAPD subtypes that are not mutually exclusive: Decoding, tolerance-fading memory (TFM), integration, and organization (Katz, 1992, 2001; Katz and Smith, 1991). Clinicians may administer other

tests (Medwetsky, 2011; Stecker, 1998) in addition to the Buffalo Model tests. See Table 29.3 for the test indicators for the Buffalo Model types of CAPD.

DECODING

Decoding has been described as the most common type, but it may not be quite as prevalent as it was in the late 1980s and early 1990s because the whole language approach is no longer used in the school system (Stecker, 2004) and more emphasis is being placed on phonemic awareness now (Tillery, 2005). The decoding type involves a breakdown at the phonemic level, causing a weakness in identifying, manipulating, and remembering phonemes. Weak oral reading or word accuracy and spelling skills are usually found in this subtype. Rapid incoming speech adds to the confusion of processing the message, and response delays are common because of the individual needing additional time to determine the verbal message. Weak discrimination and vocabulary result in the misperceptions of the heard auditory stimuli. Reported site of dysfunction for this category is the phonemic zone (Luria, 1966) of the left posterior temporal lobe, also known as the auditory cortex. Test results associated with this subtype include weak SSW right competing (RC) and left noncompeting (LNC) scores and poor Phonemic Synthesis results (Katz, 1992). Qualitative signs include delayed responses, nonfused answers, and quiet rehearsals (described in Table 29.3).

TABLE 29.3

Qualitative and Quantitative Test Indicators of Buffalo Model Central Auditory Processing Disorders (CAPD) Types

CAPD Types	Primary Indicators			Secondary Indicators			Qualifying Indicators		
	SSW	PS	SN	SSW	PS	SN	SSW	PS	SN
Decoding	RC errors LNC error Order L/H Ear H/L	Below normal	Mild		Nonfused, quiet rehearsals, delays		Delays Persevera- tions Smush	Delays Persevera- tions O/L	Mild/ moder- ate in poorer ear
TFM	Order H/L Ear L/H		Moderate or severe in poorer ear	LC errors			Quick AYR/Y TTW Smush	Omission error on first sounds	Moderate in poorer ear
Integra- tion	Type A			Sharp LC peak of errors	May be severe score		Extreme delays		
Organi- zation	Significant Reversals	Significant Reversals							

Abbreviations: SSW, Staggered Spondaic Word Test; PS, Phonemic Synthesis Test; SN, Speech-in-Noise Test [Katz, 2001 a]; RC, right competing; LC, left competing; LNC, left noncompeting; H/L, high/low; L/H, low/high; O/L, whereby client produces an /o/ sound for the /l/ sound; TFM, tolerance-fading memory; AYR, “are you ready” response; Y, “yes” response; TTW, tongue twister.

TOLERANCE-FADING MEMORY

This CAPD subtype has been considered the second most common in the general population (Katz, 1992). The theorized loci involve the frontal lobes and the anterior temporal region, which houses the hippocampus and amygdala, and are associated with memory and the limbic system (Katz, 1992; Isaacson and Pribram, 1986). Functional behavioral limitations include a weak short-term auditory memory and difficulty hearing auditory information in the presence of noise (the *tolerance* aspect of TFM), that is, individuals with TFM may exhibit significantly increased difficulty tolerating and understanding in noise as compared to individuals with other types. Other limitations associated with frontal lobe dysfunction include expressive language and difficulty inhibiting impulsive responses. Qualitative signs include quick responses, smush responses (combining the competing words of an item into a single word, e.g., “sea shore outside” = “sea shout side”), an inability to refrain from repeating carrier phrases (“Are you ready?”), and omission or errors on the first word (or the omission of the first sound on the PS test). Individuals with attention deficit/hyperactivity disorder (ADHD) are commonly found to exhibit TFM (Keller and Tillery, 2002, 2014), probably because of the close association of the frontal and the anterior temporal lobes (Katz and Smith, 1991). The frontal lobe houses executive function that serves to regulate and coordinate behaviors to the environment, inhibits irrelevant responses, and oversees cognitive processes (Barkley, 1998), which are affected by ADHD. Recent studies support the close association between short-term auditory memory and speech-in-noise difficulties (Brannstrom et al., 2012; Yathiraj and Maggu, 2013).

INTEGRATION

The integration category is considered the most severe type of CAPD. Earlier integration was divided into two subtypes, but in time it became clear that each category needed to be addressed equally and so it was unnecessary to have this division. Generally, the more severe integration case probably involves the posterior corpus callosum and/or the angular gyrus of the parietal-occipital region, which are regions thought to be associated with dyslexia (Geschwind and Galaburda, 1987). The integration problems that likely involve more anterior regions of the corpus callosum tend to be somewhat less severe. An integration sign is said to be present when one displays a type-A SSW pattern, that is, a severe peak of errors usually in one particular column of the eight columns on the SSW test response form (column F, a left competing condition). Type-A indicates difficulty in transferring interhemispheric information. To determine the likely behavioral impact of the type-A, one needs to look at the rest of the test battery findings and the Buffalo Model Questionnaire—Revised (Katz and Zalweski, 2013). In addition, a qualitative sign in those with integration difficulties

includes extremely long response times on the SSW items that are generally seen in daily life activities as well. Functional behavioral limitations include severe reading and spelling problems and difficulty in integrating visual and auditory information, and they are often diagnosed with dyslexia. Integration is often more resistant to therapeutic intervention therapy than the other three categories.

ORGANIZATION

This CAPD subtype was first reported by Lucker (1981), who recognized that reversals on the SSW test are observed in individuals who are disorganized. A reversal is said to occur when stimuli (i.e., words, sounds) are repeated out of sequence. Both the SSW and Phonemic Synthesis tests have norms for determining the presence of a significant number of reversals (ages 5 or 6 years to 69). Reversals are considered a more anterior sign (Katz, 1992). Note that those with attention disorders tend to exhibit weak organization, planning, and sequencing, all of which are associated with dysfunction in the Rolandic region (Luria, 1970, Efron, 1963). Indeed, Tillery (1999) found SSW reversals to be very common in her studies of children with ADHD.

Spoken-Language-Processing Model

This model, developed by colleagues at Rochester Speech and Hearing Clinic, New York, expands on the Buffalo Model to include a broader perspective beyond auditory processing to better understand how one perceives and processes spoken language. Medwetsky (2011) considers auditory processing to be a component of spoken-language-processing (S-LP) and limited to those perceptual mechanisms involved in the initial acoustic analysis of the incoming signal. Table 29.4 shows a summary of the S-LP Model. The CAPD diagnosis may result in the following areas of concern: Lexical decoding, fading memory, auditory-linguistic integration, sequencing, short-term memory span, prosodic perception, attention and phonologic problems.

ELECTROPHYSIOLOGICAL MEASURES AND A CENTRAL AUDITORY PROCESSING TEST BATTERY?

The proposed MTB indicated a need for electrophysiological testing that the proposers felt should be included in all CAPD test batteries (Jerger and Musiek, 2000). This recommendation was based on the fact that CANS neural synchrony in response to auditory stimuli is assessed through the application of a number of electrophysiological procedures, including auditory brainstem response (ABR), middle latency response (MLR), mismatch negativity (MMN), and late evoked potentials (LEP), including P300. However, an

TABLE 29.4

Processes Assessed through the Spoken-Language Processing (S-LP) Model (Medwetsky, 2011)

Process	Definition	Test
Temporal resolution	Ability to detect rapid changes in the speech signal	Random Gap Detection Test; Gaps-in-Noise Test
Lexical decoding speed	Ability to process words quickly and accurately	Staggered Spondaic Word (SSW) Test–Decoding Signs
Short-term memory (STM)/working memory	Severity/patterns of how information is maintained in conscious memory (i.e., initial vs. later presented information)	SSW Test–Fading Memory Signs
STM/working memory span	Amount of units/information retained in STM	Test of Auditory Perceptual Skills–Revised: 1. Auditory Number Memory–Forward; 2. Auditory Word Memory; 3. Auditory Sentence Memory
Sequencing	Ability to maintain speech sounds, words, and directions in order	SSW Test (organization), Phonemic Synthesis Test (reversals), Token Test, Pitch Pattern Sequences Test
Auditory-linguistic integration	Ability to integrate information (supra-segmental/visual/verbal) across processing regions	1. Digit Span–Rhythm Task; 2. SSW Test–Integration Sign; 3. Competing Sentences Test–right ear dominance; 4. Pitch Pattern Sequences Test (non-verbal/verbal discrepancy)
Prosodic perception	Ability to perceive/replicate rhythmic patterns	Pitch Pattern Sequences Test (significant nonverbal sign) + flat voicing patterns
Selective auditory attention	Ability to focus and recall target stimuli in presence of competition	Figure-ground tests (i.e., speech embedded in noise) and binaural separation such as on Competing Sentences Test
Divided auditory attention	Ability to recall both competing stimuli presented	SSW Test, Competing Sentences Test, Competing Words from Screening Test for Auditory Processing Disorders (SCAN)/SCAN–Revised
Sustained auditory attention	Ability to maintain attention to verbally presented information over a period of time without a break	Auditory Continuous Performance Test
Higher order phonologic skills Phonemic synthesis	Ability to blend individually presented speech sounds and derive the target whole word	Phonemic Synthesis Test
Sound–symbol associations	Ability to discriminate/sequence/represent speech sounds with symbols	Lindamood Auditory Conceptualization Test 3

abnormality of the CANS determined through electrophysiological measures does not provide specific information as to the type of CAPD or auditory behavioral deficits that can be expected based on the results obtained. That is, although electrophysiological tests may show clinical utility in assessing the CANS (Jirsa, 2002), there is a paucity of research in understanding the abnormalities of these tests relative to

the presence of learning disabilities (Cacace and McFarland, 2002). For example, clear relationships have not yet been found between the auditory behavioral limitations observed in individuals suspected of having CAPD and neural dys-synchrony ascertained via electrophysiological measures. In addition, research has revealed little evidence of an increased prevalence of abnormal ABRs or MLRs to click stimuli/tone

bursts in CAPD populations. Furthermore, it is questionable as to what information can be provided with application of traditional electrophysiological testing when providing intervention recommendations (AAA, 2010; Bellis, 2003). Obviously, electrophysiological tests control for attention, fatigue, and motivation influences when assessing the CANS, even though these areas can usually be identified and controlled for during behavior tests (Bellis, 2003; Katz and Tillery, 2005).

Some recent studies have investigated the application of electrophysiological procedures to determine clinical utility in a CAPD diagnosis. For example, MMN has been found to (1) verify neurophysiological changes because of listening training that may accompany observable auditory behaviors (Tremblay et al., 1997; Tremblay, 2007); (2) assist in differentiating phonemic (low) levels and language (higher) levels during auditory processing (Dalebout and Stack, 1999); and (3) differentiate children with and without learning problems (Banai et al., 2005). It has also been suggested that LEP measures can (1) differentiate attention disorders from other problems (Kraus et al., 1995); (2) show increased latency and decreased amplitude on P300 for children with APD when compared to those without APD (Jirsa and Clontz, 1990); (3) be used to study developmental processes in children and adults with hyperactivity (Satterfield et al., 1984); and (4) examine children with language/speech disorders (Mason and Mellor, 1984).

However, the most impressive research to date concerning the use of electrophysiological procedures and speech processing comes from Krause and colleagues (Kraus and Chandrasekaran, 2011; Kraus and Nicol, 2005; Russo et al., 2005). Please refer to Chapter 28, and Krause and Hornickel (2013).

CENTRAL AUDITORY PROCESSING SCREENING

CAP screening assesses the possibility of existence of a CAPD and, in turn, can lead to possible referral for a comprehensive CAPD evaluation. Psychologists and speech-language pathologists are two professional groups that would likely screen for CAP on a routine basis. As part of the screening process, teachers and parents may be asked to provide information on the child's behavioral functional limitations through the use of questionnaires.

Questionnaires

Questionnaires are a common tool for ascertaining the likelihood that an individual exhibits functional behavioral limitations in his/her communication, language, and learning. Because of possible bias, we must take into consideration who is rating the child's behaviors on the questionnaire. A teacher may give ratings that indicate weak attention

or motivation of the student as being the possible reason for "poor listening." However, CANS tests may indicate that CAPD is associated with the student's "listening difficulty." On the other hand, parents may insist that their child has a CAPD and reflect this bias on the questionnaire ratings for their child to receive preferential services or a referral for testing. Following is a list of questionnaires which are available through the Educational Audiology Association:

1. Fisher Auditory Problems Checklist (Fisher, 1985). This was the first developed CAP screening questionnaire, with normative data available from kindergarten to grade 6. It has been designed to rate 25 items of concern. Many of the items listed on this questionnaire are commonly used in other CAPD profiles.
2. Children's Auditory Processing Performance Scale (CHAPPS) (Smoski et al., 1992). There are six listening situations (ideal, quiet, attention, memory, noise, and multiple inputs), and the rater (parent or teacher) compares the student to children of similar age and background. There are a total of 36 questions, and the choices vary from +1 (less difficulty than others) to -5 (cannot function in the situation). Scores can range from +36 to -180, and the more negative the score, the more difficulty that is noted. A child who receives a total score of -12 to -180 is at risk for CAPD.
3. Screening Instrument for Targeting Educational Risk (SIFTER) (Anderson, 1989). There are 15 questions over five category areas: Communication, academics, attention, class participation, and social behavior. Scoring consists of 15 points per category, resulting in a failure if one is rated at or below 6 or 7 (depending on the category).
4. Buffalo Model Questionnaire—Revised (BMQ-R) (Katz and Zalweski, 2013). The questionnaire contains 39 questions dealing with CAPD including categories/sub-categories: Decoding, Noise, Memory, Various TFM, Integration, Organization, and General (more than one category). Data are provided for three age groups (<6, 6 to 18, >18) with 122 controls and 213 who have CAPD. The characteristics that were most common were for Decoding (understands oral directions) and Memory (remembers oral directions), both of which had 79% hit rates in the CAPD group. BMQ-R is useful prior to the evaluation, following the evaluation to compare with the test findings, before therapy, and independently validating the progress in therapy.

Screening Tests

Historically, screening test performance scores have sometimes been used to label a child with CAPD, rather than to refer the child for further testing (Jerger and Musiek, 2000) by an audiologist to rule in or out the diagnosis of CAPD. In general, screening tests have been designed to have high

sensitivity (Jerger and Musiek, 2000) (i.e., those having CAPD are readily identified); however, this can also lead to a high false-positive rate (i.e., identify individuals as possibly having CAPD when, in fact, they do not).

Obviously, attention, fatigue, and status of an unchecked peripheral hearing system can influence screening test findings. It is recommended that screening tests be administered in a room without any noise distractions and during the morning to control for attention and fatigue. When possible, screening tympanometry and puretone thresholds should be obtained to improve the reliability of the screening results. It is essential to obtain a thorough case history of the child or adult prior to the evaluation for medical, academic, and functional behavioral deficit information. We need to understand the individual's problems that may be related to CAPD (AAA, 2010). The following is a description of some of the CAP screening tests available:

1. The original Screening Test for Auditory Processing Disorders (SCAN) (Keith, 1986) developed over the years. Currently, for ages 5 to 12 years the SCAN-3 for Children: Tests for Auditory Processing Disorders (SCAN-3:C) (Keith, 2009b) and for ages 13 to 50 years, the SCAN-3 for Adolescents and Adults: Tests for Auditory Processing Disorders (SCAN 3:A) (Keith, 2009a) are used. Both SCAN protocols contain three screening measures (Gap Detection, Auditory Figure-Ground, Competing Words), four diagnostic tests (Filtered Words, Auditory Figure-Ground, Competing Words, Competing Sentences), and three supplementary tests (Auditory Figure-Ground at +12 dB SNR and at 0 dB SNR, Time-Compressed Sentences).

Although psychologists and speech-language pathologists typically administer the SCAN series as a screening tool for CAPD, the inclusion of the diagnostic portion of the SCAN-3:C or SCAN-3:A offers audiologists to use these instruments as a portion of their test battery. A cassette player, headphones, and a quiet environment are necessary to administer these screening procedures. I have consulted and advised psychologists to administer the SCAN in the morning and that it be the first test in their test battery to control for fatigue and attention; otherwise, fatigue and inattention could influence the occurrence of false-positive test results.

2. The Differential Screening Test for Processing (DSTP) (Richard and Ferre, 2006) was developed to differentiate skills associated with three neurologic levels of processing that are integrated depending on the communication task: (1) Perception of primary acoustic characteristics of auditory signals; (2) identification of acoustic aspects related to the phonemic portion of language; and (3) the ability to attribute meaning to language.

The authors indicate that the first level is evaluated by tests that target (a) the ability to discriminate speech

sounds (auditory discrimination); (b) binaural integration in which the client is asked to repeat numbers presented dichotically to assess communication between hemispheres, and (c) the ability to recognize acoustic patterns found in verbal communication (temporal patterning) by verbally indicating the sequence of the two presented tones (high and/or low pitched, such as high-high or low-high).

The second level is evaluated by using two subtests: "Phonemic" manipulation and "phonic" manipulation. Phonemic manipulation provides two to four sounds in which the child must properly recognize (a) the number of discrete phonemes in a provided word, (b) blend the sounds into a word, and (c) change discrete sounds when asked. Phonic manipulation assesses sound-symbol associations by providing three tasks that target (a) proper spelling with supplied tiles, (b) the ability to synthesize phonemes with the use of tiles, and (c) the ability to modify the tile representation when provided a new target word.

The third level assesses meaning to the auditory signal by providing three subtests: Antonyms, prosodic interpretation, and language organization. To assess antonym knowledge, the child must provide the opposite word to the provided target word. To assess prosodic interpretation, the child verbally responds with a "yes" or "no" to the sincerity of the message. For instance, the phrase "I am happy to be here" is provided in a sad tone of voice. The child would respond "no" because there is a discrepancy between the prosodic information and the provided statement. To assess language organization, the child must respond successfully to two different tasks. Task 1 provides eight different sentences, such as, "It's what you sit on at a table or a desk." The proper answer is chair, stool, or seat. For task 2, the child is provided pictures of objects and must describe the objects or what the objects do. For instance, a picture of a flower may be provided. The proper response can be any of the following: Smells good, attracts bees, blooms, grows in a garden, has pollen, and so on.

The DSTP was standardized by presenting the subtests to 509 students aged 6.0 to 12.11 years old, reflecting a balance across race, age, gender, grade, and all socioeconomic groups. Poor test performance in any area suggests the need for additional diagnostic evaluation(s) to establish the presence of a deficit.

3. The Auditory Skills Assessment (ASA) (Geffner and Goldman, 2010) is the first tool developed to assess the skills of young children (3.6 to 6.11 years) as CAPD weaknesses, most certainly, influence language and academic skills.

The ASA consists of six subtests: Speech discrimination in noise (+6 dB SNR, mimicry (repeat a nonsense word), blending (morphemes or phonemes are given first with a visual cue followed with no visual cue), rhyming

awareness, tonal discrimination (ability to distinguish same or different musical instrument notes), and tonal patterning (points to the picture of a piano or an oboe to indicate which sound was heard last).

The ASA was standardized by analyses of data from 475 children aged 3.6 to 6.11 years. Reading, language, and learning issues can result from a deficit found on the above ASA measures. Thus early identification coupled with intervention will assist this young population.

4. There are other possible screening tools. Speech-language pathologists routinely use the Test of Auditory Perceptual Skills—Revised (TAPS-R; Gardner, 1996), whereas psychologists typically use some form of digit span test (Wechsler, 1991) or the Visual-Aural Digit Span Test (Koppitz, 1975). Bellis (2003) indicates that the TAPS-R may be an instrument that can provide some indication of auditory perceptual ability, but it does not indicate the specific underlying auditory processing difficulties. Keller et al. (2006) found a correlation with test performance on digit span (Wechsler, 1991) and CAPD. This indicates that psychologists should refer individuals for a CAPD evaluation when a client shows weakness on tests sensitive to short-term auditory memory span.

The Dichotic Digit Test (DDT) (Musiek, 1983), administering two digits per ear, may also be a useful CAPD screening tool because it is a very quick test to administer (4-minute task) and uses very familiar items (digits) that even young children will readily recognize (Jerger and Musiek, 2000).

Combined screening measures may assist in minimizing over-referrals because of high false-positive findings (Jerger and Musiek, 2000). For example, this can be accomplished by using the combination of a questionnaire and CAP screening test measure. Another possibility posed by Jerger and Musiek (2000) is to administer both the DDT and a gap detection test; however, the authors stress the need for research to assess this possibility as a screening measure.

CENTRAL AUDITORY PROCESSING DISORDER TESTS

Auditory tasks administered to assess for auditory processing function consist of monotic (stimuli presented separately to each ear), diotic (same stimuli presented to both ears simultaneously), and dichotic (different stimuli presented to each ear simultaneously) tests. Audiologists generally choose their tests by the processes they wish to assess. Refer to the CAPD Test Battery Model discussed in earlier sections of this chapter. Table 29.1 lists CAP tests with their associated targeted process and CANS sensitivity, whereas Table 29.2 defines the function assessed by the CAP tests. The reader is referred to the previous cited test battery publications and the more recent

publications that provide a thorough description of the CAP tests seen in the various models (Chermak and Musiek, 2014; Geffner and Ross-Swain, 2013; Musiek and Chermak, 2014).

REPORTING CENTRAL AUDITORY PROCESSING DISORDER TEST RESULTS

An evaluation report must be accurate, concise, and well written. These reports communicate to families and professionals (such as physicians, speech-language pathologists, teachers, tutors, occupational and physical therapists, and psychologists) an explanation of the various test battery procedures, test performance results, and recommendations for remediation or compensations for the disorder. Professionals appreciate reports that are organized, consistent in format style, and provide details on the test performance data; in turn, this allows them to know exactly where to find a specific summary or fact, thus saving them time and effort. The reports should provide the raw scores, number of standard deviations (SD), and explanation of findings in terms that are understood by all those who read the report. When applicable, information should include both qualitative and quantitative results, severity of findings, overall implications (e.g., comorbidity associations, educational and medical aspects), and resources for the reader to consult. Reports should be sent within a reasonable time frame.

In summary, the report is likely the best opportunity to educate others about the diagnosis of CAPD; facts regarding the administered test battery; social, medical, and educational ramifications; and recommendations for assisting with the client's auditory, learning, and communicative functional behavioral limitations.

THIRD-PARTY REIMBURSEMENT

The ASHA (2005) CAPD Technical Report is the first publication to provide information on how to submit for payment for these evaluations. Perhaps this is because current procedural terminology (CPT) codes implemented in January 2005 for the first time reflected the professional time and services provided in a CAPD evaluation. The AAA (2010) document provides detailed information on reimbursement, including counseling and report writing. The first hour of administering, interpreting, and/or providing test results falls under the CPT code 92620, with each additional 15-minute increment to be billed under code 92621. These codes do not include the peripheral hearing assessment, which is billed under each individual peripheral hearing measurement administered. There are differences in insurance reimbursement seen in the United States and other countries. In the United States, the audiologist should

be well informed of what procedures are covered by the third-party insurers. Families are unaware of the differences among insurers' policies and rely on the professional to be informed.

In the past, reimbursement involved submitting for each central test administered, each with its own CPT code. Such billing was frustrating because some CAP tests would only allow a \$3.00 reimbursement for a test that took 15 minutes to administer, whereas others provided a \$25.00 reimbursement for a 10-minute test. Another billing problem in the past was that speech-language pathologists and audiologists had to bill for language and/or auditory processing evaluations under a single CPT code. Such procedures led to confusion and misrepresented CAPD test assessment. To reconcile this billing dilemma, improved reimbursement procedures were developed for CAP assessment, which ultimately led to the new CPT codes. In October 2014, the United States will be using new diagnostic codes. The codes for a CAPD diagnosis include four new codes: One for a left ear CAPD deficit, a right ear CAPD deficit, both, or non-specified.

Reimbursement Concerns

Insurance companies are not obligated to reimburse for testing, intervention, and report writing that fall under an educational-related diagnosis or experimental applications. Some insurance companies indicate that CAPD is related to educational factors (Excellus, 2002) and, therefore, is not covered, even under the diagnostic code 388.40: Abnormal Auditory Perception. When an educational-based reason is used as a reason for denial of payment of service or when an insurance company has outdated information and claims that CAPD is experimental (Aetna, 2012), information should be provided to these insurance companies that includes the most current up-to-date facts, such as studies showing the clinical utility of CAPD testing. During this interim period, the clinician would submit for payment to the insurance company for the peripheral and central assessment procedures. The client will be responsible for payment of any uncovered assessment measures.

Another concern is the need for evidenced-based research to address the types or subprofiles of CAPD in terms of both medical and educational outcomes. Insurance companies rely on evidence-based research and technical reports to justify medical needs for services rendered. At the present time, all CAPD models indicate some form of educational basis: Poor reading and spelling, weak organization, poor or inconsistent academic performance, weak expressive language written skill, and so on. If this continues to be stressed in the models of CAPD, without the medical counterpart, then insurance companies may prematurely conclude that there are only educational components of

CAPD and thus not realize the medical concerns. In turn, this will continue to result in denials of reimbursement for services associated with the current diagnostic code 388.40 Abnormal Auditory Perception.

As professionals, we are obligated to provide evidence-based research regarding areas of concern related to differential diagnosis to indicate a medical need for testing and application of intervention. Differential diagnosis involves collaboration with the psychologist, speech-language pathologist, audiologist, and possibly the physician. The end result may be a child with only ADHD who may need medication to assist with the functional behavioral limitations associated with ADHD (Keller and Tillery, 2014; Tillery, 2013). However, the auditory problems of a child with CAPD alone will not improve with medication (Tillery et al., 2000). The child with both CAPD and ADHD will need a variety of therapeutic measures to assist ADHD (i.e., medication, tutoring, behavioral modification, counseling) and unique therapeutic measures for CAPD. This example illustrates the concept of "win-win," with both the client and insurance company benefiting from the CAP evaluation and recommendations. The insurance company will not have to provide coverage for medication for someone with a diagnosis of CAPD (which could cost the insurance company thousands of dollars over the course of many years), whereas the client hopefully will obtain the treatment that will best meet his or her needs.

FUTURE CONCERNS IN AUDITORY PROCESSING TEST BATTERIES

The selection of CAP tests or a test battery approach relies on the comfort, experience, and education of the clinician, as well as the availability of a multidisciplinary team in the geographic area in which one resides. Consensus and position papers (AAA, 2010; ASHA, 2005; Canadian Guidelines, 2012) recommend that testing be done for children 7 years of age and older. However, the Buffalo and S-LP models provide qualitative data congruent with quantitative data for children as young as 5 years of age. Such testing can result in the categorization of types of auditory processing problems, initiation of therapy, and addressing educational and communication concerns before major problems occur. Hopefully, in time, there will be a general understanding that the earlier one is diagnosed the better the opportunity to provide appropriate intervention. The identification of dysfunction among specific auditory processes is the basis of the Bellis/Ferre Model and provides specific categories of auditory problems that coincide with educational and communication concerns. Some clinicians broaden these models. For instance, Medwetsky's S-LP Model (2011) uses the qualitative and quantitative data of the Buffalo Model as

a foundation and further includes attention, memory span, and phonologic awareness/phonics test performance for further analysis (Medwetsky, 2011). Stecker (1998) discusses the application of additional tests to assess localization and/or low brainstem assessment beyond the Buffalo Model. Those who work with psychologists in a team approach may not need to administer attention tests such as the Auditory Continuous Performance Test (Keith, 1994) since it is routinely administered by the referring psychologist, as is the case in Western New York.

SUMMARY

A test battery approach is recommended for the assessment of the CANS when a client presents with functional behavioral limitations in auditory, learning, and communication skills. Currently, evaluating the CANS is not a routine application of assessment among audiologists; however, it is hopeful that this will soon change with the educational opportunities offered by Au.D. programs. Research should concentrate on the application and results of CAP tests that indicate specific types of CAPD, as seen in the current models discussed which would lead to appropriate intervention. The past decade has focused on improving our awareness of the reliability of CAP test performance and the success in remediating the functional deficits associated with CAPD. The next decade should focus on improved normative data for using electrophysiological tests in certain populations with attention deficit, dyslexia, and the subtypes of CAPD. These procedures would augment current behavioral test batteries by providing objective evidence of underlying processing deficits, help determine auditory training candidacy, and, in turn, continue to evaluate the effectiveness of such therapy.

FOOD FOR THOUGHT

Perhaps in the future, there will be additional evidence-based research to validate the specific types of CAPD (ASHA, 2005). In the meantime, clinicians will continue to administer CAPD tests that are known to provide information regarding CANS dysfunction. As we work together to learn the “best of the best” in diagnosing CAPD, here are some thoughts we should be aware of and try to answer:

1. Can one test provide a diagnosis of CAPD? Although position statements indicate to be aware of the number of tests in a test battery, ASHA (2005) indicates that one test failure at 3 standard deviations below the mean or a failure of two tests by a minimum of 2 standard deviations below the mean is sufficient for a diagnosis of CAPD in the presence of functional behavioral limitations. The use of one test failure was considered

to be a lax approach, but most would agree that such a failure constitutes a dysfunction in only the specific auditory process being assessed. If the clinician controls for attention, motivation, and fatigue, then a failure of two tests at a minimum of 2 standard deviations below the mean or one test failure at 3 standard deviations below the mean would seem appropriate for the profession to consider as a criterion for the diagnosis of CAPD.

2. Please discuss what advantages you see in providing a test battery approach. Based on what you know about CAPD give some examples of how the test battery approach would be advantageous?
3. The various models for types or profiles of CAPD have many commonalities and a few differences. Actually, it is interesting that there are more similarities than differences. All of the models agree on decoding and integration subtypes of CAPD. The TFM type of CAPD is seen in the Buffalo Model, and FM is seen in the S-LP Model, whereas the prosodic category is only in the Bellis/Ferre and S-LP Models. Intervention is being used to successfully remediate the above CAPD subtypes. Tests have been found to identify auditory difficulties for designing intervention (AAA, 2010).
There is agreement with respect to the organization category among the different models. However, only one CAP test (the SSW test) provides norms for reversals. What does it mean when one reverses on other tests, especially if those tests were developed to identify those with learning disabilities, such as the Pitch Pattern Sequence Test? What does it mean when an individual passes all the CAP tests with the exception with reversals? Is there a CAPD in this case or are the reversals related to attention deficit or learning disorders?
4. Would the inclusion of electrophysiological tests assist with profiling specific types of CAPD?

Questionnaires listed in this chapter are available at Education Audiology Association (EAA): www.edaud.org.

Central Auditory Processing Disorder: Therapy and Management

Jack Katz, Jeanane Ferre, William Keith, and Angela Loucks Alexander

INTRODUCTION

In recent years, interest and involvement with central auditory processing disorders (CAPDs) has increased among audiologists, speech-language pathologists, and others. The auditory training (AT) aspect of CAPD has perhaps grown even more rapidly, as those who are drawn to rehabilitation have begun to see the benefits of this rewarding work. Providing a re/habilitative component makes the CAPD evaluation itself much more important, especially because the issues that are uncovered can be addressed and improved.

AT is based on the concept that improved central nervous system (CNS) function can increase our ability to focus on, and decode, what we want to hear. It can also increase the likelihood that the auditory information that is received will be remembered and organized accurately, as well as improve our ability to combine auditory input with other information. Improved central auditory processing (CAP) skills ultimately support higher cognitive functions (see Chapter 28). The most important auditory input we hear is speech, but because of its rapid and complex structure many people find it a major challenge in effectively communicating and in achieving academic success. Those of us who provide therapeutic services generally involve speech in some way, because of its face validity and its potential for directly improving important processing functions.

Neural plasticity enables the AT to positively change one's auditory performance. This is especially effective with repetitive stimulation, permitting our brains to facilitate processing (Skoe and Kraus, 2010).

We are not always able to choose when we can provide AT and working with older, not necessarily elderly, individuals may have some benefits. Those who know that they need the help are likely to be more determined/highly motivated compared to young children. So, age alone should not disqualify a person from getting rehabilitative services.

One of the major confounding issues for AT for those with CAPD is when the person continues to have middle ear fluctuations, which are important contributors to the faulty or vague information that the brain has stored (Bennett

et al., 2001). Ordinarily, AT has a long-term effect, but when a person continues to have middle ear issues we often see deterioration that tends to nullify the improvement.

An important aspect of working with those who have CAPD is to provide optimal hearing. This can be provided in a number of ways including hearing assistive technologies (HATs), speaking a little louder, and reducing the distance between speaker and listener.

The techniques discussed in this chapter have been used successfully for many years. They are rather simple and positively effect important communicative and/or academic functions. In addition to those improvements, we find that the individuals attend better and are much more confident when they understand what is going on around them. In a sample of 67 children who were seen (by the first author) for CAPD therapy 57% of the parents reported greatly improved self-confidence, 30% moderately improved, and just 1% with no improvement. Each of the authors has had great success and enormous satisfaction from doing this work and seeing the positive results.

BUFFALO MODEL THERAPIES

The Buffalo Model was formalized after many years of evaluating and providing therapy for those with CAPD (Katz and Smith, 1991). There are four major categories of CAPD (Katz, 1992), which are reviewed in Chapter 29. The two basic and most common categories are decoding, which is the ability to quickly and accurately analyze what is said, and tolerance-fading memory (TFM), which is primarily a difficulty in understanding speech-in-noise and with short-term auditory memory (STAM) tasks. In this section, two therapies will be described for each category.

Decoding is generally the most common CAPD category and so this therapy applies to almost all of the individuals we see. In addition, decoding is such a basic function that it is generally the first concern in therapy, along with TFM functions. Decoding is closely associated with the auditory cortex (Katz and Smith, 1991) which Luria (1970) refers to as the phonemic region of the brain. It is in the left upper,

mid-posterior region of the temporal lobe. We conceptualize these CAPD problems as vague or inaccurate encoding in the auditory cortex because of early otitis media or other etiologies. To improve on the inaccuracies and inefficiencies that are noted in understanding speech, learning to read fluently, and other functions, the therapy is directed to narrowing the phonemic boundaries (i.e., sharpening the perception) of the affected sounds.

We see that by improving the accuracy and speed of processing phonemes, it generalizes to understanding speech more broadly (Russo et al., 2005). This is likely because the therapy helps to replace the inaccuracies and inefficiencies in the way the brain perceives. Of course, what information the person has lost in the past or has misunderstood will not automatically improve and for the most part, the earlier the training, the better.

Phonemic Training Program

The Phonemic Training Program (PTP) is a basic program to improve auditory decoding. Observers are often surprised that such simple procedures can make such a significant difference in the ability, not only to process speech, but to result in improved reading word accuracy, auditory spelling, and even the clarity of the person's speech. Indeed PTP is so simple that the technique can be used from preschoolers to the elderly. Working with very young children or those with severe problems may require some modifications of the procedures. Further details of PTP and other Buffalo Model therapy procedures and forms are available elsewhere (Katz, 2009).

The purpose of PTP is to improve the speed and accuracy of processing speech. Although, the purpose is to improve speech understanding, in general, most of this work is carried out with individual speech sounds (phonemes). The procedure is given live voice at a fairly close distance. Figure 30.1 shows this close proximity to maximize the clarity of speech and the use of an embroidery hoop that is covered with acoustically transparent material (loudspeaker material) which prevents the listener from using visual cues. On the table you will see cards with letters signifying the speech sounds. Capital letters are used to simplify the visual association and diacritical marks identify long and short vowels. Some sounds that are easily confused with others have key words written at the bottom of the card.

The general plan for PTP is to start with an easy task and gradually increase the difficulty as the person improves in auditory processing of the sounds. We begin by introducing some of the most difficult sounds that have been observed for the individual. This may seem to contradict the first rule, but it does not. Initially, the difficult sounds are presented, but not contrasted with competing sounds or letters. For example, we often start with /d, ε, /, m / that are among the more difficult for those we see for CAPD evaluations. Although they may be difficult these four sounds are easily distinguishable

FIGURE 30.1 A typical setting for PTP with the therapist obscuring much of the lower face by holding an acoustically transparent screen (*hoop*) and presenting specific sounds to which the listener responds by pointing to the appropriate letter. For most of the procedures there are four or fewer cards, but in review there are eight in the General review.

from one another. We determine which of the sounds are most difficult by the use of a phonemic error analysis (PEA). PEA is based on the speech-sound errors on the three tests of the Buffalo Model which contains 926 phonemes.

PRINCIPLES

1. *Phonemes.* If phonemes are weak, vague, or inaccurately imprinted on the brain this forms a poor foundation for communication and academic success. When the foundation is improved the dependent functions also benefit. In PTP the emphasis is on improving phonemic perception.
2. *Repetition.* Starting in infancy the brain begins encoding phonemes, correctly or not, and after several years these models are strongly imprinted. Therefore, they cannot be improved simply with a cognitive approach. We cannot simply say, stop hearing the /ε/ as an /l/. Rather it should be retrained the way physical therapists reteach a person to walk. They start slowly and simply and gradually work up from there. Gradual increases are built into PTP along with repetition, but it need not be boring.
3. *Over time.* As in the case of repetition, do not expect a great deal of improvement with just one or two presentations. Just like proficiency in playing golf or tennis, improved speech-sound perception requires practice over time. PTP is surprisingly quick but still requires sufficient time to master it.
4. *Easy.* Start at an easy level and work up gradually. It is generally important for those who have less confidence in what they hear or have had academic failures to start with success and then go forward.

5. *Four sounds.* Introduce four new sounds each visit. For most children and adults, this has been quite effective. Accommodations should be made for age and severity.
6. *Consider severity.* Based on the severity of the problem (e.g., on the PEA) begin with the more difficult items first. We begin with the difficult sounds while the brain is not crowded with other sounds and because we have more opportunities to repeat them in subsequent sessions.
7. *Visual confusions.* Be mindful of visual challenges as well as auditory (e.g., a long-A and a short-A differ only by a little marking above them).
8. *Auditory confusions.* When a person has confusion in distinguishing between two sounds (e.g., f/θ or ɪ/ε), branch from the program and use a “focus” or “itch” technique as described below.
9. *Teach accurate sounds.* This is to replace vague or poorly encoded sounds with as clear and accurate sounds as possible. Therefore, when the therapist says the consonants they should not have an added vowel (e.g., /b/ and not /bə/).

PTP STEPS

With these principles in mind there are three major steps to PTP. The order of these steps differs for the first three visits.

1. *New.* For the first session there were no previous sounds so the first step is to introduce four sounds (e.g., /d, ε, l, m/). The person is told that they will hear a sound a few times and just to listen carefully to how it sounds but not to repeat it.
 - a. *Introduction without bias.* With lower face concealed say the first sound clearly, usually three times, as this will increase the person’s ability to identify it. Then without the hoop show the card with that symbol and say, “That was the /d/ or the D-sound as we hear in ‘dog.’”
 - b. *Repetition with pointing response.* Then place the card in front of the person and indicate that each time you say /d/ you want them just to (quickly) touch the card. Behind the hoop say the sound once with a response and then again. There should be no error as there is only one card to point to. Then introduce a “foil.” A foil is used occasionally to maintain attention. The therapist says, “That was good, but what if I said /s/? There is no card for /s/ so you point over here (off to one side) to let me know that I did not fool you.” Then practice pointing to the /d/ again and next give an easily distinguished sound for a foil. Use foils sparingly from time to time especially when attention is lagging or the person is ready to point to a card before the sound is said.
 - c. *Introduce a new sound and discriminate.* Remove the D-card from direct view and give the next sound in the same way without bias. But after doing the reinforcement with just the second sound, bring back the previous sound in front of the person. This discrimination task just slightly increases the challenge but is mainly to hear it again and associate the letter and point. After one presentation of the two sounds remove them and introduce the third sound. Then give the discrimination task with the three sounds, remove them and introduce the fourth sound, and finally discriminate all four sounds.
2. *Brief review.* On the next session give a brief review of the sounds from the previous session in the same way and in the same order but perhaps a little faster.
 - a. This helps to remind or reinforce the sounds from the previous lesson before any New sounds are given. The procedure is not meant to be difficult, rather to gradually teach the person what the sounds sound like individually and to associate them with their letters.
 - b. Then give the same procedures as in (a), (b), and (c) above with the New group of four sounds.
3. *General review.* A third procedure is added to the previous two on the third visit. After the Brief review of the sounds from the second lesson the General review increases the challenge and lets us know if there are sounds which confuse the person. The General review, unlike the two previous steps, presents the sounds in random order from all of the ones that have gone through the New and Brief review steps in the previous sessions. Over time most of the sounds will be contrasted with one another.
 - a. *Open discrimination 1.* From the deck of randomly ordered cards for the General review sounds for that session take the first four cards from the deck for the person to discriminate. To include the person in the process hand all four to the person to place them face up to discriminate. Without visual cues the therapist says each sound and the person points to the card. Usually the prior training enables the person to give the proper responses, but note confusions for possible repair training. If there is an error repeat the sound, but if it is still difficult indicate the card and move on. We do not want to reinforce confusions.
 - b. *Open discrimination 2.* Remove the first four cards and give the person the next four. But after this discrimination leave those cards and bring back the previous four (that were temporarily removed) and have these cards in the second row (N, AW, L, R as shown in Figure 30.1). The discrimination with eight cards is called *The Big Test*. This increases the variety and challenge of discriminations that must be made. If there are more cards go on to Open discrimination 3.
 - c. *Open discrimination 3.* Retire the cards from Open discrimination 1 and temporarily remove the second group. Give the next four cards to the person and after discriminating them bring back the group 2 cards and give *The Big Test*.
 - d. If there are more cards continue as before (i.e., remove Open discrimination 2 cards and temporarily remove group 3 and start with group 4).

- e. *Reduce the cards.* When there are as many as 20 cards or so in the General review deck, it is well to maintain that number by eliminating the easier sounds.

BRANCHING STRATEGIES

When we hit a significant bump in the road or a brick wall it is best to provide some special help for about two to five visits.

Focus

If a person confuses /ɪ/ε/ we can increase the distinction in a rather simple way. We assume in this case that the /ɪ/ is the easier of the two. It usually is but if unsure ask the individual which is easier to hear. Generally, they are correct. When they have two sounds that are weak, there is no “anchor” so we first improve the easier one and then we can improve the weaker one.

- Build up the strong sound.* The two cards are placed in front of the person and they are told they will hear the /ɪ/ sound three times and then the /ε/. Knowing which sounds beforehand will help to ensure that they respond correctly. This is important because they are often confused so they get off to a good start.
- Once the sounds have been introduced in this way the next step is to practice. Now, they are told the procedure will be the same. The /ɪ/ will always be first but the number of times it is said will vary and then the other sound will be said. This task is meant to be easy, especially if we start with the easier sound.
- For this second step, say the /ɪ/ one to four times and then the /ε/. The purpose is not to trick them as they are already confused.
- When the responses are accurate and quick, this step is completed and in the next session reverse the procedure.
- Indicate that the /ε/ will be given three times and then the /ɪ/. Then, as before, explain that the /ε/ will be said three times and then the /ɪ/ once. After that introduction indicate that the /ε/ always will be given first but you will not tell the person how many times before the /ɪ/.
- The procedure, starting with the more difficult sound, may well have to be repeated on the next visit and perhaps more.

Itch Cards

Itch cards are key-word cards. When a person begins therapy, there is not much to be done with only four new sounds. Because these are difficult sounds for the individual it is a good opportunity to reinforce the correct sounds.

- After the PTP procedure, the same four sounds can be given. Behind the hoop the therapist indicates that some sounds will be said and then they will be told to touch/point to the card and say the “Itch Word.” The name Itch Word comes from the first card that was developed for

this procedure. Itch cards show a key word with the critical letter(s) underlined and/or in a different color.

- After saying /d/, now without the hoop, say that, “the Itch Word for /d/ is Dessert” and show the card. When the person hears the sound they should point to the card and say the word “Dessert.” Place the card in front of the person and practice once or twice.
- Then remove the card and introduce the next one in the same way. After practicing one or two times bring back the first card to discriminate among the two sounds and the person pointing and saying the word for each (one time is enough).
- Finish up with the last two sounds in the same way.
- If there is a second group of cards to be reinforced do them separately in the same way.

The other decoding procedure in the Buffalo therapies is Phonemic Synthesis (PS). Generally, we do not do these tasks back to back. Rather one of the other procedures (e.g., words-in-noise training (WINT)) would be given to work on a different aspect.

Phonemic Synthesis

PS was the first of the therapy procedures in Buffalo Model. It is a sound-blending type task in which the listener hears individual speech sounds and must put them together to form the given word. This procedure both reinforces the PTP program and takes the training to a higher level. It requires not only accurate decoding of the sounds, but also memory for the sounds, maintenance of proper sequence, and relating the results to words.

Luria (1970) indicated that the auditory cortex is the center for phonemic processing. He found in his study of soldiers with gunshot wounds that the only place in the brain that was associated with phonemes was the auditory cortex (also see Chapter 28). The specific skills that he enumerated were phonemic discrimination, phonemic memory, and phonemic synthesis or analysis. Several highly respected professionals in various fields have noted the beneficial effects of sound blending-type training for reading and articulation problems. These include such luminaries as Van Riper, Orton, and others (see Katz and Harmon, 1981). Additional references for this chapter can be found on <http://Katze7...>

BENEFITS AND DISADVANTAGES OF RECORDED PHONEMIC SYNTHESIS PROGRAM

In general, the recorded program has many more positive characteristics. It is recorded so it can be delivered in the exact same way and repeated without concern that there are variations in how the sounds were spoken. Speech sounds are produced correctly by an experienced speaker. The program was carefully designed to take a person with almost

no skill to a very high level of performance by gradually increasing the level of difficulty of sounds, as well as, combinations of sounds, and words. Difficult words are often given with clues or explanations and then repeated later in the program to be sure they are processed properly and reinforced. The program is sprinkled with humor to get an occasional chuckle. This recording has been in continuous use by many professionals since 1982.

There are two disadvantages to the recorded program. The first is that it cannot be varied for the individual and the second is that the therapist's speech might be richer than the recording and inflected emphasis cannot be given to call attention to some aspect. Fortunately, using the recording does not prevent the therapist from replaying an item, skipping items, or giving parts of the program live voice when needed as well as giving cautions or instructions to focus or alert the person. In some severe cases, the program can start live voice and then the recorded program can be administered when the person is better trained.

DESCRIPTION OF PHONEMIC SYNTHESIS PROGRAM AND BASIC APPROACH

The recorded PS program* has 15 lessons that start with two very easy picture choices (i.e., distinguishing the given word "she (/ʃ...i/)") from the word "pencil" which is the foil). It is given again and then four other items are presented in the same way. All five items are also repeated later on to be sure the person knows these easy sounds and words as this program builds on itself. The next lesson has the same five words with three picture choices. The third lesson begins with the same three picture choices and then the person says the words without picture support. However, after hearing the sounds of these words so many times it is easy for almost all children (or adults even with severe/profound challenges) to make the transition to generating their own answers.

For most people with CAPD, it is not necessary to begin with lesson one. We determine this based on their PS test performance. Most people start with lesson four or five. However, the program assumes that the listener knows the previous words. Those who skip earlier lessons are given some brief training on the words that were skipped before starting the recorded program.

The words are gradually expanded (e.g., "cow" from the original five words to "couch") or changed and harder sounds (e.g., more short vowels and liquids /l, r, j, w/) are more likely to be used. Toward the end of the program, phonemic analysis is introduced. In this procedure the person is given a word and they are asked to break them up into their component sounds.

The score for each lesson is recorded on a summary sheet on which there are two sets of marks for each lesson. Toward the top of the chart are two heavy lines indicating the completion level. If a person reaches the completion level, that lesson can be considered finished. Further down the column there is a dashed line that shows the lower limit of the target zone. The person is expected to score above that level if they have been doing fairly well on the previous lessons. If the score is below the target zone there will only be frustration and lack of learning if they go on to the next lesson. So either further training is needed on that lesson (with special help, see later) or if very poor or frustrating the person needs to go back to an easier level and work their way back gradually.

On the answer sheet we currently mark PS items with an X-circled to show that there was a delay. As the individuals improve they reduce their delays and also get more items correct. Therefore, we consider both speed and accuracy when assessing improvement. This has been extremely helpful. If an item is in error, we do not show the delay.

BRANCHING STRATEGIES

General

It is permissible to repeat an item in this program, especially after the first administration of a lesson. The second time the task is generally easier. To improve the chances of getting the correct answer when an item is repeated the person may be alerted, "Listen carefully to the first sound/the vowel, etc." If it is less likely that the person will process the word correctly they could be told what the word is (e.g., jump) and say, "Listen carefully and see if you can hear 'jump, jump.'" If the person hears the recorded version soon after the word was said live voice the chances for an accurate response are increased. On the score sheet it is helpful to show the initial error and a slash to show that it was given again and a dot if it was correct the second time (but count only the first response).

Word Chart

When a person makes errors on a lesson, it is extremely helpful to address this on the following visit when their brains are clear of this confusion. We fold a piece of paper in half top down twice and then left to right. This gives us eight boxes to show four pairs (the actual word and the error given). Figure 30.2 shows an example of a word chart in which the test and error words cannot be determined from the position. The paper is folded (with the aid of a paper clip) to show one pair at a time. To be sure that the person does not stop listening after pointing to the first word, that word can be repeated a second time for a large percentage of the presentations. Then we have the Big Test in which all of them (as many as four pairs) are give at once. The person is to point to the word that was presented randomly, one sound at a time behind the hoop.

FIGURE 30.2 In the Phonemic Synthesis program, a word chart is used in the session following the errors on the PS lesson. The correct and error words are shown side by side in an order so the person does not know which one is the word on the program. The *dashed lines* show where the paper was folded so that each pair can be given one word at a time, sound by sound and then the Big Test with all eight words showing.

RESULTS OF DECODING THERAPY

In the Buffalo Model, we assess the results in three ways: How the person performed on the therapy materials themselves, how the person performed on the retest compared to the pretest, and how the person is performing on the initial concerns that brought the person for assessment originally.

Figure 30.3 shows the test–retest results for the PS test for 95 children 6 to 18 years of age who completed the first round of therapy. The average number of sessions was 13 and the total time spent on decoding skills per child was less than 6 hours. The good results that were obtained over this short period of time were supported by the assessment of parents and teachers following the first round of therapy. Figure 30.4 shows the parent–teacher assessments ($N = 88$) for that therapy period. The decoding therapies appear to have generalized by having a major effect on these skills that are associated with decoding.

Words-in-Noise Training

This is the first of the two TFM procedures that will be discussed here. A large percentage of those with CAPD have difficulty understanding speech in noise. Having better

FIGURE 30.3 Phonemic Synthesis quantitative and qualitative error scores before and after the first round of therapy ($N = 95$). Normal limits for each measure are shown by *dashed lines* for the group’s mean age [9 years].

decoding skills makes the task in noise much easier and therefore both types of therapy are often given at the same time. However, WINT is designed to address the ability to focus in on speech and to pull out the speech from the background of noise. This particular skill seems rather fragile because it is susceptible to factors such as poor sleep the night before, anxiety from a bad day at school, and inattention. This therapy is also called “desensitization training.” The anxiety and tension that are often seen in those with significant reactions to noise also appear to be addressed to some extent with this therapy.

OVERVIEW OF WINT

This program begins with single syllable words that are presented, one at a time, at a comfortably loud presentation level with no noise and the listener is asked to repeat the words. Then the task is repeated with the next group of words along with a mild noise. Then the level of the noise is increased gradually until a signal-to-noise ratio (SNR) of zero is reached (i.e., equal to the speech level).

FIGURE 30.4 Parent–teacher assessments of improvement on decoding-associated skills after one round of therapy ($N = 88$). The highest percent of moderate or great improvement was noted for phonics [91%] and the fewest was speech [76%]. The others were understanding language, understanding directions, and oral reading.

DESCRIPTION OF WINT

There are two versions of WINT[†]. The WINT-3 recording is used with a CD player and a two-channel audiometer. WINT-1 is preprogrammed so that it can be administered without an audiometer. The basic procedure for both programs is essentially the same. We will discuss the WINT-3 first. Both programs can be presented through one or more loudspeakers or through earphones. It is best when both options are available.

One track of this program is made up of 600 primary level words that are divided into 60 subgroups of 10 words each. The other track is multitalker, eight-speaker babble. A series is approximately eight subgroups that are presented in one session. Each track of the CD has eight subgroups except the last track that has four. Figure 30.5 is the scoring form for track 1. As in the other Buffalo Model procedures, a dot represents a correct answer and an incorrect response is written out for most words. If a word might be ambiguous it is spelled phonetically or phonemically.

The WINT-3 Procedure

Most individuals who have CAPD have a positive score on the Speech-in-Noise test of the Central Test Battery-CD and speech-in-noise concerns on the Buffalo Model Questionnaire that the family filled out. One can choose to start therapy with any track and move along from one track to the next and after eight tracks back to the first track again as the dates show in Figure 30.5. The person is told that they will be hearing a man say some words and just to repeat them as clearly as possible. Some people will mumble and try to hide their errors. Have them repeat the word, spell it, or tell you what it means. Sometimes, the parents, if present, can clarify the response. Also, have the person face you and turn up the talkback microphone.

The first 10 items are given with no noise and speech presented at a comfortable level. The same speech level is used for subsequent visits, if possible. Enter both errors and delays on the score sheet so that the person's performance can be assessed, reviewed, and analyzed, if desired. Next the person is told that there will be some noise in the background and not to pay attention to it and just repeat the words. For the next subgroup we start with a SNR of about +12 dB. Then on each subsequent sublist, increase the noise by 2 dB until the SNR is zero. After the first few sessions the +12 noise level may be quite easy. This level can be omitted on future visits to save time, if desired.

Those who have the poorest scores initially tend to make the most gains in therapy. Generally, an average of four to six total errors for last one or two series suggests good performance. At a later time this can be rechecked to be sure that the performance remains good. This is espe-

cially important to check if the person has middle ear problems or persistent allergies.

Additional Procedures

- Usually the first two or three series are given with little or no correction to establish baseline performance. After that corrective procedures can be used. Give preference to errors at low noise levels because they are usually the easiest to correct. Do not correct for too many errors as this can discourage the person, which will not help speech-in-noise training.
- After an error, stop the CD and simply repeat the item. If a hint will make it more likely to get the repeated item correct, the person can be instructed to listen to the first/last sound or the vowel, and so on.
- Instead of (b), if more assistance is likely to be needed, the person can be told the word and replay the item. It is good to say the word live voice once to three times just before the recorded word is heard. This will increase the person's chances of perceiving the word correctly.
- When an error is persistent, or the individuals are sure that they are correct, turn off the noise channel so the word can be heard without interference.
- Do not "beat a dead horse." If the person continues to hear the word incorrectly indicate that it will be worked on in the future and go on.

WINT Results

Figure 30.6 shows the average performance on the WINT-3 series in the first round of therapy. The average improvement is from about 18 errors initially to 6 at the end of the first round. On average, there is a rather steep decline in errors for the first five series after which the improvement is much more gradual. Most of the initial improvement is likely the "limbic effect," that is, the person getting used to the task and feeling more at ease with listening in noise. The gradual gains are likely because of the increasing ability to separate the words from the noise and to understand the words better.

Figure 30.7 shows the parent-teacher assessment of improvement. They indicated primarily great or moderate improvement for the 74 children for each of the three questions related to noise issues. For Understanding in Noise, 93% indicated great or moderate improvement. For Distracted by Noise and Hypersensitive to Noise, the ratings were 88% and 77%, respectively.

The WINT-1 Procedure

WINT-1 can be used without an audiometer as it is preprogrammed. The first seven series/tracks of WINT-1 have no noise to +12 dB SNR and then in 2-dB steps up to 0 dB SNR. The scoring is the same as for WINT-3 and all of the Additional Procedures above, except turning off the noise, can be used.

The eighth series/track of WINT-1 is available for those with severe problems or those who need to be introduced to the noise more gradually. After the no noise sublist, the noise

FIGURE 30.5 Score sheet for WINT-3 demonstrating the features and scoring. After the person goes through the 60 sublists they begin again where they started using a second column. If therapy continues in a second round then it might require the use of the third column. *Dots* represent correct responses and *words* show the errors. ⊗ indicates a delayed response on a word that was correct.

training starts with an SNR of +22 dB that should be suitable for most people. The sublists go up to +14 dB SNR. This may require a few series before the person is quite successful with the low levels of noise. When the person shows good performance for track 8, the program can continue with tracks 1 to 7.

Short-Term Auditory Memory Program

Short-Term Auditory Memory Program (STAMP) is the second TFM training program. STAM is a critical aspect of

FIGURE 30.6 Mean number of errors across 15 WINT-3 series. The first five means show a sharply descending pattern. This is primarily associated with the “limbic effect,” a reduction of anxiety and accommodating to background noise. The 10 more gradual reductions are primarily associated with increased success in understanding speech in noise.

CAPD. We often want or need to remember many things of value that we hear. A large percentage of those with CAPD have STAM issues and therefore are not able to remember nearly as much as most people. Importantly, STAM like the other aspects of CAPD responds well to AT.

OVERVIEW OF STAMP

The purpose of STAMP is to increase short-term memory. In the Buffalo Model procedures we emphasize memory for digits, words, and working memory. Our purpose is to

FIGURE 30.7 Ratings of parent-teacher regarding improvement in noise issues: Moderate or great improvement was noted in Understanding in noise [93%], Distracted by noise [88%], and Hypersensitive to noise [77%].

increase memory span by one unit and if that is successful we might try to stretch memory further. Generally, digits are the easiest and working memory the hardest. Working memory is remembering something and at the same time working with it in some way. Various tasks can be used for working memory training.

STAMP PROCEDURES

Based on pretest scores we start with a level that the person can handle well (e.g., perhaps on a pretest 90% to 100% for three digits) and plan to expand their memory span by one unit (e.g., for four digits from 30% to perhaps 90% to 100%).

Figure 30.8 shows a sample of a memory response sheet for words. That plan is for working with someone who is quite good with remembering four digits, to both strengthen that level and to increase performance for the next level (in this case five digits). There are four increasing levels of difficulty from sections A to D, that is, the items tend to be more challenging. In addition, the number of easier level items is reduced from four to one so that there is more and more training at the higher level as the person gets stronger and stronger.

The following table shows the percent correct scores for “Sam” initially:

Percent Correct for Task and Units

Units	Digits	Words	Working Memory
3	100	90	80
4	90	80	50
5	10	0	0

We might start memory training working with Sam on digits because that is the easiest type, and work from four to five units. If this is successful, it will facilitate training for words from four to five units and this in turn can increase the likelihood of success for working memory but from three to four units. Figure 30.8 shows typical results for a person using the STAMP procedure.

Branching Strategies

- Generally, it is a good idea to administer a sublist without correction the first time to establish a baseline and to see the issues.
- When a person makes a small error it may be corrected by a simple repetition. To make the error more obvious one might emphasize the unit that was in error if this is thought to be necessary. Show the improvement on the response form but count only the first try.
- For greater challenges it is well to tell the person the error and then repeat the item.
- If this is still difficult or there are several errors at a particular level, one can use a “modified” procedure that will

FIGURE 30.8 A section of the Word Memory Training form for four and five words show the scoring procedures. A dot [•] is correct, a dash [–] is an omission, a substitution is written in after the printed word, and the incorrect sequence is designated by numbers next to words. An R that is circled designates a reversal. When the person is given a second try at an item a slash [/] is shown and then the second score [if any] is shown. Only the first administration is considered in the scoring to the right. Because of the errors initially in sublist B it was administered again showing some improvement.

simplify the task to enable the person to achieve an accurate response. Then the regular items can be given again. Some considerations in modifying the items are given below.

- e. For digits, numbers 1 to 5 are generally easier than 0 or 6 to 10; giving two in order (e.g., 4, 5) is generally easier than 3, 5 or 5, 4.
- f. For words, shorter, more common nouns are easier than other words.
- g. For working memory, consider (a) and (b) above. Also teach the tasks individually (e.g., putting digits in order from small to large and then add a word to the task)
- h. For each of the procedures when a person performs well with perhaps three memory units, but four units are very hard, modify the four units by first giving the first three units and when successful then indicate that you will just add one unit at the end.

Results

STAMP is the most recent addition to the Buffalo Battery therapies. We have seen positive results in therapy with both children and adults. We have received very good feedback from others who are using these procedures which supports our findings (see Katz, 2009). For example, one adult with a degenerative neurologic disorder after working with digit memory began word memory going from three to four

units. He quickly improved from 88% to 100% for three words and from 78% to 97% for four words. He is now at 100% for four words and at 62% for five words. Instead of degenerating, he continued to improve (Figure 30.9).

FIGURE 30.9 Memory training means and standard deviations are shown for four-digit items for 21 to 12 children for sublists 4A to 4D with a median of 17 children. Data for three digits are not shown as the target was four digits. If the therapy had not begun with 4A and ended with 4D we might have expected the initial scores to have been poorer initially for the later sublists.

SUMMARY OF BUFFALO MODEL THERAPY PROCEDURES

The Buffalo Model therapies have been highly successful when the specific categories have been identified. It is also a rather brief therapy averaging 13 (50-minute) sessions for the first round of therapy. Most children with mild and moderate CAPD complete the program in one round. Therapeutic benefits are determined by improvements on the therapy materials themselves, test–retest comparisons, and independent assessments by parents and or teachers regarding the observed changes.

M3 THERAPIES

The M3 model for remediation of auditory processing deficits is an integrated approach to treatment that uses a combination of bottom-up and top-down activities to improve specific auditory skills and to empower listeners to manage any residual adverse effects of the deficit on their lives (Ferre, 1997, 1998). The program conceptualizes communication as the interaction of three factors—the *message*, what we listen to, the *medium*, the environment in which we listen, and *me*, what the listener brings to the communication event. Negative changes in any of these three will adversely affect communication, for example, an acoustically or linguistically unclear signal, an excessively noisy or reverberant environment, or poor listening habits or impaired auditory processing skills of the listener. Conversely, positive changes will enhance communication. Applicable to all types of auditory processing deficits, the M3 model teaches the client (i.e., top-down activities) to effect positive change in themselves, the listening environment, and/or the message to maximize communication and *trains* the system (i.e., bottom-up activities) to work in a more efficient, age-appropriate manner.

MESSAGE refers to “what we hear,” including speech sounds, words, phrases, sentences, patterns, and conversations. Therapy activities include minimal pairs auditory discrimination training, temporal pattern recognition, dichotic listening exercises, rhyming, sound-blending exercises, auditory closure exercises, and identification of key elements in targets. Intertwined with these activities is a discussion of familiarity, redundancy, and using contextual, syntactic, semantic, and nonauditory cues to assist recognition and listening comprehension.

MEDIUM refers to the environment in which we listen with sessions focusing on impact of noise, reverberation, distance, and lighting on speech recognition. Therapy activities include listening in noise and using visual cues.

ME refers to the unique combination of strengths and weaknesses that a listener brings to any communication event. Discussion focuses on using visual cues and active listening strategies, advocating for oneself, and training those auditory (and related) skills that may be deficient. Parents

and caregivers are integral to the model, extending benefits of therapy beyond an individual session by regularly engaging the student at home in these same activities or analogous commercially available games.

For many students, computer-assisted auditory and/or multimodality training is included as an adjunct to the traditional therapeutic program. Detailed discussions of the specific activities noted above can be found elsewhere in this book and in other sources (Baran, 2013; McAleer-Hamaguchi, 2013). This section will describe the application of the model for specific auditory processing deficits, particularly as it relates to the student’s need to meet the educational Common Core Standard for speaking and listening (CCSSI, 2012). Goals and representative examples of therapy benchmarks are provided for each type.

The student with auditory decoding deficit (Bellis and Ferre, 1999) exhibits poor discrimination of fine acoustic differences in speech with behavioral characteristics similar to those observed among children with peripheral hearing loss. The deficit can create secondary difficulties in communication (e.g., vocabulary, syntax, semantics, and/or second language acquisition) and/or academic (e.g., reading decoding, spelling, note-taking, and/or direction following) skills. The individualized education plan (IEP) for this student should include goals for improved auditory discrimination and closure, use of visual cues, noise tolerance, sound blending, auditory vigilance, and use of metalinguistic/metacognitive and active listening strategies. Metalinguistic strategies refer to the listener’s ability to apply higher order linguistic rules when confronted with adverse listening situations. These include auditory closure (i.e., using context to fill-in missing pieces), schema induction (i.e., using expectations and experience to fill-in the message), use of discourse cohesion devices (e.g., learning to “key-in” to tag words and conjunctions), and prosody training (i.e., learning to use the rhythmic and melodic features of the signal to “get the message”). Metacognitive strategies refer to the listener’s ability to think about and plan ways to enhance spoken language comprehension. These include attribution training (i.e., self-identification of the sources of listening difficulties), use of metamemory techniques (e.g., chunking, mnemonics), and self-advocacy (i.e., learning to modify one’s own listening environment). Taken together, metalinguistic and metacognitive strategies enable the listener to be an active, rather than passive, participant in a communication event. The listener learns to use all available cues as well as their own knowledge and experience, altering behavior as needed, to enhance communication and improve processing. For a detailed discussion of metacognitive and metalinguistic therapies, the reader is referred to Chermak (1998) and/or Bellis (2003).

Auditory discrimination and closure. Student will recognize speech presented under a variety of listening conditions.

Benchmark examples. Student will discriminate minimally contrasted phoneme pairs presented auditorily only

(i.e., no lipreading/speechreading cues) in a background of multispeaker babble that is of equal loudness (i.e., at a 0 SNR) and emanates from the same location as the target signal with 90% accuracy. Activity examples: Student is given two choices, for example, *shuh* – *chuh* printed on individual cards. Therapist says one word at a time that either begins or ends with the phonemes and student determines which phoneme was spoken at the beginning of the word or at the end (e.g., *ditCH* – student points to *ch* card, *SHoe* – student point to *sh* card). Student will recognize words presented with visual cues in a background of multispeaker babble that is much louder than the target with 90% accuracy.

Use of visual cues. Student will use visual cues to improve speech recognition.

Benchmark examples. Student will discriminate same-difference for target presented visually only with 90% accuracy. For example, therapist “mouths” two words and student determines if the two words “look” the same or look different (e.g., *fail-rail—different*, *fail-fail—same*). Student will identify target compound word presented visually only (i.e., no auditory input) from among a closed set of no more than 30 printed words or picture choices with 90% accuracy. That is, therapist mouths a compound word and student identifies word from among a printed word list.

Noise tolerance. Student will recognize speech under adverse listening conditions.

Benchmark examples. Student will recognize everyday sentences presented *without* visual cues in a background of equal loudness noise with 85% accuracy. Student will recognize everyday sentences presented *with* visual cues in a background of noise that is much louder than the target with 75% accuracy.

Sound blending/synthesis. Student will recognize and manipulate multiple auditory targets.

Benchmark examples. Given a word and using a “phoneme list,” student will create as many rhymes as possible within 2 minutes. Student will smoothly blend three nonsense syllables (e.g., *puh-tuh-kuh*, *spruh-struh-skruh*) using equal stress on each phoneme (or varying stress across phonemes, e.g., *SPRUH-struh-skruh*).

Auditory vigilance. Student will recognize change in a string of auditory targets.

Benchmark examples. Given a string of random words (or phonemes), student will indicate through hand signal each occurrence of predetermined “target” word (e.g., target word is *TREE*—string is *house*, *car*, *boat*, *TREE*, *dog*, *mom*, *TREE*). Student will indicate through hand signal “rare” or different target from within a string of common targets (e.g., *buh-buh-dee-buh-buh-buh-buh-dee*). That is, student indicates when there is a change in stimulus.

Use of metalinguistic strategies (listening comprehension). Student will recognize and use key elements in spoken targets.

Benchmark examples. When given a sentence, student will state what information is conveyed by key (i.e., stressed)

word with 90% accuracy (e.g., My sister baked two dozen chocolate chip cookies on TUESDAY. Key word: Tuesday. Information conveyed: When).

When given a sentence, student will state what information is conveyed by two (or more) key (i.e., stressed) words with 90% accuracy (e.g., MY sister baked TWO DOZEN chocolate chip cookies on Tuesday. Key words: My, two dozen. Information conveyed: Who, how many).

When given a short passage, student will answer fact-based questions posed by speaker with 80% accuracy (e.g., *who*, *what*, *amount*, *date*, *place names*).

Use of metacognitive strategies (active listening). Student will demonstrate understanding of active listening strategies.

Benchmark examples. Student will state two “self-help” strategies for use in highly noisy or reverberant environments. Student will state two “self-help” strategies for use when signal message is acoustically or linguistically unclear.

Therapy activities given above can be supplemented through the use of simple low-cost or no-cost games such as the “telephone game,” *A Rhyme in Time*, and the “ending sound game,” in which each player says a word beginning with the last sound of the previous word (e.g., caT-ToP-PiG-GuM-MuD-DoG). Regular use of these games extends the training beyond the individual session to maximize benefit.

The student with integration deficit, likely because of inefficient interhemispheric communication, struggles to perform tasks that require intersensory and/or multisensory communication. The child does not synthesize information well, may complain that there is “too much” information, and, without adult assistance, has difficulty determining task demands, starting complex tasks, transitioning from task to task, or completing tasks in a timely fashion. Impact on communication is variable with, typically, observation of academic effects in reading, spelling, writing, and other integrative tasks. In therapy, this student needs activities designed to improve interhemispheric integration, including dichotic listening, intersensory integration (e.g., use of visual cues), sound blending, listening comprehension and working memory/rapid recall, vigilance, and active listening (i.e., using metalinguistic and metacognitive strategies). Dichotic listening underlies our ability to listen actively in a classroom and is a necessary first step in a protocol to improve auditory processing and classroom listening abilities.

Dichotic listening. Student will recognize dichotically presented targets.

Benchmark examples. Student will repeat two digits presented simultaneously, one to each ear, with 90% accuracy for each ear. Example: Right ear—6, left ear—8, student repeats (6,8). Student will repeat four words presented simultaneously, two to each ear, with 80% accuracy for each ear. Example: Right ear—*house*, *car*; left ear—*goat*, *dig* where *house* and *goat* overlap and *car* and *dig* overlap. Students repeat all four words.

When given two sentences, presented simultaneously, one to each ear, student will repeat sentence directed to right ear only (or to left ear only) with 90% accuracy (binaural separation).

Interhemispheric integration. Student will increase communication between the two hemispheres.

Benchmark examples. Given an array of common objects, student will name object without looking at it with 90% accuracy. Given an array of common objects, student will “find” a named object without looking at it with 90% accuracy.

Listening comprehension. Student will recognize and use key elements within a spoken target.

Benchmark examples. When given a sentence, student will identify stressed word in the sentence with 90% accuracy. When given a sentence, student will identify two stressed words with 90% accuracy. Student will follow two-part, three-element verbal directions (e.g., *point to the large white square and the small blue triangle*), presented without visual cues in a background of equal loudness multispeaker babble with 90% accuracy.

Working memory/recall. Student will synthesize and manipulate auditory and auditory–visual information.

Benchmark examples. Given a “deck” of 50 word cards, student will generate single rhyming word for printed target within 2 minutes with 90% accuracy. Given a list of 50 words, student will generate two rhymes for each word within 3 minutes with 90% accuracy.

Active listening. Student will demonstrate ability to use active listening strategies. Active listening requires taking responsibility for one’s listening success or failure by understanding the impact of the auditory impairment in one’s life, recognizing those aspects of the communication experience that are under the listener’s control, displaying effortful listening behaviors, and taking overt steps to avoid or correct potential communication mishaps.

Benchmark examples. Student will state two difficult listening situations that he/she has encountered. For a self-reported difficult listening situation, student will state (and practice) one strategy to minimize the listening difficulty.

Outside of the “therapy room,” integration and related functions can be enhanced through regular use of commercially available games/toys such as Twister, Bop-It, Simon, and interactive video games (e.g., Wii system games).

Prosodic deficit is characterized by deficiency in using prosodic features of a target, a predominantly right hemisphere function. This student exhibits difficulty in auditory pattern recognition, important for perceiving running speech and following directions. Student may have difficulty recognizing and using other sensory patterns (e.g., visual, tactile). Adverse effects are observed in pragmatic language (e.g., reading facial expressions, body language, and gestures or recognizing or using sarcasm or heteronyms), rhythm perception, music, and nonverbal learning. Therapy goals focus on improving right-hemisphere–based auditory pat-

tern recognition, recognition and interpretation of rhythm and stress cues in words and sentences (e.g., using prosodic cues), use of visual cues to assist recognition, and application of metacognitive and metalinguistic strategies, and self-advocacy.

Temporal pattern discrimination and recognition. Student will discriminate and recognize auditory patterns presented in quiet or noise.

Benchmark examples: Discrimination. Student will determine same-difference for two-, three-, or four-tone sequences composed of soft and loud (e.g., loud-soft), high and low (e.g., high-low-high), short and long (e.g., short-short-long-short) tones with 90% accuracy.

Identification. Student will identify three-tone sequence presented in quiet in a four-alternative forced choice (4AFC) format using printed choices with 90% accuracy for loudness, pitch, or duration sequences.

Imitation/recognition of tonal patterns. Student will imitate two-, three-, or four-tone patterns, presented with equal stress in quiet with 95% accuracy.

Imitation/verbal labeling of tonal patterns. Student will attach verbal label to two-, three-, or four-tone sequences presented in quiet, varying in pitch, loudness, or duration with 90% accuracy.

Use of prosody. Student will discriminate, recognize, and interpret stress in speech.

Benchmark examples. (a) Same-different discrimination—student will determine same-difference for two- or three-phoneme combinations presented in quiet with 95% accuracy. Example: Therapist says *muh-muh-muh* and *muh-luh-muh*, student states whether targets are same or different. (b) 3AFC identification—student will identify three-phoneme sequence from among a closed set of three choices, when presented in quiet, with 90% accuracy. (c) Open set recognition of stress—student will imitate (exactly) three-phoneme sequences presented in quiet with 85% accuracy. (d) Student will judge intent of statements presented in quiet with 85% accuracy, including sincerity/insincerity and emotion conveyed (e.g., anger, happiness, fear, sadness).

Use of visual cues. Student will use visual cues to assist message comprehension.

Benchmark example. Given picture choices, student will match “emotion” word/phrase, for example, *They are frightened*, with corresponding picture with 90% accuracy. Given printed sentences, student will identify and imitate the “prosodic” marker in the sentence with 90% accuracy (e.g., identify the ? in a sentence to denote questioning/rising intonation and imitate the same).

Metalinguistic/metacognitive goals for students with temporal patterning/prosodic deficit are similar to those of students with impaired integration or auditory–language association (see below). Self-advocacy goals are similar across all processing deficit types in that all students should be able to demonstrate an understanding of the nature of their deficit and describe the uses of self-help strategies. At

home, students can practice temporal processing/prosodic skills using musical instrument training and games such as *MadGab* and *Simon*.

The associative deficit profile is not true central auditory impairment but instead represents significant auditory-language processing difficulties. Children with this deficit do not infer and/or apply the rules of language as well as their peers. Although normal processors too often do not “think outside the box,” these children rarely are “in the box”; the “box” being those rules of language, both explicit and implicit, that we use to “get the message” of an auditory-verbal target. They may exhibit specific language impairments in syntax, vocabulary, semantics, verbal and/or written expression, pragmatics, or social communication. More importantly, though, they exhibit functional communication deficits even in the absence of specific language impairment.

A key behavioral characteristic is a finding of adequate academic performance in early elementary grades with increasing difficulty as linguistic demands increase in upper grades. This child may present with subaverage to subnormal intellectual potential when assessed using standard (language-biased) intelligence tests. This student’s overall rehabilitation program will include an array of goals and benchmarks (implemented by the speech-language pathologist) addressing specifically impaired language and language processing skills as well as functional communication. Applicable goals within the M3 model appropriate for this student include those that address listening comprehension, working memory and recall, use of visual cues, and self-advocacy as opposed to those that train auditory-specific skills.

Listening comprehension. Student will use stress cues to interpret auditory information.

Benchmark examples. Given a short passage, student will write three key or stressed words or phrases within the passage with 90% accuracy.

Working memory/recall. Student will use key linguistic elements in a target.

Benchmark examples. Given no more than three clues, student will recognize word (e.g., given *white, fluffy, falls* students would respond *snow*) with 90% accuracy. When given a sentence, student will state what information is conveyed by two (or more) key (i.e., stressed) words with 90% accuracy (e.g., *MY sister baked TWO DOZEN chocolate chip cookies on Tuesday*. Key words: *My, two dozen*. Information conveyed: Who, how many).

Use of visual cues. Student will use visual cues to comprehend message.

Benchmark examples. Given printed or picture clues, student will “guess” target word or phrase (e.g., *the\$\$\$bank = money in the bank, the\$cccc = the seven seas*) with 90% accuracy.

To extend the benefit of these language usage goals and activities beyond the therapy session, teen listeners can practice recognition and use of visual cues to “get the mes-

sage” using the road signs section of *Rules of the Road* books. Additionally, students with auditory-language association issues should be encouraged to play language-based board games, such as *Scattergories*, *Password*, and *Taboo*, and verbal problem-solving games such as *Clue* and rebus-type and crossword puzzles.

Another secondary type of processing deficit exhibiting a unique pattern on central auditory tests is the output-organization deficit. This deficit is characterized by difficulty on tasks requiring efficient motor path transmission/motor planning and is likely a behavioral manifestation of impaired efferent or executive function. Behaviorally, the child may be disorganized, impulsive, and a poor planner/problem solver. Difficulties in expressive language, articulation, and syntactic skills may be observed as well as educational problems in direction following, note-taking, and remembering assignments. Like their peers presenting with the associative profile, students with output-organization issues benefit from activities to enhance use of visual cues, working memory, rapid recall, listening comprehension, especially as it relates to note-taking, and self-advocacy (see previous examples). Additionally, this student needs therapy to improve sequencing and, often, noise tolerance.

Sequencing. Student will apply verbally mediated strategies to sequence and organize auditory information.

Benchmark examples. Given a single word target, student will create as many rhyming words as possible in 2 minutes and in alphabetical order with 90% accuracy. Student will execute three-step sequential directions, in which each direction has one or two critical elements, with 90% accuracy when presented in a quiet environment. For example, *First, draw a straight line, then draw a circle below the line, and then draw a red star above the line*.

Noise tolerance. Student will tolerate extraneous noise/reverberation of varying loudness levels.

Benchmark examples. Student will repeat monosyllables presented without visual cues in a background of multi-talker babble that is louder than target with 90% accuracy. Student will execute multistep, single-element sequential directions with 90% accuracy when presented without lip-reading cues in a background of equal loudness multitalker babble. Games and activities that can enhance organization and sequencing skills include *Bop-it*, *Twister*, *Simon Says*, and “treasure hunt” games.

Treatment Effectiveness

To document treatment effectiveness, there must be evidence that change has occurred because of the treatment and not maturation or some uncontrolled factor (Goldstein, 1990). A growing body of research supports the use of top-down and/or bottom-up treatment to reduce or resolve specific auditory processing impairments and to support development of compensatory strategies (Bellis, 2003; Bellon-Harn, 2011; Chermak, 1998). Ferre (2010) examined change in

performance on a degraded speech task (Low Pass Filtered Speech) and a dichotic listening task (dichotic digits) for two groups of children diagnosed with CAPD characterized by impaired auditory discrimination and/or impaired binaural integration/separation. Twenty students received either weekly individual hour-long aural rehabilitation sessions supplemented with 60 minutes per week of the same therapy exercises administered by parents (120 minutes per week therapy) or 120 minutes per week of computer-assisted AT. Test scores obtained at initial evaluation (pre) and again following 30 hours of treatment (post) indicated significant improvement following treatment for both groups on both tasks, with scores for most students at or very near normal limits for age at post-test. Improvement noted in dichotic listening, despite neither group engaging in specific dichotic listening training, was hypothesized to be related to impact of poor discrimination/closure on the ability to recognize dichotically presented words. That is, these students exhibited poor dichotic listening on initial CAP evaluation not because of (truly) impaired binaural integration but because of poor decoding/discrimination. As discrimination/closure abilities improved, ability to recognize dichotically presented targets also improved. The results support the notion that therapy also can improve other related skills that were not targeted specifically.

Also of interest was the finding that while all students exhibited significant improvement, individualized “live” treatment/training provided greater overall improvement than computer-based training alone for these auditory skills. It is likely that the best possible therapy outcomes will be realized through the combination of individual treatment supplemented by computer-assisted training.

Summary of M3

Having defined as clearly as possible the disorder’s nature and impact through the assessment process, one can develop deficit-specific intervention strategies designed to minimize the adverse effects of the deficit on the listener’s life and (re)habilitate the system. The intervention process must meet each child’s unique functional needs, be provided in a timely manner, use resources effectively, and be extended beyond the therapeutic environment into all aspects of the listener’s daily life. In *M3* therapy, “top-down” strategies designed to teach the listener how to maximize auditory skills and compensate for residual effects of the processing disorder are paired with “bottom-up” techniques designed to improve specific auditory (or related) skills. The breadth and depth of the activities and strategies chosen will be unique to each student depending on specific processing deficit type and daily listening needs. All students, regardless of deficit type, will benefit from exercises to improve self-advocacy, empowerment, and active listening. Supplementing individual therapy with auditory, language, or multi-sensory games as well as computer-assisted auditory and/

or multimodality training appears to maximize treatment outcomes, allowing students to meet their “auditory” goals in relatively short periods of time.

OTHER TREATMENTS

Treatment for Amblyaudia

Amblyaudia, abnormal interaural asymmetry on dichotic tasks, affects half or more of children with CAPD. As amblyaudia may not be corrected by remote microphone hearing aid use or general AT, it often requires specific remediation. Methods include the Dichotic Interaural Intensity Difference (DIID) procedure (Musiek and Schochat, 1998) and Auditory Rehabilitation for Interaural Asymmetry (ARIA, Moncrieff and Wertz, 2008), among others. Treatment of amblyaudia is similar to the treatment of the visual analogue, amblyopia. In amblyopia the dominant eye is inhibited by application of drops or an eye patch to reduce sensory input. In amblyaudia, input to the dominant ear is reduced by decreasing the stimulation intensity on dichotic training tasks. A variety of dichotic training materials can be used and presentation can be by loudspeakers (ARIA) or either headphones or loudspeakers (DIID). With the intensity fixed at a comfortable level in the nondominant ear, the level of competition in the dominant ear is gradually increased from a low starting level over a number of training sessions until the nondominant ear can achieve normal performance in the presence of equal intensity stimulation in the dominant ear. Binaural separation and integration tasks are used. Early trials involved training a number of times per week over many weeks. However, the ARIA procedure has been refined to require only four 1-hour sessions over 4 weeks in the majority of cases. Amblyaudia treatment appears to work by releasing the nondominant pathway from suppression by the dominant side.

Software and Other Materials for Auditory Training and Language Therapy

CAPD therapy can be categorized as bottom-up or top down. Bottom-up treatments encompass strategies to enhance signal quality, such as amplification and discrimination training, and include training of psychoacoustic skills (Sharma et al., 2012). Treatments which use higher level processes such as cognition, language, and metacognitive functions to understand the auditory message are classified as top down. They include therapy to improve vocabulary, word understanding, prosody perception, inferencing, reasoning, working memory, verbal rehearsal, summarizing, language, reading, and other high-level skills. As members of the multidisciplinary team involved in treating CAPD, audiologists tend to concentrate on bottom-up treatments and speech-language pathologists on top-down approaches.

There are numerous training packages, workbooks, and software programs promoted for CAPD treatment. Many are in a game format. Some are advertised direct to consumers. Auditory training games are also increasingly becoming available as mobile applications. Not all software packages, and few if any mobile applications, are evidence based, and some programs that have been extensively investigated are the subject of both positive and negative reviews. No single program is likely to meet all of a child's training and therapy needs and a particular child is unlikely to need all of the subcomponents in a particular package or software program. Hence, they are best used as home training adjuncts to clinician-directed therapy with clinician guidance to ensure that a child works at an appropriate level and on appropriate subtasks within any given program. Some of the popularly recommended programs for CAPD, for example, Earobics (Houghton Mifflin Harcourt), are primarily reading programs with auditory processing and phonics subcomponents. Some are generic adult brain training programs which happen to have auditory processing subcomponents. CAPD textbooks list many of the programs available but clinicians are still advised to review available evidence. The What Works Clearinghouse (Institute of Education Sciences, US Department of Education) is a useful source of reviews.

LiSN & Learn auditory training software (National Acoustic Laboratories, Australia) is a game-format evidence-based software training program specifically designed to remediate a particular central auditory deficit, spatial processing disorder (hearing in noise). Like the LiSN-S test of spatial stream segregation developed by the same research group, LiSN & Learn produces a virtual three-dimensional environment under headphones. Through a variety of games children learn to attend to target stimuli and suppress background noise.

Sound Auditory Training (Plural Publishing) is a software tool to enable clinicians to customize web-based auditory skills training for individual clients. Tasks train intensity, frequency, and temporal detection, discrimination, and identification using a variety of nonverbal and minimally loaded verbal stimuli. Immediate feedback for error correction and reinforcement is provided through animations in a game format.

Listening and Communication Enhancement (LACE, Neurotone) is an adaptive AT program designed to improve listening and communication skills. It is oriented to adults with sensory hearing loss and is evidence based. It contains useful training materials for adults and older children with CAPD.

CLASSROOM ACCOMMODATIONS AND HEARING ASSISTANCE

The Classroom Environment

Classrooms are a critical auditory environment for children yet many do not provide favorable conditions for hearing.

The classroom environment is one that must be controlled to provide favorable conditions for hearing. There are three important variables to be noted: Noise, reverberation, and distance from the teacher. Sources of classroom noise may include the children themselves, furniture noise, ventilation systems, and external ambient noise. Ambient noise levels often exceed an optimum 35 dBA (unoccupied), and hard surfaces can reduce hearing effectiveness by increasing reverberation time beyond an optimum maximum of 0.3 to 0.6 seconds (American Academy of Audiology; AAA, 2011a). Signal level and SNR decrease with distance from the signal source. The primary signal decreases by 6 dB with each doubling of distance. However, in a reverberant environment the overall signal level may decline less, because of reverberation enhancement. Early reflections enhance the signal. Conversely late reverberation, while increasing the amplitude, degrades intelligibility. For all these reasons audibility in classrooms is best at a close distance to the teacher.

Children require a greater SNR than adults for speech recognition. Young children require speech levels that are at least 20 dB above those of interfering noise and reverberation (AAA, 2011b). In practice, this is difficult to achieve without amplification. Consequently, even children with normal hearing may experience difficulty hearing in class. Many children with CAPD particularly have difficulty hearing in background noise. The noise level does not need to be loud to disrupt auditory input. Adults with CAPD describe how noise from a fan or refrigerator can interfere in properly decoding speech. Some children with CAPD are overwhelmed by all classroom noise levels, becoming distressed and unable to function. Such children are sometimes withdrawn from school.

Sometimes, minor modifications to a classroom, for example, sealing obvious entry points of external noise and introduction of absorbent materials, may improve the acoustic classroom environment, but are unlikely to sufficiently improve the audibility for a child with CAPD. This is because some children with CAPD may need amplification of the primary signal, not just an improved SNR, to hear well (see Section "Amplification"). Hearing assistive technologies (HATs) and in particular remote microphone systems can alleviate or overcome all three sources of signal degradation in the classroom: Noise, reverberation, and distance from the talker.

Other Environments

Children with CAPD have difficulty when speech is rapid or degraded by distance, acoustic conditions, or accent, when information streams are complex or lengthy, and when competing sounds are present. It follows that HAT can be helpful to them in many aspects of their lives besides the school environment. Moreover, given the positive neuroplastic changes that occur over time from wearing amplification (Friederichs and Friederichs, 2005; Hornickel et al.,

2012), children with CAPD should be encouraged to use their HAT as much as possible.

Amplification

TERMINOLOGY

The majority of recent studies of amplification for children with CAPD have used remote microphone hearing aids, with body- or head-worn receivers, which receive a signal from a microphone worn by the speaker. The transmission medium has typically been frequency modulation (FM). Hearing systems of this type are usually referred to as “personal FM systems.” This term is ambiguous, because it refers to accessory FM systems used by wearers of conventional hearing aids or cochlear implants. Furthermore, FM is increasingly being replaced by digital modulation (DM) technology. From the point of view of advocacy as well as accuracy, use of the term “remote microphone hearing aids” reinforces the point that children with “central deafness” require amplifying hearing aids in much the same way as do children with peripheral hearing loss.

Until remote microphone hearing aids become recognized as simply another type of hearing aid they remain classified as assistive listening devices (ALDs) or, in more current terminology, a type of hearing assistive technology (HAT).

REMOTE MICROPHONE HEARING AIDS

Low-powered remote microphone hearing aid systems designed specifically for children with normal or near-normal peripheral hearing include the Phonak iSense Micro and the Oticon Amigo Star. In each case there is a choice of transmitter microphones which transmit to behind-the-ear receivers (Figure 30.10). Body-worn systems are also available though less popular. Placement of the transmitter microphone at chest level or beside the mouth in the case of boom microphones provides speech input levels of 80 to

85 dB SPL and 90 to 95 dB SPL, respectively. The high-level input and additional amplification, if required, enable output levels in the ear to be maintained at levels of 70 to 90 dB SPL. SNRs of the order of 20 dB can be achieved. Adaptive technology in some systems actively maintains the signal-to-noise advantage by varying the signal level up or down according to the background noise level. The signal level is enhanced in noisier conditions to maintain an optimal SNR. The systems are output limited at approximately 100 dB SPL. Eiten (2010) recommends that peak real-ear saturation response should not exceed 105 dB SPL when fitting ears with normal puretone hearing thresholds.

RESEARCH

The discovery of a therapeutic benefit of amplification for children with CAPD is one of the most exciting research findings in the treatment of CAPD. The assistive benefits have been long known, but recent studies repeatedly show improved auditory skills after a period of use of amplification when tested without the hearing aids, reflecting a neuroplastic change as a consequence of amplification use.

Friederichs and Friederichs (2005) followed 20 children with CAPD and comorbid ADHD over 1 year and assessed them on behavioral and electrophysiological measures. The experimental group of 10 wore binaural EduLink remote microphone hearing aids for at least 5 hours per day at school throughout the year. The experimental group showed continuing improvement relative to the control group on a variety of measures as the year progressed. Significant improvements were seen on teacher and parent assessments of Understanding the Teacher, Focus, School Results, and Dictation. Social behavior and attentiveness improved, with significant improvements on two of five psychoacoustic measures, frequency discrimination, and binaural temporal resolution. On auditory-evoked response measures using tones and an oddball paradigm there was impressive maturation of the N1 P2 (see Chapter 17) complex over time in the experimental group, only with the morphology improving

FIGURE 30.10 Remote microphone hearing aid systems. Phonak iSense Micro [left] and Oticon Amigo Star FM receivers with optional transmitters [right].

and P2 amplitude increasing from test to test. All tests were carried out without the remote microphone hearing aids on. The results provided evidence of improved ability to hear, improved ability to access learning, and neuroplastic development, as a result of the hearing aid use.

Johnston et al. (2009) studied 10 children with CAPD compared to a normal control group on measures of speech perception, academic performance, and psychosocial status. The experimental group wore binaural EduLink remote microphone hearing aids at home and school for at least 5 months. All children in the experimental group improved on measures of speech perception both in quiet and in noise (from spatially separated locations) irrespective of whether they had a specific hearing in noise deficit at the outset. These results are indicative of improvement in hearing ability because of beneficial treatment-induced neuroplastic development. The experimental group also improved on measures of academic performance and psychosocial status.

Smart et al. (2010) studied 29 children with CAPD, some with comorbidities. The children wore EduLink remote microphone hearing aids at school for 5 months. They were tested on a CAPD test battery and the Lexical Neighborhood Test presented with background noise from spatially separated loudspeakers. Pre- and post-treatment teacher and parent report data were also collected. Teachers and parents reported positive benefits. Significant positive improvements in auditory skills were reported post-treatment on two tests: The Frequency Pattern Test and the Lexically Controlled Words presented in noise. The post-treatment improvements were observed without the hearing aids which indicated positive neuroplastic changes as a result of the amplification. Umat et al. (2011) showed improvement on auditory working memory and Yip and Rickard (2011) showed improvement on spatial stream segregation ability from remote microphone use in children with central auditory deficits.

Sharma et al. (2012) carried out a randomized controlled trial of bottom-up versus top-down therapy on children with CAPD and comorbidities on 55 participants of an initial cohort of 90 children. Two subgroups additionally used EduLink remote microphone hearing aids at school during the 6-week course of therapy. Amplification was not tested independently, but as a supplement to therapy. The results were limited by the small group sizes and short period of amplification. Nonetheless, therapy plus amplification was shown to significantly improve some measures of core language and phonologic awareness compared to therapy alone. The authors suggested that remote microphone hearing aid use provided additional benefit over therapy alone.

Hornickel et al. (2012) studied 38 children with dyslexia and normal peripheral hearing over an academic year. CAPD is believed to contribute to the impairments in phonologic awareness and phonologic memory seen in children with dyslexia. Nineteen children comprising the experimental group wore EduLink remote microphone hearing aids at school during the year. Nineteen matched controls also with dys-

lexia attended the same schools. The children were assessed on reading ability, phonologic awareness, and auditory brainstem function. The auditory brainstem response stimuli were synthesized ba, da, and ga syllables. The children in the experimental group improved on phonologic awareness and reading, and their auditory brainstem responses demonstrated significant improvements in neural consistency. Moreover, the children who demonstrated the greatest improvement in phonologic awareness also demonstrated the greatest improvement in auditory brainstem function. In addition, neural response consistency was predictive of improvement in phonologic awareness. All tests were carried out without the use of remote microphone hearing aids. The matched control group did not demonstrate similar effects on any of the measures. The results provide strong evidence of auditory neuroplastic improvement as a result of amplification.

In combination, the studies reported above show improved performance on the following measures (recorded without the use of remote microphone hearing aids) as a result of amplification treatment: Cortical auditory-evoked potential amplitudes to tone stimuli, auditory brainstem responses to speech stimuli, frequency discrimination, binaural temporal resolution, frequency pattern recognition, auditory working memory, core language, phonologic awareness, and speech perception in noise (spatial stream segregation). Amplification appears to treat a wide range of auditory skills simultaneously.

Clinically, children will often pass previously failed CAPD tests at a review 1 year following the fitting of amplification. Interestingly, they usually do not wish to relinquish their hearing aids at this point. If, as it seems, amplification facilitates positive neuroplastic change, children should be encouraged to wear amplification as much as possible and not just in school for the assistive benefits in the classroom. The use of amplification during AT and language therapy may also be beneficial, though this does not appear to have been investigated.

Most recent research on amplification for children with CAPD has used remote microphone hearing aids, in particular the Phonak EduLink, the predecessor to the iSense. The positive results are generally attributed to a belief that most children with CAPD have difficulty hearing in background noise and that this is ameliorated by the beneficial SNR generated by remote microphone hearing aids. However, classrooms are not always noisy when the teacher is speaking. In addition, clinical experience shows that more than half of children with CAPD can pass the LiSN-S test of spatial stream segregation, a test which simulates hearing a signal against competing speech from a different location. Most children with CAPD benefit from amplification (Johnston et al., 2009). A similar argument applies to speculation that the principal benefit of amplification is improved attention. Attention is certainly a precondition for successful learning, but not all children with CAPD have attention deficits. There may be an additional explanation.

SNR is not an independent parameter; it is a product of two other parameters, noise level and signal level. In theory the SNR can be improved by reducing the noise level (unmasking), by increasing the signal intensity, or by a combination of both. But with the open canal fittings necessary when peripheral hearing is normal, noise cannot be blocked from entering the ear canal. Thus, signal level is the only parameter to change significantly in remote microphone hearing aid fittings for children with CAPD. The neurophysiological response to an increase in signal intensity is not entirely the same as the response to unmasking. The effect of increasing signal intensity on evoked auditory responses is well known. As signal intensity increases more axons are recruited, more synapses connect, synchrony of firing improves, response amplitude increases, response latency decreases, and response morphology becomes more clearly defined and repeatable. The common factor in the research reported above is increased signal gain delivered (binaurally) to the ears of the experimental subjects. This significant parameter of stimulus amplitude may be an important contributing factor in the success of amplification in remediating CAPD and in neuroplastic change.

Clinical observations also suggest that SNR improvement cannot be the sole explanation for treatment success with amplification. Some children with CAPD immediately hear better in an audiology test room, a quiet environment, when speech is amplified through audiometer headphones or trial hearing aids. Some clinicians claim excellent results in treating CAPD in children with conventional hearing aids. Some children with CAPD who are home-schooled wear hearing aids. Adults with CAPD may wear conventional hearing aids as their primary form of assistance. Conventional hearing aids do not share the same degree of SNR advantage of remote microphone hearing aids, but they do share potentially similar gain levels. Although not discounting the importance of improved SNR, perhaps the almost universal positive effects of amplification for children with CAPD might be due, in large part, to increased synchrony of firing in the CANS as a result of increased signal intensity.

The benefits of amplification for children with CAPD are not confined to hearing, learning, and neuroplastic development. Children's self-confidence, self-esteem, and social behaviors improve and listening effort is reduced. Friederichs and Friederichs (2005) reported behavioral improvements and Johnston et al. (2009) reported multiple benefits across a broad range of psychosocial measures. When asked about benefits of amplification parents frequently report improved self-confidence and markedly reduced tiredness after school.

Although this chapter is focused on CAPD, there is a small but growing body of evidence suggesting remote microphone hearing aids may also be beneficial for children with dyslexia, autism spectrum, attentional, and language disorders.

CONVENTIONAL HEARING AIDS

Kuk et al. (2008) and Kuk (2011) reported on a 6-month trial of binaural mild-gain conventional hearing aids with open fittings on 14 children with CAPD and normal peripheral hearing. The aids were worn at home and school. Kuk used gain levels of approximately 10 dB for conversational speech. Anecdotally, some clinicians report positive results with conventional hearing aids, but with possibly higher gain levels. If conventional hearing aids are ultimately proven to be of benefit for CAPD, then they may be useful in cases where having to use a transmitter microphone is an impediment. If hearing aids without remote microphones are used, then the child should sit close to the teacher to optimize the input signal level.

CLASSROOM AMPLIFICATION SYSTEMS

Classroom amplification systems, also referred to as sound distribution or sound field systems, provide amplification of the teacher's voice through loudspeakers. Their efficacy is variable, depending in particular on the room acoustics. Classroom amplification systems typically improve SNR by 3 to 5 dB, but may worsen SNR in classrooms with very poor acoustics. Adaptive systems which increase the amplification as the noise level increases can achieve better than 5 dB. Portable desktop systems in which a small loudspeaker is placed on the desk of an individual child provide a slightly better SNR, perhaps 10 dB, for that child. Remote microphone hearing aids can provide at least 20 dB improvement in SNR. A meta-analysis by Schafer and Kleineck (2009) comparing speech discrimination in noise with various FM systems in trials involving cochlear implant users showed no significant improvement with sound field systems but 17% improvement with desktop systems and 38% improvement with personal direct auditory input FM systems.

CANDIDACY FOR AMPLIFICATION

It is sometimes mistakenly assumed that only children with CAPD who complain of difficulty hearing in noise, or who score poorly on a speech-in-noise test, will benefit from remote microphone hearing aids. In fact, research results and clinical experience indicate that nearly all children with CAPD show classroom benefit from personal amplification as long as the classroom teacher is cooperative. Results range from children whose hearing ability in class is instantly transformed through to those in whom benefits are more subtle and slower to manifest. There is no known predictive test of degree of benefit to be derived from amplification (though the Hornickel et al. study reported above shows an interesting correlation between initial inconsistency of the brainstem response and subsequent benefit). However, recommendation of amplification only for children with abnormal scores on tests of hearing in noise undoubtedly denies potential benefit to many children.

FIGURE 30.11 Example of electroacoustic verification of remote microphone hearing aid. *Upper curve [vertical hatches]* represents audibility of the amplified pathway. *Lower curve [horizontal hatches]* represents audibility of the unamplified pathway through the open ear canal. [From Eiten L. [2010] Assessing open-ear EduLink fittings. In: *Achieving Clear Communication Employing Sound Solutions – 2008: Proceedings of the First International Virtual Conference on FM*; pp 77–85.]

WHEN TO FIT AMPLIFICATION

When a number of treatments may be beneficial it can be difficult to decide where to start. Amplification treats the underlying hearing disorder and it may be beneficial if amplification is worn during AT and subsequent top-down therapies. Amplification can address various auditory deficits simultaneously and it can, in many cases, provide immediate benefit in the learning environment.

ELECTROACOUSTIC VERIFICATION OF AMPLIFICATION

Professionals prescribing amplification for CAPD should be familiar with the relevant section of the AAA (2011b) Guideline and see Eiten (2010). Two methods of electroacoustic verification are described. One utilizes targets based on audiometric thresholds, the other sets the system gain at unity for a 75-dB SPL speech-weighted input. One issue is the lack of research-based guidelines for target output levels for use with CAPD. However, it is recommended that the microphone is placed 1 to 6 inches

from the speaker's mouth to enhance close speech input.

Figure 30.11 shows a typical real-ear output curve.

There is little if any research guidance on whether to fit amplification monaurally or binaurally in children with CAPD. Given all that is known about the effects of auditory deprivation and the benefits of binaural hearing, the safe course is to fit binaurally. Monaural amplification may actually cause deprivation effects in the neglected ear and initiate or increase interaural asymmetry.

The therapeutic benefit of amplification raises the question of how long hearing aids are needed for children with APDs and there is no research to provide us with an answer. Clinical experience suggests a wide range of individual differences, with significant numbers of children able to relinquish amplification after about 2 years, whereas a minority might require lifelong amplification. In the studies on treatment effects reported above, the greatest effects were seen in the longer studies of a 1-year period. Friederichs and Friederichs (2005) reported that they observed continuing improvement on various measures including cortical-evoked responses as the year progressed.

BEHAVIORAL VERIFICATION OF AMPLIFICATION

The AAA (2011c) Clinical Practice Guidelines (Supplement A) recommend behavioral (also referred to as functional) verification of HAT using speech-in-noise with speech at 50 dB HL (65 dB SPL) to represent the teacher's voice at a distance of 2 m, or speech at 40 dB HL to represent conversational level at 2 meters, with noise at 0 dB SNR. To simulate double the distance from the teacher (4 m) the signal level should be reduced by 6 dB. Materials and methods are outlined in the Guidelines and in Eiten (2010).

The Functional Listening Evaluation (FLE) (Johnson, 2004) provides a method for evaluating the effectiveness in the classroom. This is a procedure to test hearing with and without amplification at different distances in the classroom with and without background noise. Any speech material may be used and one of the test distances can be matched to the child's usual distance from the teacher. Consideration should be given to using materials that are more challenging than standard word lists for children with CAPD, for example, sentences or nonsense words.

Pre- and post-trial teacher, parent, and student observation questionnaires are also commonly used to evaluate amplification benefit in the classroom and home. Commonly used instruments are the Screening Instrument for Targeting Educational Risk (SIFTER), the Children's Auditory Performance Scale (CHAPS), and the Listening Inventories for Education (LIFE).

SCHOOL AND TEACHER GUIDANCE

One of the most critical factors affecting amplification success is the quality of the intervention with the school. Delegating school intervention to parents is also frequently unsuccessful. A very high acceptance rate can be obtained if a professional communicates with appropriate staff members including the teacher. Also advise and assist in the following areas: Explain the nature of CAPD and the child's difficulties, suggest management strategies, management of the amplification system, techniques to facilitate acceptance by the child and his/her peers, observe the child's auditory behavior and participation in class, manage an amplification trial, and where necessary assist in the preparation of individual education plans and applications for HAT funding. Educational audiologists or speech-language pathologists may perform this role. However, the more background and experience in special education, CAPD, and hearing aid management, the more likely the school will be to accept outside information and recommendations.

Teachers need advice on how to work with pupils with CAPD. First, their cooperation must be won by a collegial approach which acknowledges and emphasizes the importance of their role. Position in class is often emphasized as a first step in classroom management. Optimal audition is within about 2 m from the teacher but this is not an issue if the child is wearing remote microphone hearing aids.

Clear speech, that is, speech at a slightly reduced rate and slightly raised intensity, is helpful for children (and adults) with CAPD. Instructions will be better understood if they are brief, clear, and simple. The teacher should verify that instructions have been understood. A hearing buddy beside the child with CAPD can assist. Complementary aids such as visual cues and written materials can support oral communication. Sometimes special accommodations for assessments and assignments will be necessary. More detailed advice on teacher guidance is available from CAPD texts.

SUMMARY

This chapter presented a number of effective approaches by experienced audiologists who have had wonderful results in helping those with CAPD. The consistent theme has been "if you do it, it will come." Taken together and with all of the research reported in Chapter 28, there should be no question, in the reader's mind, that CAPD is a treatable condition and that audiologists can contribute importantly to improving this prevalent disorder in a relatively short period of time in most cases.

FOOD FOR THOUGHT

You are an audiologist in a private practice. An important aspect of your work is evaluation of CAPD. Because of the great demand for services and the important contributions from therapy and management you would like to introduce these services. Based on what you have read and what you know about the topic, please answer the following questions:

1. Explain what services you would provide regarding individual and/classroom assistive devices. Please tell why and what procedures/devices you would employ and whether you would include orientation sessions and/or guidance for teachers, classmates, and/or families.
2. Do you think it would be advisable to employ bottom-up training/therapy approaches? Please explain why and, if so, what procedures would you include?
3. Do you think it would be advisable to employ top-down training/therapy approaches? Please explain why and if so what procedures would you include?

Individuals with Multiple Disabilities

Anne Marie Tharpe and Samantha Gustafson

INTRODUCTION

Individuals with hearing loss and additional disabilities represent a widely diverse and complex group. They differ in the type and degree of their hearing loss, the type and degree of their accompanying disability, and their overall level of functioning. Approximately 25% to 50% of newborns who are deaf or hard of hearing have additional neurodevelopmental conditions, most often cognitive, behavioral-emotional, and motor problems (Chilosi et al., 2010; Fortnum et al., 2006). Similarly, the Gallaudet Research Institute (GRI, 2011) indicated that approximately 41% of deaf or hard-of-hearing school-age children have additional disabilities. As seen in Table 31.1, the most prevalent of these conditions were intellectual disabilities, followed by learning disabilities and vision deficits. It is also possible that some disabilities may not

become apparent until well into childhood or adolescence, further increasing these numbers.

There is also some evidence to suggest that the number of people with hearing loss who have additional disabilities is on the rise (Synnes et al., 2012). Several reasons have been suggested to account for this increase including improved survival rates among very low (<1,500 g) and extremely low (<1,000 g) birth weight infants who have a high risk of disability (Cristobal and Oghalai, 2008). Once-extraordinary measures are now routinely used to save preterm infants who, even a decade ago, may not have survived. Most agree that those who do survive the traumas of birth are at higher risk of lifelong disorders than full-term infants (Robertson et al., 2007; Stoinska and Gadzinowski, 2011; Wilson-Costello et al., 2005). However, some studies suggest that the technology and intervention that have improved survival rates have also resulted in improved overall outcomes for premature babies (Jonsdottir et al., 2012; Washburn et al., 2007).

Genetic causes also contribute to the number of individuals with hearing loss and additional disabilities. Approximately one-third of those with multiple handicapping conditions have a syndromic cause of hereditary deafness (Picard, 2004). The most common of these include Down, Usher, Pierre Robin, Treacher Collins, and CHARGE syndromes. In underdeveloped countries where consanguinity is high and genetic forms of hearing loss are more prevalent than in the developed world, education and counseling about inherited forms of hearing loss might lead to a decrease in inheritable hearing loss (Smith et al., 2005). Maternal infection remains a contributing causative factor of hearing loss. Although the prevalence of maternal rubella infection is down worldwide, cases of cytomegalovirus (CMV) are on the rise. CMV is associated with hearing loss and motor and cognitive deficits. Additional risk factors for developmental delays include environmental teratogens (i.e., factors that have adverse effects on embryos or fetuses), maternal substance abuse, and environmental deprivation.

Clearly, the high prevalence of infants and children with hearing loss and additional disabilities serves to emphasize the need for audiologists to acquire knowledge and competence to meet the challenges posed by their complex needs into adulthood. This chapter reviews some of the general characteristics of children and adults with hearing loss and

TABLE 31.1

Percentage of Disabilities that Occur in Children with Hearing Loss

Additional Disability	% Children with Hearing Loss
No additional disabilities	61.1
Vision impairment (including deaf-blindness)	5.5
Intellectual disability	8.3
Autism	1.7
Orthopedic disability (including cerebral palsy)	4.4
Specific learning disability	8
Attention-deficit disorder/attention-deficit hyperactivity disorder	5.4
Emotional disability	1.8
Other	14.3

additional disabilities. Basic principles for assessment and suggestions for management of these special populations are offered. In considering these suggestions, a few points should be kept in mind. First, it is likely that young patients with hearing loss and other disabilities will have some conditions that have not been identified at the time of the audiologic assessment. Therefore, audiologists should be mindful of the possibility that unknown conditions might influence the testing and management of some patients. This is especially true of more subtle conditions such as attention deficits and emotional problems. Second, the combined effects of some conditions may confuse or delay a diagnosis of hearing loss. For example, a child with autism and hearing loss might be nonresponsive to sound, in part, because of “tuning out” behavior and, in part, because he or she truly cannot hear some sounds. Third, a lack of training or experience might lead audiologists to think that some individuals with multiple disabilities are untestable by behavioral measures, which could result in a reliance on physiological measures alone. Certainly, physiological measures contribute valuable information about the integrity of the auditory system. However, we should keep in mind that behavioral tests provide an indication of how an individual *uses* his or her hearing, a very important factor when considering management needs. Collectively, age-appropriate behavioral and physiological test methods can result in an accurate assessment of hearing in most individuals with multiple disabilities and will result in an improved ability for audiologists to develop management strategies.

CUSTOMIZING THE HEARING ASSESSMENT

When evaluating individuals who have multiple disabilities, consideration must be given to any physical or cognitive limitations that could affect the assessment procedures. A thorough case history, review of prior evaluations, and keen observation can often identify the potential obstacles to assessment and may highlight individual strengths or interests that can be used to enhance the evaluation process. Obtaining as much information about the patient before the evaluation can help an audiologist prepare appropriately for the test session. For example, prior developmental testing or the use of developmental checklists will help audiologists determine an individual's ability to participate in behavioral tasks. Checklists are widely available and can be completed by parents or caregivers prior to their arrival at the clinic or while seated in the waiting room prior to the appointment. Likewise, when physical limitations exist (e.g., cerebral palsy (CP) or other gross motor deficits), modifications to any behavioral task requiring a motor response must be considered.

The widespread implementation of electronic medical records affords timely access to current medical histories and test results, thus avoiding repetitive tests and saving audiologists time in formalizing a profile of their patients. This

is especially important when working with those who have multiple disabilities as they are likely to be receiving services from a number of professionals, thus providing a source of multidisciplinary information. More health systems today are moving toward an interdisciplinary model of care whereby several disciplines work together during a single consultation, assessment, or management session to provide an integrated plan of care. Interdisciplinary approaches to care can have an advantage over multidisciplinary care in that a patient's time is streamlined and communication among professionals should be enhanced. Another model of care is a transdisciplinary approach whereby representatives of several disciplines work together during the assessment and development of a care plan, but only a few members of the team provide the services. Regardless of the approach taken, communication among providers is of utmost importance when working with those who have multiple disabilities.

An initial observation without the patient's awareness can be helpful in determining typical behavior of the individual. Discretely observing the interactions between the patient and the caregiver in a waiting area can provide insight into the type, amount, and quality of communication or accommodation that may be effective (Dean and Harris, 2003). These initial observations aid in predicting how much cooperation can be expected and thus determining how to proceed with the assessment. For example, pretest observations of physical and cognitive engagement might reveal that an individual will not be able to participate in behavioral testing, and therefore, reliance on physiological measures will be necessary. Whether testing adults or children, individuals with multiple disabilities are more likely than typically developing individuals to require a heavy reliance on physiological measures over behavioral procedures. Observing the patient's behavior when his or her name is called in the waiting room can also provide some useful insight into the individual's level of functioning. Importance of the pretest interview cannot be overemphasized. Parents, care providers, therapists, and anyone who spends significant periods of time with the patient can provide valuable input about home and other environments, cognitive or physical limitations that might affect assessment or management, and potential compliance concerns.

Based on the review of case history information, previous evaluations, and observations of the patient, audiologists can prioritize the tests in the battery so that those likely to yield the most useful information and that are most easily obtained for the patient are conducted first. The order of the tests in the protocol might be quite different than that used with typically developing individuals. Audiologists should be mindful of the distinction between hearing sensitivity and responses of young children or those with developmental disabilities when interpreting the results of a behavioral test. Matkin (1977) coined the term *minimal response level* to describe the level at which a behavioral response to sound occurs, but also while recognizing that it might be elevated

as a result of nonsensory factors such as attention, motivation, or behavior.

CUSTOMIZING TECHNOLOGY MANAGEMENT

There is ample evidence to suggest that children with hearing loss and additional disabilities are likely to be fit with hearing technology (e.g., hearing aids, cochlear implants) later than otherwise typically developing children (Kaga et al., 2007; Oghalai et al., 2012). It is also reasonable to assume that adults with multiple disabilities receive hearing technology at a lower rate than adults with hearing loss who have no additional disabilities. There can be several explanations for this delay or lack of intervention including delayed confirmation of precise hearing levels, family/caretaker priorities on other health concerns, or concerns regarding one's ability to secure, care for, and safely wear technology. One way to assist in individualizing the hearing technology candidacy and selection process is the use of functional auditory assessments.

It is not uncommon when assessing the hearing of some individuals with multiple disabilities to obtain little in the way of formal behavioral test results during an initial visit because of difficulty gaining a necessary level of cooperation. However, even without the patient's cooperation, useful information can be acquired through the use of functional auditory assessment tools. These assessments evaluate listening behaviors in real-world settings—outside the confines of sound-treated booths where most formal audiologic testing takes place. The goal of functional assessments is to tell us not only *what* an individual hears, but more importantly, how the individual *uses* what is heard in everyday situations. In addition, information can be obtained about how listening behavior might change in different settings, under different conditions, or with different speakers. This information can then be used to guide more formal evaluation and management plans for these patients. Typically, this information can be obtained from self-assessment, parent, teacher, or caregiver questionnaires. Although these tools have primarily been designed for use with children, it is reasonable to adapt such questionnaires for information gathering purposes when assessing the needs of individuals of any age who have cognitive or behavioral disorders.

The following sections provide some limited guidance when considering hearing technology options for those with a variety of disabilities. Although expectations for benefit will naturally need to be adjusted relative to expectations of typically developing individuals, there is reason to believe that these patients can obtain significant benefit from various forms of hearing technology for daily living activities and in educational settings (Kaga et al., 2007; Oghalai et al., 2012). Counseling families regarding appropriate expectations for their child or family member receiving hearing technology, especially if receiving a cochlear implant,

requires relaying a clear message that improvements in hearing might have little if any impact on nonhearing-related developmental concerns.

AUTISM SPECTRUM DISORDER

Autism spectrum disorder (ASD) is a developmental disorder characterized by symptoms appearing in early childhood and impairing day-to-day life function. These symptoms include qualitative impairments in social/communication interaction and repetitive and restricted behaviors, according to the *Diagnostic and Statistics Manual of Mental Disorders* (5th ed.) (DSM-5) (American Psychiatric Association, 2013). Under the umbrella of ASD, a patient's symptoms will fall on a continuum, with some showing mild symptoms and others, more severe. A diagnosis under the general diagnostic category of ASD is relatively new. Prior to the publication of DSM-5, there were five ASDs, each of which had a unique diagnosis: classic autism, pervasive developmental disorder (PDD), Asperger's disorder, Rett's syndrome, and childhood disintegrative disorder. With the exception of Rett's syndrome, these disorders are now subsumed into the diagnosis of ASD. Rett's syndrome is now its own entity and is no longer a part of the autism spectrum.

ASD is thought to have an early onset, with symptoms appearing before 24 months of age in most cases (Baghdadli et al., 2003; Ozonoff et al., 2010). Although a definitive diagnosis of autism is not generally made until the age of 3 years or later (Mandell et al., 2005), there are a growing number of reports of stable diagnoses following identification as young as 2 years (Chawarska et al., 2009). Prevalence estimates of ASD have increased steadily over time from reports of 1 to 5 children per 10,000 in the 1970s (Brask, 1972) to reports of 5 to 60 per 10,000 in the 1990s and early 2000s (Bertrand et al., 2001; Yeargin-Allsopp et al., 2003). Current numbers from the Centers for Disease Control and Prevention suggest a prevalence of 114 per 10,000 children (Baio, 2012; Rice, 2009). It remains to be seen whether there has been a true increase in prevalence of ASD over time or the reported changes in prevalence can be explained by changes in diagnostic criteria and increased awareness of the disorder by parents and professionals (Fombonne, 2003; Rutter, 2005). Boys are more likely to be affected with autism than girls, at a ratio of more than 3:1 (Van Bourgondien et al., 1987). About 50% to 70% of children with ASD also have an intellectual disability (LaMalfa et al., 2004).

There is no strong evidence to suggest that individuals with ASD have a greater risk of hearing loss than the general population. However, the presence of unusual sensory responses, including abnormal responses to sound, is considered an associated feature of ASD. For example, individuals with ASD might completely ignore sounds that would result in a reaction from typically developing individuals. Other times, they often appear to be overly sensitive to sound by covering their ears with their hands when loud or unexpected

sounds occur. In addition to these abnormal responses to sound, young children with ASD are known to lag behind on language milestones. Therefore, those with ASD will likely be referred to audiologists for hearing assessments as part of the developmental evaluation to rule out hearing loss as the cause of language delay. On average, behavioral responses to sound of children with ASD who have normal hearing are elevated and less reliable relative to those of typically developing children (Tharpe et al., 2006). Relatively little is known about higher order auditory abilities of individuals with ASD. However, altered temporal processing has been recorded in both adults (Samson et al., 2011) and children with ASD (Groen et al., 2009; Kwakye et al., 2011).

Special Testing Considerations

Children with ASD who have hearing loss are diagnosed, on average, almost 1 year later than those without hearing loss (Mandell et al., 2005). Therefore, it is reasonable for audiologists to be alert to the general behavioral characteristics of childhood ASD to facilitate referral for evaluation when indicated. Several screening tools are available that can be used by audiologists. These include, among others, the Modified Checklist for Autism in Toddlers (M-CHAT) (Robins et al., 2001) and the Pervasive Developmental Disorder Screening Test II (PDDST-II) (Siegel, 1996).

Understanding the general behavioral characteristics of those with ASD can also be helpful to audiologists as they consider modifications to the traditional test battery. Because the majority of those with ASD exhibit cognitive deficits, behavioral abnormalities, and hypersensitivity to sensory stimulation, audiologists should be prepared to address those issues during the test session. For instance, transitions are often difficult for individuals with ASD. When possible, audiologists should avoid travel from room to room with the patient, taking care to escort the patient to the testing area immediately rather than keeping him or her in the waiting area. Audiologists will want to minimize physical contact with those who have tactile sensitivities. This may require initial testing in sound field, because of the possibility of aversion to the tactile stimulation created by earphone placement. A quick inquiry with the parent or caregiver might alert audiologists to any sensitivity that could affect testing.

Regardless of the chronologic age of the individuals, audiologists will need to use behavioral test procedures that are appropriate for their patient's cognitive level. This may mean that procedures typically used with infants and young children (described in Chapter 24) such as visual reinforcement audiometry (VRA) or play audiometric techniques will be used with older children or even adults. If VRA is used, one should consider minimizing the impact of the reinforcement by turning off the animation (if a lighted, animated toy is used) or using a video reinforcement. Other testing options for patients functioning at a developmental level of 2.5 years or greater are conditioned play audiometry

(CPA) and tangible-reinforcement operant conditioning audiometry (TROCA) (Lloyd et al., 1968). Although not commonly seen in audiology clinics, TROCA is often used in pediatric practices that specialize in serving those with multiple disabilities. TROCA requires the patient to press a bar or a button whenever a sound is heard, which is paired with the dispensing of a tangible reinforcement (e.g., small piece of food). TROCA is noted to be particularly effective with children having cognitive or behavioral (e.g., ASD) disorders. A significant number of children with ASD receive other clinical services (e.g., speech therapy). A thorough review of reports from other providers as well as a brief discussion with a caregiver can alert audiologists to reward techniques that work with an individual patient.

Patients with ASD are often resistant to earphones or probes used for individual ear testing. Audiologists can ask the parent or caregiver to practice listening activities with headphones with the patient prior to the appointment. If a patient with ASD will not allow the placement of earphones or probes, audiologists might have to resort to sedated procedures. This is certainly true if one plans to fit hearing aids. Individuals with ASD are known to be difficult to sedate with currently available pediatric sedating agents and are at risk for seizures while under sedation (Mehta et al., 2004). Therefore, consultation with the physician in charge of administering and monitoring the sedation process will need to include notification of the patient's diagnosis of ASD.

Special Management Considerations

For individuals with ASD, tactile sensitivities, and hearing loss, one can expect some resistance to wearing hearing technology. Therefore, maintaining consistent hearing aid or cochlear implant use might take longer to achieve with these individuals than with typically developing individuals. One technique for introducing amplification is to start by having the parent or caregiver gently massage the patient's ears several times a day until little or no resistance is offered. This may take anywhere from a few days to weeks. From there, one can introduce, to one ear only, a soft earmold without the device connected and build up wear time starting with a few minutes until the patient is willing to wear it for longer periods of time. Once the earmold is tolerated with little resistance, the device can be coupled to the earmold, and eventually, both devices can be introduced. Of course, this process will be slower or faster depending on the degree of tactile sensitivity and resistance offered. Hearing technology will need to be secured to the patient's clothing by use of retention devices designed specifically for that purpose. Such devices will leave the technology secured to the patient's clothing even if they are pulled from the ears. Once the individual becomes accustomed to wearing hearing technology, he or she may no longer need to use retention devices.

Loudness discomfort or hypersensitivity to sound has frequently been documented in children with ASD

(Tharpe et al., 2006). As such, it is essential that audiologists carefully adhere to prescriptive formulae for the selection and verification of hearing aid gain and output characteristics. Because it may be difficult or impossible to measure the patient's comfortable loudness levels, audiologists will often need to use age-appropriate normative targets provided by the prescriptive formulae. It is reasonable for audiologists to consider initially lowering the gain and output levels below those prescribed and gradually raising them as the patient becomes accustomed to the amplified sound. However, gain levels should always make speech audible for the patient.

PHYSICAL DISABILITIES

Persons who are deaf or hard of hearing should have similar motor development and skills as those with normal hearing unless vestibular function is affected. That is, deafness alone does not affect motor abilities or balance function. In fact, 93% of children with deafness have average to above average motor skills (Lieberman et al., 2004). Environmental factors such as emphasis on physical skills in the school curriculum, opportunities for practice and play, and parenting styles are believed to influence physical development of children with hearing loss. Audiologists should be aware of expected gross motor milestones in typically developing children. If a child with hearing loss is not walking by 15 months of age, a referral for further evaluation by a developmental psychologist or pediatrician is warranted.

Vestibular abnormalities that can result in gross motor problems include cochlear malformations such as Mondini's deformity and cochlear hypoplasia. Other congenital causes of gross motor deficits in children with hearing loss include syndromes such as CHARGE syndrome and Usher syndrome type I (described in a later section) and CP. CP is a disorder of neuromotor function. Approximately 3% of children with hearing loss also have been diagnosed with CP, which is characterized by an inability to control motor function as a result of damage to or an anomaly of the developing brain (GRI, 2011; Roush et al., 2004). This damage interferes with messages from the brain to the body and from the body to the brain. The effects of CP vary widely from individual to individual. There are three primary types of CP:

- Spastic—characterized by high muscle tone (hypertonia) producing stiff and difficult movement
- Athetoid—producing involuntary and uncontrolled movement
- Ataxic—characterized by low muscle tone (hypotonia) producing a disturbed sense of balance, disturbed position in space, and general uncoordinated movement

These three types of CP can coexist in the same individual. CP can also be characterized by the number of limbs affected:

- Quadriplegia—all four limbs are involved

- Diplegia—all four limbs are involved and both legs are more severely affected than the arms
- Hemiplegia—one side of the body is affected and the arm is usually more involved than the leg
- Triplegia—three limbs are involved, usually both arms and a leg
- Monoplegia—only one limb is affected, usually an arm

CP is not a progressive condition. The damage to the brain is a one-time event. However, the effects may change over time. For example, with physical therapy a child's gross and fine motor skills may improve with time. However, the aging process can be harder on bodies with abnormal posture or that have had little exercise, so the effects may result in a gradual decline in motoric ability. It is important to remember that the degree of physical disability experienced by a person with CP is not an indication of his or her level of intelligence.

The brain damage that caused CP may also lead to other conditions such as learning disabilities or developmental delays. Approximately 20% of children with CP will also experience hearing or language problems (Robinson, 1973). The hearing loss is typically sensory/neural in nature. In addition, between 40% and 75% of individuals with CP will also have some degree of vision deficit.

Special Testing Considerations

Individuals with motor delays may not respond behaviorally to auditory stimuli because their physical disabilities limit their ability to orient to sound (Moore, 1995). However, when testing children, VRA can still provide reliable information even for those with poor head and neck control. Modifications that might need to be made in the test arrangements for VRA include the use of an infant seat to provide additional head support. However, audiologists should ensure that head supports do not block the ears and impede sound field stimuli. If children with motor difficulties cannot make a head-turn response to sound, response modifications can be made. Modifications include alternative responses such as localizing to the sound stimuli with their eyes as opposed to head turns. CPA (see Chapter 24) might also require modifications. Response modifications might need to include options that do not require the use of fine motor skills. Examples of such modifications could include asking a child to drop a ball into a large bucket rather than having the child insert a peg in a pegboard, partial hand raising, or even just a head nod. Additionally, a variety of gross motor responses (e.g., hand motion) can be used to trigger an electronic switch that will, in turn, activate a computer screen programmed for appropriate visual reinforcement.

If the physical disability has a neuromotor component, such as with CP, physiological measures might be affected (Yilmaz et al., 2001). That is, abnormality in measures such as the auditory brainstem response (ABR) may be misinterpreted as indicative of hearing loss when, in fact, the

abnormality is in neurotransmission. Therefore, interpretation of the ABR must be made cautiously and in concert with the entire battery of auditory tests, behavioral and physiological. Sedation may be required when conducting ABR with individuals who have CP in an attempt to relax their head and neck or to reduce extraneous muscle movements, thus reducing myogenic artifact.

Special Management Considerations

When selecting and fitting hearing technology on someone with physical impairments, there are a number of factors that must be considered, including the types of activities in which the individual participates (e.g., physical therapy) and his or her fine and gross motor ability (e.g., use of a wheelchair with head supports). When fitting children, it is important that the audiologist consider input from the parents and other professionals working with the child when determining amplification options. Children who require amplification for their hearing loss are typically fit with behind-the-ear (BTE) hearing aids. However, use of this type of aid may be inappropriate for children or adults with physical handicaps if they have poor head control (Tharpe et al., 2001). The close proximity of head supports or the person's own shoulders, if the head is leaning to one side, may result in excessive feedback or discomfort from BTEs. Problems with feedback might be reduced by selecting a hearing aid with a feedback cancellation feature, although care must be taken to ensure audibility across the speech spectrum is maintained. Another feature that might be beneficial for those with poor head control is a remote control. This can provide easier manipulation of the controls (e.g., volume control) of the hearing aid by caretakers (Roush et al., 2004).

Body-worn hearing aids and cochlear implant speech processors, although rarely used today, provide another option and would eliminate many of the problems that BTEs pose for patients with poor head control. However, body-worn hearing aids also require special consideration when being used with patients who have physical disabilities. For example, for very young children and for those of any age with oral-motor difficulties, the microphone of the aid may be vulnerable to food and drink. Moreover, clothes may rub on the microphone port, resulting in extraneous noise, and wheelchair harnesses can rub or press against the aid, resulting in discomfort or damage. Although children are not typically fit with in-the-ear (ITE) hearing aids, they may be an appropriate solution for adults or children who spend part of their day in atypical positions or who use a wheelchair with headrests.

INTELLECTUAL DISABILITY

The term intellectual disability includes impairments of general mental abilities that impact adaptive functioning. Symptoms of intellectual disability first appear during the

developmental period and diagnosis requires a comprehensive assessment of intelligence across conceptual, social, and practical domains (American Psychiatric Association, 2013). Adaptive skill areas include:

- Conceptual
 - Language
 - Reading
 - Writing
 - Math
 - Reasoning
 - Knowledge
 - Memory
- Social
 - Empathy
 - Social judgment
 - Interpersonal communication skills
 - Ability to make and retain friendships
- Practical/self-management
 - Personal care
 - Job responsibilities
 - Money management
 - Recreation
 - Organizing school and work tasks

As seen in Table 31.1, almost 10% of children with hearing loss also have intellectual disabilities (GRI, 2011). Those with an intellectual disability are at an increased risk for visual or hearing impairment or both (MacFarland, 2003). Detection and treatment of hearing loss in adults and children with intellectual disabilities is of utmost importance because hearing loss can exaggerate intellectual deficits by impeding the learning process (Roush et al., 2004).

Down syndrome, also referred to as trisomy 21, is the leading cause of hearing loss and intellectual disabilities and occurs in approximately 1 in 700 births in the United States (Parker et al., 2010). Audiologists are very likely to see a large number of children and adults with Down syndrome, a genetic disorder always associated with some degree of cognitive impairment. As individuals with Down syndrome age, there is a decline in intellectual ability. In fact, almost 100% of individuals with Down syndrome over 40 years of age demonstrate degenerative neuropathologic changes consistent with Alzheimer-type dementia (Zigman et al., 1995). Furthermore, some have speculated that the precocious aging of individuals with Down syndrome results in early presbycusis in this population (Dille, 2003). Hearing loss progresses more rapidly in adults with Down syndrome than those with other forms of intellectual disability or adults in the general population. Down syndrome is also frequently associated with conductive hearing loss and, less often, sensory/neural hearing loss. Although the majority of the conductive hearing losses in those with Down syndrome are secondary to middle ear effusion, some are the result of middle ear anomalies, such as ossicular malformations and damage to middle ear structures as a result of chronic

infection. In contrast to the typically developing population, the prevalence of middle ear effusion tends to remain high in individuals with Down syndrome regardless of age. Marcell and Cohen (1992) found that adolescents with Down syndrome have poorer hearing and greater incidence of conductive hearing loss than their peers with intellectual disability, but without Down syndrome. For a comprehensive review of hearing loss associated with Down syndrome, see Porter and Tharpe (2010).

Special Testing Considerations

Little has been published on hearing assessment of adults with intellectual disability. However, it is well documented that audiologists must use test techniques that will bridge the difference between the chronologic and developmental age of individuals with cognitive disabilities to obtain valid test results (Diefendorf, 2003; Roush et al., 2004). The patient's mental or developmental age, not their chronologic age, should be considered when selecting appropriate test procedures and materials. Several investigators have evaluated the effectiveness of VRA with children having intellectual disabilities, including those with Down syndrome (Greenberg et al., 1978; Thompson et al., 1979). With typically developing children and those with intellectual disabilities, VRA is effective with infants as young as 6 months cognitive developmental age. However, children with Down syndrome require a cognitive developmental age of 10 to 12 months to successfully participate in a VRA procedure. Furthermore, behavioral thresholds of infants with Down syndrome have been found to be 10 to 25 dB poorer than those of typically developing infants when all had normal hearing verified via ABR (Werner et al., 1996). This elevation of behavioral thresholds is presumed to be the result of more inattentive behavior on the part of the children with Down syndrome relative to their typically developing peers. Moreover, this inattentive behavior provides additional reason to utilize a test battery that includes physiological measures when testing children with Down syndrome.

Although it is recommended that audiologists attempt to elicit a spontaneous head-turn response during the VRA conditioning process (Tharpe and Ashmead, 1993), some children with intellectual disability may not have developed auditory localization ability. Recall that auditory localization is a higher order skill than detection, the required skill for VRA. In such cases, several administrations of paired conditioning trials (pairing the stimulus and the reinforcer) may be required. If the patient does not respond to the auditory stimuli, the audiologist may be left with the question, "Does the patient not hear the stimuli, or can she or he not perform the task?" One method that can answer this question is for the audiologist to place the bone vibrator either in the patient's hand or on the head and, using a low-frequency stimulus at approximately 50 to 60 dB hearing level (HL), determine if the patient can perform the task using

this vibrotactile cue. In this way, the patient is able to feel the stimulus and, thus, is not required to hear to participate. If the patient is able to cooperate for the task under these vibrotactile conditions, then the audiologist should return to the auditory stimuli and continue testing with the knowledge that the patient understands the task.

If using a play audiometric technique, it is often appropriate for the audiologist to demonstrate the play task to the patient with intellectual disability rather than attempting to explain the instructions verbally. Because learning the desired response behaviors may take longer for children and adults with intellectual disability, it may be useful to have them practice the listening task at home before coming to the clinic. It is important to keep the task as similar as possible to what actually will be expected in the clinical setting. Another approach is for the audiologist to demonstrate the task engaging the patient's parent or caregiver as the one being tested. The patient can then observe the procedure being conducted and see what is required. If the patient has use of some language, the audiologist should keep verbal instructions short, simple, and accompanied by gestures. Nonverbal expressions of reinforcement can be used generously (e.g., smiles, clapping, thumbs up) to indicate to the patient that he or she is complying with the task. Audiologists should keep in mind that the reinforcement is provided to support the response behavior of the patient, not to indicate if the patient is correct or incorrect (i.e., can hear or not hear the stimulus). Additional time will likely be needed to complete the play task, and the audiologist should expect response delays as a result of additional time needed for the patient to process the instructions and formulate a response. It is not unusual for patients with intellectual disability to have to return for more than one visit to complete testing. However, the visits should not be so far apart in time as to result in a significant delay in diagnosis. It is important in these cases to keep the examiner and the test procedures the same so that a routine can be established with the patient. This differs from testing with typically developing children where the examiner often has to change the task to keep the child's attention.

Whether using VRA, CPA, or conventional test procedures, it is recommended that control trials (no sound trials) be included throughout the testing session. This is especially true if working with individuals who have Down syndrome, because they typically are eager to please others and this often results in a high number of false-positive responses. Control trials are inserted randomly into the testing procedure at times when the audiologist would otherwise present the auditory signal. If a response is noted during a control trial, it is evidence of a false-positive result and should not be reinforced. This lack of a reward for false responses should reduce their frequency.

Although important for complete evaluation of all patients, it is particularly important to monitor the middle ear status of those with intellectual disabilities, because they

are known to have a higher degree of abnormal tympanometry and conductive hearing loss than the general population (May and Kennedy, 2010). Those with Down syndrome have an even higher incidence of otitis media than others with intellectual disability, because of the anatomic anomalies of the head and neck including the cochlea, ossicles, Eustachian tube, and nasopharynx. Chronic ear infections afflict approximately 70% of children with Down syndrome (Mitchell et al., 2003). In addition, those with Down syndrome are highly susceptible to impacted cerumen, because of narrow or stenotic external ear canals. Therefore, all hearing test procedures (e.g., ABR, VRA, play or conventional audiometry) should include the use of bone-conduction testing when possible. A conductive component can mask the presence of sensory hearing loss, thus delaying the fitting of amplification.

There will likely be a heavy reliance on physiological measures during the hearing assessment of patients with intellectual disabilities. One should be mindful of the impact of abnormal middle ear function on otoacoustic emissions (OAE) and ABR. That is, OAEs will be absent in the presence of impacted cerumen or middle ear effusion. Therefore, immittance audiometry will be an important component of the test battery. In a review of ABR studies in persons with Down syndrome, Dille (2003) concluded that ABR testing should be interpreted with caution, because it is likely that those with Down syndrome demonstrate a neural developmental time course that is uniquely different than that of typically developing individuals. Thus, comparing latency-intensity functions to normative values might result in erroneous conclusions. Widen et al. (1987) suggested that the ABR interpretation be based on both threshold of the response and latency-intensity series.

Special Management Considerations

Because of the high incidence of middle ear disease in those with intellectual disability, especially those who are institutionalized or have Down syndrome, it is most efficient to have otologic examinations immediately prior to audiologic assessments. The otologic examinations can serve to ensure that the external canals are free of cerumen and that no active middle ear infection is present. Individuals with Down syndrome, regardless of age, should receive otologic and audiologic monitoring about every 3 months to manage cerumen and middle ear disease. By school age, between 45% and 93% of children with Down syndrome have had pressure-equalizing (PE) tubes (Mitchell et al., 2003; Shott et al., 2001). However, diligent audiologic and otologic monitoring is required because of the high failure and complication rates of PE tubes in those with Down syndrome (Iino et al., 1999).

For those requiring amplification, several issues must be considered. First, the implementation of prescriptive amplification fitting is recommended for all children and

adults. Individual or age-appropriate ear acoustics should be taken into account in the hearing aid selection and fitting process. This is accomplished by measurement and application of the real-ear-to-coupler difference (RECD) (see Chapter 40). It is not uncommon for audiologists to use age-average RECD values as opposed to measuring them directly. However, one must consider the potential impact that any craniofacial anomaly (including Down syndrome) might have on this practice. Because of the typically smaller ear canals in individuals with Down syndrome, it is quite likely that an age-average RECD will result in an underestimation of ear canal sound pressure level, thus leading to overamplification.

Second, individuals with craniofacial anomalies or who have intellectual disabilities may have difficulty keeping hearing aids in place for a number of reasons. The use of wig tape or other hearing aid retention devices can help them stay in place behind the patient's ears.

Third, bone-conduction hearing aids may need to be considered for patients with chronic or recurrent middle ear disease or stenotic canals. Bone-anchored hearing aids have been used successfully in some children with Down syndrome (e.g., McDermott et al., 2008). In addition, for those with draining ears who use traditional air-conduction hearing aids, aids may need to be removed temporarily during times of active drainage.

Finally, the fitting of amplification may be delayed in individuals with intellectual disabilities because of other healthcare needs and concerns of the family. However, the earlier the amplification is introduced, the easier it may be to incorporate it into the patient's daily routine and the better the prognosis is for long-term acceptance. The parents or caretakers of patients with intellectual disabilities should receive careful and frequent instruction on the use and care of the amplification devices. Of course, to the extent possible, patients should be included in this educational process and encouraged to participate in the care of their devices.

VISUAL IMPAIRMENT

The combination of vision and hearing deficits may be congenital or acquired later in life. Although often referred to as “deaf-blindness,” one should keep in mind that the term “deaf-blind” typically refers to persons with dual sensory impairments who have some residual hearing and usable vision (Miles, 2003). Possible etiologies include syndromes such as:

- CHARGE syndrome—A specific pattern of birth defects represented by the acronym CHARGE: “C” for coloboma, “H” for heart defects, “A” for atresia choanae, “R” for retardation of growth and development, “G” for genitourinary problems, and “E” for ear abnormalities.
- Usher syndrome—The most common condition that involves both hearing and vision problems; an autosomal recessive disorder with primary symptoms that include

hearing loss and progressive retinitis pigmentosa. The vision difficulties include the onset of night blindness, which might become apparent during a child's school years, followed by loss of peripheral vision typically leading to severe low vision or blindness.

- Bardet–Biedl syndrome—A complex disorder that affects many parts of the body including the retina. Individuals with this syndrome have a retinal degeneration similar to retinitis pigmentosa.
- Goldenhar syndrome—A congenital birth defect that involves deformities of the face. Characteristics include a partially formed or totally absent ear (acrotia or anotia) and one missing eye.

Other causative factors for vision and hearing deficits occurring together include congenital prenatal infections (e.g., rubella, toxoplasmosis, herpes, CMV). The rubella epidemic of 1963 to 1965 contributed to the birth of more than 2,500 children with deaf-blindness in the United States. By 2011, there were almost 10,000 children in the United States alone who were considered to be deaf-blind (Teaching Research Institute, 2012). There are also postnatal causes of vision and hearing deficits (e.g., meningitis, asphyxia, stroke). The majority of individuals who are deaf-blind have additional disabilities such as physical impairments, cognitive impairments, and behavior disorders. In fact, more than 60% of individuals who are deaf-blind have intellectual disabilities (National Consortium on Deaf-Blindness, 2007).

Children with hearing loss are two to three times more likely to develop ophthalmic abnormalities than their normal-hearing peers (Guy et al., 2003). The irony is that people with hearing loss have a greater reliance on their vision for communication and environmental monitoring than those with normal hearing. Therefore, audiologists should encourage families of patients with hearing loss to have their vision monitored on a regular basis.

Special Testing Considerations

One of the first things that an audiologist should determine is the patient's preferred sense (typically, it is tactile), and then the audiologist should let the patient explore the test environment for a short period of time or until the patient appears to be comfortable. In addition to the environment, the patient must be given time to "find the audiologist," rather than the audiologist imposing on the patient's space. It is important to remember that individuals who are deaf-blind may explore their environments tactilely, but many are also tactile-defensive, so they must be approached slowly. As the patient becomes more comfortable in the environment and with the test situation, the rules about space and touching may change (Mascia and Mascia, 2003).

During activities that require the audiologist to touch the patient (e.g., otoscopic examination, insertion of earphones), it is recommended that the patient be given as much involvement as possible. That is, the patient should

be allowed to examine the equipment (e.g., otoscope, earphones) tactilely. Then, with the patient's hand still in contact, the otoscope, probe, or earphone can be slowly guided to the patient's ear. This process will require patience by the audiologist and may require more than one visit (Mascia and Mascia, 2003).

Auditory responsiveness of individuals who are deaf-blind may be compromised by their lack of curiosity. Thus, they may not turn toward the source of sound for a VRA procedure. As discussed in the section on individuals with intellectual disabilities, pairing the auditory stimuli with a vibrotactile stimulus may be necessary to condition the patient to the task (Mascia and Mascia, 2003). Once the patient has learned to respond consistently to the paired auditory and tactile stimulation, it can be assumed that the task is understood, and the tactile stimulation can be eliminated.

The selection of an appropriate reinforcement for behavioral tasks is critical. As previously mentioned, most individuals classified as deaf-blind have some residual vision. Therefore, even light perception can allow for successful implementation of visual reinforcement. This may require a slight dimming of the test suite lights to enhance the visual reinforcement for the patient. In some cases, a penlight positioned close to the patient and activated in response to a head turn or searching behavior can be implemented. If visual reinforcement is not possible, some patients may enjoy feeling specific textures, vibration, social praise, juice, food bits, or interesting toys. In any case, it will be important to consult with the patient's caregivers or teachers to assist in determining a desirable reinforcement.

It is also important when behaviorally assessing the hearing of a patient who is deaf-blind to determine an appropriate response to the stimulus. Parents, caregivers, and teachers may all be valuable resources in evaluating what kind of motor response can be expected from the patient in response to sound. Some possible responses include a head turn, reaching, arm raise, finger raise, or leg swing. Additionally, it may often be necessary to physically "show" the patient when and how to perform the response by manipulating the patient's hand, leg, or foot into place when the auditory stimulus is presented. This assistance can gradually be decreased using successive approximations until the child is able to respond with no cueing or assistance from the clinician.

Special Management Considerations

It is likely that individuals with dual hearing and vision impairments will welcome the use of amplification when indicated. After all, the majority of this population has some degree of residual hearing ability, and enhancement of hearing could serve as an important supplement to less-than-optimal visual input. A survey of clinical audiologists confirmed the belief that those with vision and hearing difficulties could potentially benefit more from amplification

than those with hearing loss alone (Tharpe et al., 2001). In addition, amplification for those with dual impairments has a role beyond that of only enhancing speech perception ability (Wiener and Lawson, 1997). That is, audiologists need to consider more than just enhancing speech perception and must also focus on the role hearing has in orientation and mobility, which is essential to the development of successful independent living skills (Tharpe et al., 2002).

Experts in the rehabilitation of visual impairment use the term “orientation and mobility” to refer to one’s location relative to environmental features and moving safely through one’s environment. Much research has been conducted on hearing aid specifications designed to enhance speech perception ability, but considerably less research exists on enhancing the detection of environmental auditory cues. It is unknown whether there is a combination of hearing aid characteristics that can be used to enhance speech perception and also improve detection of environmental cues or that can possibly affect one or the other adversely. The need for an integrated approach is apparent for individuals with dual sensory impairments who need to coordinate the aspects of guiding, route instruction, and verbal communication. Even the limited research that has been done on sound localization with hearing aids has not considered the specific spatial hearing needs of persons with visual impairments. Because speech recognition is based mostly on frequencies above 500 Hz, it is common for hearing aids to attenuate frequencies below a cutoff level in the range of 500 to 1,000 Hz. This low-frequency cutoff is designed to reduce background sounds that can interfere with speech perception. However, that frequency range contains critical information for orientation and mobility with respect to traffic sounds (Wiener and Lawson, 1997) and environmental surfaces, such as walls (Ashmead et al., 1998). A third important property of hearing aids is the flexibility to switch between different programs. That is, hearing aids that are programmable can be set to optimize listening in different environments. Assuming that different listening needs require different hearing aid settings for optimal perception, this flexibility will be important to consider in rehabilitation strategies for those with vision and hearing impairments.

Numerous investigators have found that directional microphones provide an advantage when listening to speech in noise under laboratory conditions. However, omnidirectional microphones appear to enhance localization ability under certain laboratory conditions and, perhaps, in real-world settings (Tharpe et al., 2002). A considerable amount of research is still needed to enhance our knowledge in this area. In the meantime, one should be cautious when selecting microphone options for use by individuals with significant vision and hearing deficits. It appears reasonable to offer a switchable directional/omnidirectional microphone option to those with significant visual impairments who must rely on their hearing for getting around their environments safely. Instruction regarding careful head positioning

during communication, especially when using a directional microphone, appears warranted.

SUMMARY

The assessment and management of individuals with multiple disabilities is a great challenge for audiologists. However, with some knowledge of the characteristics of a number of disabilities, early planning for and adjustments to diagnostic procedures, and careful consideration of individual and family needs, one can obtain valid and reliable test results that lead to meaningful audiologic management.

Part of facing this challenge requires recognizing and admitting that no one can be an expert on all disabilities. With these patients, probably more than most, we must acknowledge that our expertise may be limited and that we must work with a multidisciplinary or, optimally, with an interdisciplinary team of professionals, the patient, and the patient’s family in developing effective diagnostic and management strategies.

Finally, as with all patients, audiologists must consider the patient’s and family’s priorities as they relate to the hearing loss. For example, those with multiple disabilities may have other significant medical needs requiring substantial time and emotional energy. As such, the family may choose to defer the management of hearing loss until a time when they can more readily accept the challenge. Audiologists must be respectful of a family’s decisions and be prepared to support and encourage families in their choices.

FOOD FOR THOUGHT

1. You are suspicious that a child you are evaluating in clinic might have ASD. What additional tests/screenings might you conduct in addition to your traditional audiologic testing and what referrals might you make to other professionals?
2. You see that there is a 28-year-old patient with Down syndrome on your schedule for next week. This patient has used hearing aids for a few years. What pre-visit recommendations would you have for this patient’s caregiver to prepare for this appointment?
3. You are attending an interdisciplinary team meeting to discuss a 9-year-old child who has hearing loss and significant vision problems that are not correctable with glasses. What are the most critical pieces of information you need from other team members and what is the most critical information for you to share with the others?

ACKNOWLEDGMENT

The authors thank Jamie L. Watson for her assistance in the research and preparation of the original version of this chapter.

Noise Exposure

Brian Fligor, Marshall Chasin, and Rick Neitzel

HISTORY OF THE STUDY OF NOISE EXPOSURE

Noise can be defined simply as “unwanted sound.” Noise—or even desirable sound—above a given sound pressure level, and experienced over a sufficient duration of time, has the capacity to cause temporary or permanent changes in the structure and function of the auditory system. These changes result in the disruption of the normal function of the hearing apparatus, primarily through cochlear damage resulting in sensory/neural hearing loss; this is referred to as noise-induced hearing loss (NIHL). Unlike many other causes of sensory/neural hearing loss, NIHL is a fairly recent phenomenon in the history of human existence. Few naturally occurring sounds are of sufficient intensity to cause NIHL without also being a catastrophic threat to individuals—volcano eruptions, for instance. The human auditory system is amazingly refined to detect very soft sounds (such as a snap of a twig from a predator or the subtle acoustic difference between the /f/ and unvoiced /th/). A human voice can hit very high sound levels (e.g., shouting near an individual’s ear produces levels of approximately 115 dBA), but it does not have the ability to sustain these levels continuously for long durations; one must breathe, and hoarseness ensues with continued vocal fold abuse. Thus, the human auditory system is designed to function over a wide dynamic range (from the threshold of hearing to roughly 75 dBA) without sustaining any noise-induced changes. However, our ability to produce intense levels of sound as a by-product of industrial, transportation, and economic activities (as well as from recreational pursuits) has outpaced our auditory system’s evolution; NIHL is therefore almost entirely man made. Combating its ill-effects through prevention or mitigation should also be possible as a human endeavor.

There are accounts of hearing impairment in the Middle Ages in church bell ringers, miners, and blacksmiths (Berger et al., 2000). In the 19th century, medical literature made reference to “boiler-maker’s deafness” and “blacksmith’s deafness.” NIHL began affecting a large proportion of the population with the onset of the Industrial Revolution (and the automated machines of industry), and later with surviving veterans of World War II returning home after being

exposed to gunfire, explosions, and military machinery and aircraft noise. The prevalence of NIHL (particularly in the military) in the 1940s and 1950s was a major driving impetus to the massive expansion of the profession of audiology, which at the time was in its fledgling state.

MEASUREMENT OF NOISE EXPOSURE

Quantitative measurement of noise, conducted through use of sound level meters and noise dosimeters, is a relatively recent phenomenon and represents the foundation of all modern hearing conservation programs. Although sound level meters were in use for research purposes as early as the 1920s, they were not standardized until the following decade, and the first commercially available units were not introduced until the 1960s. Personal dosimeters, widely considered to be the gold standard for personal noise exposure assessment, did not become widely available until the 1970s. For evaluation of occupational noise exposures, sound level meters are typically used to make measurements of specific areas or short-term measurements on stationary workers whose noise levels are relatively steady over time. Dosimeters, which are small units designed to be worn by individuals for extended periods, may be used in these situations as well as in environments with time-varying levels and high worker mobility. Some dosimeters are also equipped with alarms that notify workers when their exposures exceed some predefined level—for example, one-half of their allowable daily noise dose—and other dosimeters are capable of making measurements inside workers’ hearing protection.

Measurements with sound level meters are typically made as snapshots over short periods of time (from a few minutes to a fraction of an hour). Such measurements can be quite useful for determining whether or not hearing protection is needed in a particular area, as well as to develop a “noise map,” that is, a facility map denoting noise levels in specific areas or in reference to specific machines or operations. Measurements made via dosimeter are typically made over an entire workshift and represent the gold standard, for example, the measured dose on a specific worker. Both types of instruments may be used to measure point-in-time

broadband sound pressure levels (in decibels), and dosimeters and integrating sound level meters may also be used to integrate broadband sound pressure levels into an average level over the examined time period. For 8-hour measurements, these integrated levels are referred to as time-weighted averages (TWAs). More sophisticated sound level meters have the additional capability of assessing frequency spectra in octave bands, 1/3 octave bands, and even narrow bands.

Regardless of the type of instrument used to measure noise, a single measurement is typically insufficient to adequately characterize noise exposure, and repeated measurements—under differing work conditions, if possible—are preferred. An integrated noise exposure assessment is the best approach to achieve a comprehensive understanding of noise exposures within a given facility or company; in other words, they collect area measurements, short-term measurements on workers, and full-shift measurements on workers. Measurements are becoming easier and less disruptive to administer because of continuing trends in miniaturization of dosimeters, and most modern dosimeters (and many sound level meters) also have powerful datalogging capabilities, which offer the ability to review and analyze minimum, average, and maximum noise levels with very high resolution (datalogging intervals of as little as 1 second).

HISTORICAL EVIDENCE OF AUDITORY DAMAGE FROM NOISE

One of the earliest studies of NIHL from workplace noise was a 1965 report of hearing thresholds of current and retired weavers who had a well-documented history of steady noise exposure for up to 40 years (Taylor et al., 1965). The pattern of hearing loss showed wide variability in hearing thresholds across individuals, but showed greatest hearing loss at 4,000 Hz (compared to lower and higher frequencies) with the most rapid onset of hearing loss occurring in the first 12 years, followed by continued (but slower) progression of hearing loss (Rosenhall et al., 1990). Numerous cross-sectional studies of noise-exposed workers have corroborated these classic findings, that hearing loss is greatest around 4,000 Hz and hearing loss progresses and includes lower and higher frequencies with increasing exposure.

The Environmental Protection Agency (EPA) estimated that 9.1 million workers in the United States were exposed to levels at or above 85 dBA (EPA, 1981) across a variety of industries, including manufacturing, mining, construction, agriculture, and transportation. From 1981 to 1983, the National Institute for Occupational Safety and Health (NIOSH) conducted noise surveys across a wide range of workplaces in the United States (excluding most mining operations) and estimated 16.9% of the workforce examined was exposed to levels at or above 85 dBA, although in some industries the fraction of potentially overexposed workers was much higher. For instance, follow-up surveys

in the mining industry conducted from 1984 to 1989 estimated that 84.5% of miners were potentially exposed to noise in excess of 85 dBA (NIOSH, 1998).

CURRENT PERSPECTIVES ON THE PATHOPHYSIOLOGY OF NOISE-INDUCED HEARING LOSS

Sensory/neural shifts in puretone thresholds resulting from noise exposure are generally classified as noise-induced temporary threshold shift (NITTS or TTS) and noise-induced permanent threshold shift (NIPTS or PTS). Additional injuries associated with NIHL include tinnitus, hyperacusis, and abnormal pitch perception. The focus of this chapter will be on noise-induced threshold shift, as other chapters deal with these other injuries in great detail. This is not to minimize the significance of these other injuries. As will be described later in this chapter, there is a relationship between TTS and PTS, but decades of research attempting to use TTS to predict PTS have fallen far short of developing robust models for hearing loss risk estimation (Melnick, 1991). It is now better understood that the underlying mechanisms giving rise to TTS and PTS are markedly different, and these differences might account for limitations in predicting PTS from TTS.

Gradually developing cochlear hearing loss can result from long-term exposure to moderately intense noise ranging from roughly 75 to 78 dBA (EPA, 1974; Melnick, 1991; Prince et al., 1997) to 132 dB peak SPL (Price and Kalb, 1991). Those factors that influence the degree of hearing loss are the sound level of the exposure as well as the duration of the exposure. In addition, the spectrum of the offending sound does influence the relative risk for hearing loss. The primary site of lesion in gradually developing NIHL is the death of outer hair cells (OHCs) (Henderson et al., 2006), resulting in a 40- to 60-dB hearing loss (HL). The frequency region that is typically affected first is between 3,000 and 6,000 Hz (most often in adult males, 4,000 Hz has the poorest hearing threshold), with better hearing thresholds at 2,000 Hz and below, and at 8,000 Hz (and above). With further exposure, hearing loss extends to lower and higher frequencies, and degrees of hearing loss greater than 60 dB HL are observed as inner hair cells (IHCs) and auditory nerve fibers are damaged. See Figure 32.1 for an example of significant NIHL and stereotypical bilateral 4,000-Hz “noise notch” in a 42-year-old professional drummer who has 26 years of experience, 15 years of which were without hearing protection. He used combination hearing aid–tinnitus masker devices, as well as undergoing extensive tinnitus management, to cope with his hearing loss and tinnitus.

In most cases, gradually developing PTS develops insidiously, as the challenges associated with communication and changes in perception of music often are not obvious until the degree of hearing loss is quite significant. The degree of

FIGURE 32.1 Audiogram of a 42-year-old drummer with significant noise exposure and noise-induced permanent threshold shift and tinnitus. [Courtesy of the Musicians' Clinics of Canada.]

hearing loss is cumulative throughout one's life, and by the time NIHL has direct impact on communication, considerable damage has been done that might have been avoided with earlier detection and mitigation of noise exposure.

In contrast, damage to the auditory system following a single, extremely intense, acoustic event may be marked by a large hearing loss that may not fully resolve to baseline. Such an event is commonly referred to as acoustic trauma and can affect a wide range of cochlear structures, such as OHCs and IHCs, supporting cells, the tectorial membrane, and the cochlear partition.

The mechanisms of cell death in both gradually developing PTS and acoustic trauma, the implications of these mechanisms for degree and range of frequencies affected by the hearing loss, and possible drug therapies for intervention will be covered in greater detail later in this chapter.

APPLICATION OF WEIGHTING FILTERS: dB SPL, dBA, AND dBC

Units of sound are typically expressed as a level that is a logarithm of the ratio between the sound pressure of interest (in Pascals) and the sound pressure at the threshold of human hearing at 1,000 Hz (i.e., 20 μ Pa). This ratio is expressed in decibels (dB) of sound pressure level (SPL). By definition, it is not weighted as a function of frequency. However, human hearing is most sensitive between 1,000 and 5,000 Hz and is less sensitive at lower and higher frequencies. Instrumentation used to measure sound exposures have built-in weighting filters that de-emphasize the relative contribution of sound energy at lower frequencies and give very slight emphasis to the frequency range that is most sensitive. The

shape of the A-weighted filter is based on the 40-phon curve in the Fletcher–Munson equal loudness contours. Sound with the majority of energy between 1,000 and 5,000 Hz and very little energy below this range will have nearly the same level in both dB SPL and dBA. However, sound with the majority of energy in low frequencies (for instance, 200 Hz and below) will have a much higher level in dB SPL than in dBA. Those seminal cross-sectional studies that have provided the data relating degree of hearing loss with past noise exposure measured that exposure in dBA (with A-weighted filter applied). As well, the measures were made in the free field (or diffuse field), or at the shoulder of an individual, and so the measures of sound exposure do not account for individual differences, such as differences in ear canal acoustics, across individuals. Figure 32.2 shows a comparison of A- and C-weighting filters relative to unweighted dB SPL. The C-weighting filter (dBC) is quite similar to the unweighted dB SPL except in the very low frequency region.

There is a controversy whether the use of the A-weighted filter is appropriate in measuring noise levels that may pose a hazard. The A-weighted filter is based on the 40-phon equal loudness contour; 40 dB SPL is equal to 40 phons at 1,000 Hz, but roughly 60 dB SPL is needed to achieve the same loudness perception (40 phons) at 100 Hz (because of the nature of reduced perception of loudness to low-frequency sound energy at this moderately low sound level). By contrast, the C-weighted filter is based on the 100-phon equal loudness contour; 100 dB SPL is equal to 100 phons at 1,000 Hz, and 100 dB SPL is equal to 100 phons at 100 Hz. This is due to the fact that the Fletcher–Munson equal loudness contours flatten out across the frequency spectrum as the sound level increases. Those sound exposures that place hearing at risk are much closer to the 100-phon equal loudness contour (C-weighting) than the 40-phon level (A-weighting). Regardless, given that our current models of hearing loss risk as a function of

FIGURE 32.2 A-weight and C-weight filters that de-emphasize certain frequencies to which the human ear is less sensitive, relative to "0 dB" which is unweighted dB SPL.

sound exposure are based on exposures measured in dBA, and that we cannot ethically repeat studies of unprotected noise-exposed workers, dBA continues to be the required unit of measure of sound when considering risk for NIHL. The proponents of using dBC have advocated, with some success, the use of measures reported in dBC (or unweighted dB SPL) for very high level transient sounds (for instance, impact or impulse noise), so as to not de-emphasize the contribution of very intense low-frequency sound that would happen if high-level transients were reported in dBA.

WHY A NOTCH AT 4,000 Hz?

In humans, the frequency of maximum cochlear damage is one-half to one octave above the frequency of maximum stimulation (Royster, 1996). This phenomenon has to do with the angle of curvature of the human cochlea as well as less blood perfusion in the basal end of the cochlea compared to the apex. The human external ear (pinna and ear canal) influences the physical properties of sound outside the head (i.e., in the diffuse field) by resonating at frequencies between 2,000 and 4,000 Hz, depending on the volume and the length of the ear canal; for larger adult ears the maximum ear canal resonance, as measured with a probe microphone, is 2,600 to 3,000 Hz (Schotland, 1996). In children, with shorter ear canals with a smaller diameter, this ear canal resonance is higher in frequency. This resonance serves to amplify sound by 15 to 25 dB relative to the diffuse field (for instance, as measured at the shoulder) at the resonant frequency.

Acousticians and engineers have referred to this resonance as the transfer function of the open ear (TFOE) or the external ear transfer function and is known to audiologists as the real ear–unaided response (REUR). When fitting hearing aids, placement of an earmold results in disruption of this normal ear canal resonance, resulting in insertion loss. The real ear–aided response (REAR) must provide amplification to compensate for the insertion loss, just to get back to the sound level that would arrive at the eardrum without the earmold or hearing aid in place. For broadband sound, the result of the TFOE (REUG) is an overall level measured at the eardrum roughly 7 dB higher than measured at the shoulder. Given that most environmental sound is relatively broadband, the frequency range of maximum stimulation is roughly one-half to one octave below 4,000 Hz. This is another reason why the 4,000-Hz frequency region is the most susceptible to damage.

HISTORICAL DEVELOPMENT OF NOISE EXPOSURE MODELS

There are two types of studies typically performed to assess the potential effects of noise on the auditory system. These consist of (1) large-scale studies of populations of humans who were exposed to well-defined noise levels for well-defined durations and (2) laboratory-based animal studies.

With actual humans, the most common type of experiment is to elicit a TTS in a subject's puretone thresholds after exposure to a significant level of noise or music and for a well-defined time period. As stated earlier, long-term studies of workers over many years can also provide evidence of the nature of permanent hearing loss (PTS). With laboratory-based animal studies, PTS can be studied in a more direct and controlled environment. A drawback of the large-scale studies, such as in industrial settings, is the possibility of contamination of the results by noncontrolled factors such as middle-ear disorders, smoking, and other forms of unreported (recreational) noise and music exposure; and a drawback of well-controlled laboratory studies is the limitations to generalizing results to human hearing loss.

Relationship between TTS and PTS

It would be tempting to be able to derive a relationship between TTS and PTS. If an individual worker were quite susceptible to TTS, then perhaps there is something that can be said about his or her future PTS. As far back as 1966, the Committee on Hearing and Bioacoustics (CHABA) attempted to establish a model that would define a relationship between TTS and PTS. In the words of CHABA, “If any single band exceeds the damage-risk contours specified, the noise can be considered as potentially unsafe” (Kryter et al., 1966).

For a number of reasons, CHABA made several assumptions to derive the damage-risk contours. One was that the recovery from TTS was only based on the magnitude—the larger the TTS, the longer it took to resolve. However, subsequent research demonstrated that recovery depended on both the duration and the sound level of the noise exposure (Melnick, 1991). Another erroneous assumption that was made is that an intermittent noise exposure with significant quiet periods was less damaging than a steady-state noise exposure. Again, for the purposes of the damage-risk contours, this assumption was shown to be false (Ward et al., 1976). It does appear that intermittent noise exposure does reduce hazard, but that is about all that can be said.

Some excellent research studies were performed in the 1980s and 1990s showing that there does not appear to be a high correlation between TTS and PTS. A person who demonstrates a large TTS after an exposure to noise or music is not any more nor any less susceptible to permanent hearing loss years later. TTS is simply not a predictor of PTS (Henderson et al., 1993). The association that can be made between TTS and PTS is that if a sound exposure is sufficient to cause a TTS (of any degree), then it is sufficient to cause a PTS (although not necessarily of the same magnitude as the TTS) (Melnick, 1991).

PTS and Some Historical Models

Between 1968 and 1973, there were a number of large-scale field studies on the relationship between noise exposure

TABLE 32.1**Summary of Five Studies on Predicted PTS (in dB) at 4,000 Hz for Three Exposure Levels**

	Passchier-Vermeer	Robinson	Baughn	NIOSH	ISO R-1999
85 dBA	8	6	9	5	6
90 dBA	15	12	14	11	11
95 dBA	23	18	17	20	21

and PTS (Baughn, 1973; Lempert and Henderson, 1973; Passchier-Vermeer, 1968; Robinson, 1971). The Passchier-Vermeer, Robinson, and Baughn studies formed the basis of the 1973 US EPA's Criteria Document and noted very little (average) PTS for exposures below 85 dBA if exposed for 8 hours a day for 40 years. It should be pointed out though that this average PTS was calculated for 500, 1,000, and 2,000 Hz. There was poor correlation for hearing loss at 4,000 Hz, especially for higher exposure levels.

The Lempert and Henderson (1973) study formed the basis for the NIOSH model and is in good agreement with the previous studies at lower exposure levels, but tended to predict a greater PTS (average of 500, 1,000, and 2,000 Hz) at higher exposure levels.

A more recent model is based on the International Organization for Standardization (ISO) standard R-1999 (1990) which appears to be in good agreement with the previous models. Indeed, "models such as ISO R-1999 are sufficiently accurate to support the needs of most regulators, administrators, and others who need rough predictions on the effects of noise on groups of workers" (Johnson, 1991, p 174). There are some criticisms of ISO R-1999 and these mostly revolve around the interaction between noise exposure and presbycusis. Rosenhall et al. (1990) showed that by age 79, there was no longer a difference between those who have been exposed to noise and those who had not. That is, eventually presbycusis becomes a more dominant factor.

Table 32.1 summarizes the PTS at 4,000 Hz for a number of models for three exposure levels of 85, 90, and 95 dBA. There are limited data available in large-scale databases for exposure levels below 85 dBA.

PTS and Exchange Rates

The exposure–response or dose–response (also known as the damage-risk contours from the 1966 CHABA document) refers to contours or "equal risk" of PTS for a given average sound level (dBA) for a given duration (hours). That is, a relationship exists between the average exposure in dBA and the length of exposure in hours. This relationship is called the exchange rate (or time–intensity trading ratio). A 3-dB exchange rate means that there is an equal risk if the sound level is increased by 3 dB but for only half the amount of exposure time; in other words, for each increase in sound level of 3 dB, the damage-

risk is doubled (and halved for an equivalent decrease of 3 dB). A 5-dB exchange rate implies that the risk is doubled for every 5-dB increase in exposure level. Table 32.2 shows the relationship for equivalent exposures for both a 3-dB exchange rate (NIOSH) and a 5-dB exchange rate (OSHA). Note that the 5-dB exchange rate is more "conservative" where there is a prediction of a lower risk at any given level and exposure time. When noise exposures are measured simultaneously using a 5-dB and 3-dB exchange rate, and all instrument settings are otherwise identical, the measurement made using the 3-dB exchange rate will always have an equal or higher average level than the measurement with the 5-dB exchange rate.

Equal Energy Hypothesis

The "equal energy hypothesis" is a concept that equal amounts of energy should produce equal amounts of hearing loss, regardless of the duration and variability of the exposure. The relationship of the PTS because of steady-state noise exposure with that of fluctuating noise exposure is complicated, but most researchers, basing their conclusions on the work of Martin (1976) and Robinson (1971), have argued that fluctuating noise can be equally hazardous as a steady-state noise

TABLE 32.2**Allowable Times Under NIOSH Recommendations and OSHA Regulations at Each Noise Level (in dBA)**

Noise Level (dBA)	T (hours)	
	NIOSH	OSHA
85	8	16
86	6.4	13.9
87	5.0	12.1
88	4	10.6
89	3.17	9.2
90	2.5	8
91	2	6.9
92	1.6	6.01
93	1.0	5.3
94	0.9	4.6
95	0.8	4

of equal energy. Proponents of the equal energy hypothesis would advocate for a 3-dB exchange rate; an increase of 3 dB equals a doubling of sound energy, and a decrease of 3 dB equals halving the sound energy. However, some researchers working in the realm of TTS studies (e.g., Ward et al., 1976) have argued that noises that produce equal amounts of TTS are equally damaging. Proponents of this point of view would advocate for a 5-dB exchange rate, which assumes regularly spaced recovery periods throughout the workday.

Embleton (1994), in reporting on the results of an International Institute of Noise Control Engineering Working Party paper, concluded that “the scientific evidence is that 3 dB is probably the most reasonable exchange rate for daily noise exposure. Statistically it is also a good approximation for the results of many epidemiological studies relating to intermittent exposures even though these show considerable spread about any mean curve” (p 18). It should be emphasized that these exchange rates are meant only to summarize data and they are necessarily an oversimplification of a very complex relationship.

NOISE STANDARDS AND THEIR HISTORY

The earliest regulations designed to protect workers' hearing from NIHL were adopted by the US armed forces as a result of the tremendous amount of NIHL suffered by US service members in World War II (Gasaway, 1985). The first recommended exposure limit (REL) was issued by the US Air Force (USAF) in 1948, followed by the first enforceable hearing conservation regulation (also by the USAF) in 1956 (Suter, 1988). The 1956 USAF regulation identified five aspects of hearing conservation which still form the basis of modern standards:

- Noise reduction efforts
- Measurement of noise exposure
- Education of workers
- Use of hearing protection
- Audiometric surveillance

These requirements evolved from research and recommendations made by CHABA (Suter, 1988). After initial development by the armed forces, several groups, most notably the American Conference of Governmental Industrial Hygienists (ACGIH), established RELs for the civilian workforce. In 1969, ACGIH issued a voluntary threshold limit value (TLV) for noise that represented a greatly simplified version of the CHABA recommendations (Suter, 1988). In 1969 the TLV was adopted by Occupational Safety and Health Administration (OSHA) under the Walsh-Healey Public Contracts Act, which applied to large federal contracts, and separately under the Federal Coal Mine Health and Safety Act (Suter, 1988). Then, in 1971, following the establishment of the OSHA, the Walsh-Healey exposure requirements were promulgated as a permissible exposure

limit (PEL) for noise in general industry and construction (Suter, 1988). This PEL remains in force today and specifies a TWA exposure limit (referred to as a criterion level, or L_C) of 90 dBA over an 8-hour workshift, with a 5-dB exchange rate (OSHA, 1981). The PEL requires that employers attempt to reduce noise exposures above 90-dBA TWA through noise controls, though subsequent OSHA policy interpretation effectively raised this level to 100 dBA. Workers exposed above the 90-dBA TWA limit must use hearing protection devices (HPDs), and hearing protectors are further required for exposures that exceed 115 dBA for 1 second or more. OSHA also recommends hearing protectors for exposures above 140 dB SPL regardless of duration. To provide further protection to noise-exposed workers, OSHA promulgated the Hearing Conservation Amendment in 1983, which requires employers to provide baseline and annual hearing conservation training to workers exposed above an action level of 85-dBA TWA, requires baseline and annual audiometric surveillance, and requires that workers exposed between 85 and 90 dBA be offered hearing protectors. OSHA's Hearing Conservation Amendment does not apply to workers in a number of industries, including agriculture, construction, oil and gas extraction, and offshore marine work. Miners are covered by an essentially equivalent PEL administered by the Mine Safety and Health Administration (MSHA), railroad workers fall under a similar regulation administered by the Federal Railroad Administration, and offshore workers fall under the jurisdiction of the US Coast Guard, which administers, though rarely enforces, a similar regulation.

The NIOSH, established in 1971, is tasked with conducting occupational health and safety research and recommending best practice exposure limits (as compared to OSHA, which uses public rulemaking to set mandatory exposure limits, and therefore must include factors such as economic feasibility in their rulemaking efforts). In 1972, NIOSH established a REL of 85-dBA TWA L_C with a 5-dB exchange rate (Suter, 1988). However, in 1998, NIOSH revised its REL to incorporate a 3-dB exchange rate, while retaining the 85-dBA exposure limit. This is consistent with the TLV for noise, which was updated to these same specifications in 1994. Both of these voluntary limits recommend that audiometry, noise controls, and use of hearing protection begin at TWA exposures of 85 dBA and may therefore be considered more protective than the OSHA regulation. The US Department of Defense, as well as the USAF, US Army, and US Navy, have all moved to exposure limits that are consistent with the current NIOSH REL and TLV. Individual states in the United States can opt to have state OSHA programs that administer regulations at least as protective as those promulgated by federal OSHA. None of the state OSHA programs have PELs or hearing conservation requirements that differ considerably from the federal OSHA programs, though several states, including Washington and Oregon, extend coverage to industries such as construction and agriculture.

Noise regulations around the globe are much simpler to describe. Virtually every high-income country in the world, and many medium- and low-income countries as well, has adopted exposure regulations that specify an 85-dBA TWA L_C and 3-dB exchange rate. For example, these limits are required in countries within the European Union. Outside of the United States, only a handful of countries—including Brazil and Israel—use regulations consistent with the OSHA PEL, or a mix of the OSHA PEL and NIOSH REL (e.g., an 85-dBA TWA exposure limit combined with a 5-dB exchange rate). A summary of US and worldwide noise standards and regulations can be found at http://sitemaker.umich.edu/neitzel/files/hearing_loss_references.pdf.

In addition to these regulatory and voluntary occupational exposure limits, limits have been recommended for the protection of public health. Specifically, both the US EPA (EPA, 1974) and World Health Organization (WHO, 1999) have recommended a 24-hour exposure limit of 70 dBA with a 3-dB exchange rate. This is equivalent to an 8-hour exposure at 75 dBA, with no noise exposure for the other 16 hours per day; note that this represents a strong and highly debatable assumption in modern societies. This 24-hour exposure limit is intended to protect against any hearing loss at 4,000 Hz among any exposed individual and can be considered truly “safe”—whereas many occupational exposure limits accept some level of excess risk of hearing loss (e.g., as many as one-third of workers with sound exposures at the OSHA PEL of 90-dBA TWA daily over a 40-year period are expected to sustain a material hearing impairment).

All noise regulations and standards specify—either implicitly or explicitly—methods to determine individual workers’ noise exposures. Such determinations can be simple, as is the case when comparing a measured TWA exposure level for a worker to the relevant exposure limit. However, when noise measurements are made with a sound level meter and involve exposures to different noise levels for varying periods of time, it becomes necessary to convert these noise levels and durations into an accumulated personal noise dose. This is done by comparing the ratio of exposure time (C) at each given level to the allowable time (T) at that level, as shown in the equation below:

$$\text{Dose}\% = 100(C_1/T_1 + C_2/T_2 + \dots + C_n/T_n)$$

Allowable times can be determined by referencing the relevant exposure standard: For compliance purposes, these times are located in Appendix A in the OSHA Noise Regulation (29 CFR 1910.95), whereas the NIOSH best practices recommendation can be found in Chapter 1 of the 1998 Criteria Document for Noise Exposure (DHHS/NIOSH report number 98-126, NIOSH, 1998). Example T values from each standard are based on the data in Table 32.2 presented earlier.

If a worker had an exposure of 4 hours at 95 dBA, 2 hours at 90 dBA, and 2 hours at 85 dBA over the course

of a workshift, the OSHA dose would be computed as follows:

$$\begin{aligned} \text{Dose}\% &= 100(4/4 + 2/8 + 2/16) \\ &= 100(1.0 + 0.25 + 0.125) \\ &= 100(1.375) \\ &= 137.5\% \end{aligned}$$

For comparison purposes, the NIOSH dose for the same exposure would be 605%.

Allowable times that are not specifically listed in the relevant standard can be computed directly using the equation below:

$$T = 480 \text{ minutes} / 2^{(L_p - L_C/ER)}$$

where L_C is the criterion level, L_p is the measured sound pressure level in dBA, and ER is the exchange rate (in decibels).

The dose value resulting from a dosimeter measurement or computed using the equation above can be computed into a TWA value using the equation below:

$$\text{TWA} = (ER / \log 2) \times \log_{10} (D/100) + L_C$$

where ER is the exchange rate, D is the dose, and L_C is the criterion level. In the case of the worker described earlier, the OSHA TWA (using a 5-dB exchange rate and 90-dBA L_C) would be 92.3 dBA, whereas the NIOSH TWA (using a 3-dB exchange rate and 85-dBA L_C) would be 92.8 dBA.

Reduction of Occupational Noise Exposures

Exposures can be reduced at three points: (1) The source where the noise is generated; (2) along the pathway the noise travels; and (3) at the receiver (a worker, in this case) (Figure 32.3).

In occupational health practice, and in public health generally, there is a traditional approach to reducing the risk of health effects from any environmental hazard, including noise. This approach is referred to as the “hierarchy of controls” and is displayed in Figure 32.4.

Adherence to the hierarchy of controls, which stresses source control as primary, followed by pathway treatments, followed by a focus on worker behavior, is a requirement of most occupational noise regulations. When workers are overexposed to noise, the hierarchy of controls dictates that the first approach should entail elimination of the noise source

FIGURE 32.3 Generic noise exposure pathway illustrating the three points at which noise levels may be modified. [Used with permission. Courtesy of the Musicians’ Clinics of Canada.]

Elimination	Most reliable and desirable
Substitution	↑
Engineering controls	
Administrative controls	↓
Personal protective equipment	Least reliable and desirable

FIGURE 32.4 Industrial hygiene hierarchy of exposure controls.

where possible—thereby eliminating the overexposure. Where elimination is not possible, substitution should be attempted—in other words, replacement of the high noise source with another lower noise source. Noise from sources that cannot be replaced should be minimized through the use of engineering controls, that is, changes to the source (e.g., addition of mufflers) or to the pathway between the sources and the exposed worker (e.g., addition of source or worker enclosures or addition of sound-absorbing coatings or materials to walls and ceiling). Where engineering controls are not sufficient to control exposures, administrative controls can be used to alter the timing or duration of the exposure. Examples of administrative controls include conducting noisy operations when and where few workers are nearby and establishing limits on exposure durations. Finally, when all of the above steps have been attempted, and excessive exposures persist, use of personal protective equipment is needed. Note that this is the last and least desirable approach to exposure control, because it relies on workers having access to protective equipment (HPDs, in the case of noise) as well as knowing when and where to use the equipment and how to use it properly. In the United States, many noisy workplaces do not follow the hierarchy of controls and instead depend on HPDs to reduce workers' exposures. This reliance on the least effective approach to exposure reduction is likely at least part of the reason that tens of thousands of US workers suffer hearing loss each year and why NIHL continues to be one of the leading occupational diseases in the United States (<http://www.bls.gov/news.release/pdf/osh.pdf>, accessed August 14, 2013).

NOISE AND ITS EFFECTS ON THE EAR: TTS AND PTS

TTS

TTS is understood to result from a variety of reversible physical changes in the cochlea, including broken tip links between OHC stereocilia, loss of contact between the stereocilia and the tectorial membrane, swelling of auditory nerve fibers because of overrelease of neurotransmitter from the IHC, and reduction in cochlear blood flow (Henderson et al., 2006). With adequate recovery time with sound exposure no higher than 76 to 78 dBA (Melnick, 1991), many of these physical changes reverse and hearing sensitivity returns

to pre-exposure baseline. TTS is understood to behave in a fairly uniform manner, in that it grows to an asymptotic degree over the course of 8 to 10 hours, and the degree of TTS is a function of the level of the sound and the frequency spectrum. As well, the recovery from TTS follows a predictable pattern (an exponential decay in threshold shift over time), so long as the individual is in an environment less than 76 to 78 dBA (“effective quiet”) and the degree of TTS is not greater than 30 dB (Melnick, 1991).

New perspectives on TTS have surfaced suggesting that this condition is not entirely benign. Kujawa and Liberman (2006) compared hearing thresholds in quiet-reared mice (control group) and mice that were exposed to noise sufficient to cause a large TTS, but were confirmed to have no PTS. The inbred mouse strain used in this experiment was chosen because they demonstrate considerably less variability in susceptibility to NIHL as compared to outbred mice and because they tend to maintain good hearing sensitivity into more advanced age. Those mice with early noise exposure (sufficient to cause 40 dB of TTS 2 weeks after the noise exposure, relative to the control group) showed markedly poorer hearing thresholds near the end of their lifespan compared to the quiet control group. The study concluded that the site of lesion of this accelerated age-related hearing loss was neural, rather than cochlear. The implications are that although hearing thresholds may recover to normal levels following a TTS, permanent loss of auditory nerve fibers may have occurred and the consequences will be seen later in life. It is important to note, however, the degree of TTS induced in these mice was just below the exposure necessary to cause a PTS (from acoustic trauma). It is not yet known how these results translate to humans, particularly when the TTS is of a much less significant degree.

PTS

The interested reader is referred to “The role of oxidative stress in noise-induced hearing loss” by Henderson et al. (2006) for a detailed review of the processes that direct cochlear hair cell death and resultant PTS.

As noted previously, PTS is the remaining hearing loss following incomplete recovery from TTS. When this occurs following long-term exposures to moderately intense sound, the primary site of lesion is the OHCs. It is thought that the OHCs are vulnerable because of their high metabolic activity associated with electromotility. Overexposure to noise results in a metabolic challenge to these cells, and the mitochondria of the OHC use large amounts of oxygen to keep up with the energy demands, and consequently a large amount of reactive oxygen species (ROS) by-product are produced. Unwanted ROS by-products, such as superoxide (O_2^-), are free radicals (molecules with an unpaired electron), which are highly reactive and scavenge for electrons from other molecules in the neighborhood. These free radicals

are capable of breaking down lipid and protein molecules in the cells and damaging the cell's DNA (Henderson et al., 2006).

When there is a massive acoustic or chemical insult, cells may die through a passive process of cell death termed necrosis. In necrotic hair cell death, cells swell and rupture, and the contents of the ruptured cell cause an inflammatory response in neighboring cells. The consequence tends to be widespread cell death that continues hours or even days after the resolution of the insult. This tends to be the process of cell death associated with acoustic trauma.

When an overexposure occurs that results in ROS production sufficient to do irreparable damage that will result in the cell's death, an organized process of the cell disassembling may be triggered. This organized process, known as apoptosis, is part of normal development and is important in vital aspects of life, such as maturation (e.g., pruning of redundant neuronal connections) and in the body's defense against cancer cells. Overabundance of ROS results in oxidative stress which triggers a cascade of intracellular events, including release of cytochrome *c* from mitochondria and activation of enzymes known as caspases, which cause fragmentation of the DNA in the cell's nucleus (Matsui and Cotanche, 2004). Throughout this process, the cell wall remains intact, and as the cell breaks apart, it is either ejected from the basilar membrane or engulfed by neighboring cells. The contents of the cell are not spilled, minimizing inflammatory responses of other cells, and damage is minimized.

When the hair cells die, they are replaced with supporting cells, which maintain the integrity of the basilar membrane, but do not contribute to the active process of electromotility. Humans are born with a full complement of roughly 12,000 OHCs and 4,000 IHCs in each cochlea, but once these cells die, they do not regenerate. A considerable number of OHCs tuned to a specific frequency may die without a change in the threshold of puretone detection (i.e., hearing threshold on the audiogram). Once enough OHCs in a specific frequency region have died, hearing sensitivity in that region decreases, permanently. With continued exposure, continued damage to OHCs progresses. It is believed that once exposure ceases (for instance, terminating employment at a noisy job), the degree of NIHL stabilizes. However, the loss of hair cells is cumulative throughout lifetime, and consequently, so is the degree of hearing loss.

NIHL is typically bilateral and symmetrical, because in most circumstances, the soundfield of exposure is typically diffuse. Only in rare situations, for instance, shooting a firearm braced against the shoulder or using a tool or instrument very close to only one ear, might a sound exposure be considerably higher on one side of the head compared to the other. In these rare situations, an asymmetric NIHL could occur. Unexplained asymmetries in presumed NIHL should trigger referral to appropriate medical professionals

for evaluation of possible sinister causes, such as autoimmune disorder or eighth nerve tumor.

NIHL from Single Events: Acoustic Trauma

Very high level acoustic events, such as explosions, can result in immediate, permanent damage to the cochlea and to the middle ear. The acoustic parameters dictating the degree of hearing loss do not follow standard damage-risk or exposure-dose. There is not an established "dose" of high-level transient noise equating hearing loss risk with level over time. Single marked overdoses (such as 105 dBA for 6 hours, which is roughly 7,600% noise dose by the NIOSH REL) can result in immediate PTS (Henderson et al., 1993) and so do not follow the expected cycle of TTS growth to TTS recovery; there is incomplete recovery, leaving a PTS. Nonetheless, certain acoustic properties of very high level sound are understood to influence the type and degree of auditory damage.

When an acoustic trauma triggers necrotic cell death in the cochlea, the resulting audiogram may show a 4,000-Hz notch or may have a flat configuration or steeply sloping high-frequency hearing loss. Both OHC and IHC may be affected, as well as damage to supporting cells and the tectorial membrane as a result of the pressure wave traveling through the cochlea exceeding the tissue's elastic limit. The resulting mechanical damage could leave holes between the cochlear partition, allowing perilymph and endolymph to mix, causing widespread destruction. Tinnitus is a very common concomitant injury in acoustic trauma and is often more distressing than tinnitus that builds gradually with long-term progression of NIHL. This is particularly true if there is a psychologic component associated with the event, such as post-traumatic stress disorder (Fausti et al., 2009).

Although OSHA mandates that no single unprotected sound exposure should exceed 140 dB SPL (OSHA, 1983), there is evidence that suggests a much lower "critical level" of 132 dB SPL for threshold of acoustic trauma in highly susceptible individuals (Price and Kalb, 1991). Below this threshold of acoustic trauma, it is believed that NIHL risk is predicted by the established damage-risk criteria (DRC). Between the critical level for acoustic trauma and 170 to 180 dB peak SPL, the cochlea bears the greatest brunt of damage. For higher sound levels, the eardrum may rupture and/or the middle-ear ossicles are disarticulated. When damage occurs in the middle ear, significant energy is dissipated before it reaches the cochlea and considerably less cochlear damage may occur. Thus, peak sound pressure levels between 132 and 140 dB peak SPL and below 170 to 180 dB peak SPL result in greater cochlear damage, and levels above 170 to 180 dB peak SPL result in less cochlear damage, but do result in middle-ear damage (Fausti et al., 2009; Liang, 1992).

Otoprotectants and Reactive Oxygen Species

Antioxidants are molecules present in the body that have an extra electron which can be donated to the free radical. Donating this electron converts the free radical into a less dangerous molecule, thus neutralizing the potential for damage. Naturally occurring antioxidants provide a balance with ROS within the body's systems, unless a pathologic process causes a marked increase in the production of ROS (resulting in apoptosis, or worse, necrosis). Antioxidants can be increased endogenously, such as through exposure to moderate sound conditioning; exposure to sound that causes modest TTS can reduce the degree of future PTS from acoustic trauma (Henderson et al., 2006). The fact that antioxidants can be increased endogenously suggests that they can also be caused to be increased exogenously, such as with drug therapies.

There is now an aggressive search for otoprotectant compounds which can increase antioxidant production and prevent or disrupt the cascade of cell death from noise exposure. Several compounds have been identified as being effective in reducing or eliminating PTS in animal models, such as *n*-L-acetylcysteine (LNAC) in concert with salicylate, D-methionine (DMET) (Henderson et al., 2006), and a combination of dietary supplements (beta-carotene, vitamin C, vitamin E, and magnesium; "ACEMg") (Le Prell et al., 2007). Clinical trials are currently underway to determine if any of these compounds are safe and efficacious in humans. In the not too-distant future, there may be pharmaceutical interventions that either reduce the degree of PTS following a noise event or eliminate PTS altogether.

NIHL FROM LONG-TERM EXPOSURES: NIPTS PREDICTION AND POPULATION FRACTILES

As noted previously in this chapter, there is wide variability in the degree of hearing loss sustained across a noise-exposed population; the observed differences are due to differences in individual susceptibility to NIHL, which are due to both exogenous and endogenous reasons (Henderson et al., 1993). Population fractiles (i.e., fractions of a population) are used to describe the variability in susceptibility across individuals in an exposed population. The median NIPTS risk is defined as fractile of 0.5 (i.e., one-half of individuals noise-exposed have greater hearing loss, and one-half have less hearing loss). The 0.1 fractile describes the population of highly susceptible individuals (only 10% of the exposed population has greater hearing loss; 90% has less hearing loss). The 0.9 fractile describes very low susceptibility (90% of the exposed population has greater hearing loss; 10% has less hearing loss). The American National Standards Institute (ANSI) and the ISO have mathematical

models that allow one to calculate the predicted degree of NIPTS at each audiometric frequency for given exposure levels (dBA TWA) and given exposure duration (in years) for various fractiles of the population (ANSI S3.44-1996; ISO 1999:1990). These models were developed from the seminal studies of noise-exposed workers and observed degree of NIPTS (e.g., Lempert and Henderson, 1973).

From these mathematical models of predicted NIPTS, the percent of individuals whose hearing loss exceeds a level deemed a "hearing handicap" or "material hearing impairment" can be calculated. For this purpose, material hearing impairment is defined as the maximum acceptable hearing loss. This percent of an exposed population with a "material hearing impairment" or greater is the excess risk of NIHL from a given exposure. For instance, using a material hearing impairment defined as average hearing thresholds at 500, 1,000, and 2,000 Hz of >25 dB HL in both ears (i.e., the three-frequency puretone average hearing loss), NIOSH (1974) estimated that 40 years of 8-hour TWA to 80, 85, and 90 dBA would result in 3%, 15%, and 29% excess risk, respectively. In other words, 29% of workers exposed to 90 dBA TWA for 40 years would have three-frequency puretone hearing loss (500, 1,000, 2,000 Hz) greater than 25 dB HL. A reanalysis of risk estimates from the Lempert and Henderson (1973) data, defining material hearing impairment as a four-frequency average hearing loss >25 dB HL (frequencies 1,000, 2,000, 3,000, and 4,000 Hz weighted according to the articulation index), showed excess risk of 1.2%, 7.6%, and 22.3% for 40 year, 8-hour TWAs of 80, 85, and 90 dBA, respectively. In summary, NIOSH REL and ACGIH TLV of 85-dBA TWA, not to mention OSHA and MSHA PEL of 90-dBA TWA, are not *safe*. Some people with high individual susceptibility exposed to these "protected" levels will develop NIHL. Still, these recommendations (NIOSH, ACGIH) and regulations (OSHA, MSHA) are *safer* than no limits at all.

NONAUDITORY EFFECTS OF NOISE EXPOSURE

Nonauditory effects of noise exposure are those effects that do not cause hearing loss. Some of these are seen by changes in body functions, such as heart rate, and in learning/cognition in children, and sleep disturbances (Goines and Hagler, 2007). Nonauditory effects of noise exposure have been noted as far back as 1930 (Smith and Laird, 1930). In that specific study, nonauditory effects pertain to stomach contractions in healthy human beings when exposed to noise.

In the past 25 years, an increasing body of evidence has connected occupational and community noise exposures to a wide range of adverse health effects. These range from cardiovascular disease and sleep disturbance—effects which likely have a substantially larger public health impact than does NIHL—to stress, annoyance, and cognitive effects,

including learning disorders among children (van Kamp and Davies, 2013). A more complete overview of this area with the relevant historical references can be found in the appendix at the end of the book.

MUSIC AS NOISE

People recognize that the military and industry are high noise sources. In the military, there is equipment such as tanks, jet aircraft, and other heavy machinery, and personnel are exposed to rifle fire and explosions (in training and combat). Thus, noise exposure is an ongoing risk. In industrial settings, heavy equipment, machinery, printing presses, and so on, also create an environment in which individuals may be exposed to hazardous noise levels. However, it is more difficult for the average person to recognize that everyday noise may be a contributing factor in the development of NIHL.

Musical instruments also have the capability to generate high levels of sound both at the location of the musicians' ears and at the ears of their other musician colleagues who have the bad fortune to sit downwind. Unlike "noise" (the unwanted by-product of another activity), music is the purpose of the activity which is generating sound that may be potentially harmful. Table 32.3 is adapted from Chasin (2006) and shows a selection of sound levels measured on the horizontal plane and at a distance of 3 m. Also shown is the sound level (dBA) of the violin measured near the left ear. These data are based on over 1,000 measurements with the top and bottom 25th percentiles removed.

For nonmusicians (and musicians), a significant source of noise exposure outside of occupational and military environments is from "portable" music exposure. "Portable music" such as portable digital music players (MP3 players), as the name suggests, can be used in noisy environments

such as city streets where ambient noise masks the music if earphones provide no sound isolation for the listener. The MP3 player user turns the volume control up to achieve a chosen (or preferred) listening level. In these situations, the most comfortable listening range is at a higher sound level than in quieter or in more controlled environments (Fligor and Ives, 2006; Portnuff et al., 2011).

Since the introduction of the first Walkman-style cassette player, numerous studies have reported potential for NIHL from using portable music inappropriately (Fligor and Cox, 2004; LePage and Murray, 1998; Portnuff et al., 2011; Rice et al., 1987; Turunen-Rise et al., 1991). Fligor and Cox (2004) reported that all evaluated commercially available portable CD players produced sound levels that could easily exceed DRC (with equivalent-continuous levels up to 121 dBA) if the user chose levels near maximum. As well, these levels depended on the earphone that was used. For example, with certain earphones, the outputs were 7 to 9 dB higher than the same CD player with the manufacturer-supplied earphone. Peak SPLs in the music (percussion transients) were found in excess of 130 dB SPL at the highest volume control setting. In general, Fligor and Cox (2004) found that greater outputs were produced when using physically smaller earphones. Fligor and Cox (2004, p 513) concluded that "based... on the noise dose model recommended by the National Institute for Occupational Safety and Health (NIOSH) for protecting the occupational worker, a maximum permissible noise dose would typically be reached within 1 hour of listening with the volume control set to 70% of maximum gain using supra-aural headphones." In the interest of providing a straightforward recommendation, they state, "reasonable guidelines would [be] to limit headphone use to 1 hour or less per day if using supra-aural style headphones at a gain control setting of 60% maximum" (p 513).

Similar results have been obtained with other music media such as MP3 players—the potential for music-induced hearing loss based on models of noise exposure is quite real, and the output is related not only to the setting of the volume control and duration of listening, but also to the nature of the earphone/earbud that is used. Portnuff et al. (2011) measured output levels of MP3 players and recommended a reasonable guideline for mitigating hearing loss risk from music listening on these devices was to limit use to 90 minutes per day with the volume control set to 80% of maximum or lower, using the earbud headphone that came with the device. Contrary to what one might expect, the output levels of MP3 players (Portnuff et al., 2011) were consistently lower than the output levels of CD players (Fligor and Cox, 2004). However, extended battery life and nearly infinite length of music playlists might give an MP3 player user the capacity to listen much longer than was convenient with a CD player. Level-over-time guidelines (such as "80 for 90") might provide users with an "acoustic speed limit" for using headphones with less risk than not having guidelines for safer listening.

TABLE 32.3

Average Sound Levels of a Number of Musical Instruments Measured from 3 Meters

Musical Instrument	dBA Ranges Measured from 3 m
Cello	80–104
Clarinet	68–82
Flute	92–105
Trombone	90–106
Violin	80–90
Violin (near left ear)	85–105
Trumpet	88–108

Also given is the sound level for the violin measured near the left ear of the players. Adapted from Chasin M. [2006] Music and hearing aids. *Hear Rev.* March, 34–41. Courtesy of the *Hearing Review*.

Fligor and Ives (2006) showed in adults, and Portnuff et al. (2011) showed in teenagers, that a small but significant percent of MP3 player users chose listening levels in quiet that exceeded 85 dBA, and that the chosen listening levels were the same for the individual subject regardless of the type of earphone (e.g., earbuds vs. over-the-ear vs. in-the-canal). As ambient noise increased, so did the percent of people who chose levels in excess of 85 dBA (as many as 80% of people chose levels in excess of 85 dBA in a simulated commercial airplane cabin when using both earbuds and over-the-ear headphones). This ambient noise masking problem was consistently managed when subjects used earphones engineered to attenuate ambient sound. They concluded that it is not the absolute level that earphones could produce at maximum volume control, but the ambient level that dictates riskier listening behavior, and sound-isolating earphones reduced the need for choosing levels that put hearing at risk.

Acoustic Trauma and the Musician

In addition to the overall long-term music exposure for musicians, exposure may include feedback squeals during sound checks, inappropriately set limiters, percussive blasts from cannons, and being stuck in front of a large stack of speakers for an extended performance. Whereas there is scant research in the literature on the effects of single-trauma impulses in music venues, hearing loss has been confirmed clinically where the source was a single or relatively short-duration blast. Reports of hearing loss because of long-term industrial noise exposure are numerous and, in some ways, better controlled because musical environments are often much more poorly defined. Most musicians serve as independent contractors and could not easily be tracked with baseline and annual audiometry in a hearing conservation program. In addition, unlike a worker in an industrial setting, musicians (and avid music consumers) may be subject to damaging levels of music exposure in their off-work hours.

HEARING PROTECTION DEVICES

History of HPD and How the NRR Evolved

The first commercially available HPD was the V-51R pre-molded hearing protector, introduced in 1945 (Humes et al., 2005). The HPD market was slow to develop, however, and following the introduction of this device, only a few types of HPDs were available through the 1960s (Gasaway, 1985). In the 1970s, a wider variety of earplugs and earmuffs became available, including the roll-down slow-recovery foam earplug and other devices made of newly introduced materials. HPDs continued to improve in the 1980s and 1990s with the introduction of minor technological and cosmetic

changes that increased comfort but did not result in appreciably improved performance. Since 2000, HPD technology has advanced substantially, with the introduction of passive as well as electronic “level-dependent” HPDs that provide variable levels of attenuation depending on the external exposure level (Humes et al., 2005). The market has continued to grow, as well, with more than 300 models of HPD available in the United States in 2003 (NIOSH, 2003).

The attenuation that earplugs provide users can be measured in a variety of ways. In the United States, all non-custom HPDs are required by law to be labeled with a noise reduction rating (NRR), a single-number rating (SNR, in decibels) of the amount of protection a trained user can expect to receive while wearing a specific HPD. The NRR was established by the US EPA in 1979 through a rule titled “Noise Labelling Standards for Hearing Protection Devices” (<http://www.gpo.gov/fdsys/pkg/FR-2009-08-05/pdf/E9-18003.pdf>, accessed August 24, 2013). Prior to this regulation, there had been no requirement for standardized testing procedures and labeling approaches for HPDs, and adoption of the rule created a powerful new tool by which users could compare attenuation across different HPDs. The NRR is a simplified interpretation of the expected performance of a given HPD across seven different frequencies between 125 and 8,000 Hz when the protector is fit on a trained user by an experimenter under laboratory test conditions. The NRR is computed from test data taken across multiple test subjects, and then subtracts twice the standard deviation around the mean attenuation at each frequency to account for individual user variability. This subtraction exercise is intended to result in an NRR that can be achieved by 98% of users of the HPD in question.

While the NRR labeling requirement benefits consumers, the NRR itself has been heavily criticized. A large body of research on attenuation achieved by actual users in work settings—as opposed to trained test subjects in a laboratory setting—is substantially lower than the NRR suggests (Berger, 2000) and often bears little relation to the labeled value. These differences stem from a variety of causes, most notably poor hearing protector fit among users in field studies. Differences between the NRR and field measurements of attenuation are generally smaller for earmuffs than for earplugs, as earmuffs are generally much easier to fit correctly. EPA has acknowledged the limitations with the current approach to measuring and labeling NRRs and has for some years been considering an update to the NRR regulation.

Computation of Attenuated Exposure

Whereas attenuation with a given HPD is known to vary widely across individuals, use of the NRR to estimate the attenuated (e.g., underneath the HPD) noise exposure for workers is nevertheless common. The nominal approach for computing attenuated noise exposures for workers whose

A-weighted TWA noise level is known is shown in the equation below:

$$\text{Nominal attenuated exposure (dBA)} = \text{TWA(dBA)} - (\text{NRR} - 7)$$

The 7-dB value in the equation is a spectral correction factor required to account for differences in the way noise is measured during the NRR test (using dBC) versus measurements made in the workplace (using dBA).

The equation above can be applied to TWA values measured according to either the OSHA PEL (using a 90-dBA L_C and 5-dB exchange rate) or the NIOSH REL (using an 85-dBA L_C and 3-dB exchange rate). However, this equation does not take into account variability in achieved attenuation, but rather assumes that all users of a hearing protector will achieve the labeled NRR. As described above, this is an unrealistic expectation. There are two approaches for accounting for expected differences between labeled and achieved attenuation. The first is recommended by OSHA and involves derating the labeled NRR of a HPD by 50%:

$$\begin{aligned} \text{OSHA attenuated exposure (dBA)} \\ = \text{TWA (dBA)} - [(\text{NRR} - 7) \times 50\%] \end{aligned}$$

The second approach is recommended by NIOSH and assumes patterns in achieved attenuation by the type of HPD used:

$$\begin{aligned} \text{NIOSH attenuated exposure (dBA)} \\ = \text{TWA(dBA)} - (\text{NRR}_d - 7) \end{aligned}$$

where NRR_d is the derated NRR for the type of earplug being considered. NIOSH's recommended deratings involve subtracting 25% of the NRR for earmuffs, 50% for foam earplugs, and 70% from all other earplugs. So, as an example, if a worker uses a foam earplug with an NRR of 30 dB, the NIOSH NRR_d would be $30 - (30 \times 70\%) = 9$ dB.

Workers with very high exposures (>100- or 105-dBA TWA) should be fitted with dual protection, that is, a pair of earmuffs over earplugs. The general rule of thumb for estimating attenuation for dual protection is to add 5 dB to the attenuation of the HPD with the higher NRR (NIOSH, 1998).

Whereas the NRR is the required standard for testing and labeling HPDs in the United States, there are other standards in use around the world. Common testing and labeling schemes include the SNR (used in the European Union) and the sound level conversion (SLC_{80} , used in Australia and New Zealand). There are several differences between the NRR, SNR, and SLC_{80} , including the fact that the NRR calculation subtracts 2 SD to account for user variability, whereas the other two schemes subtract only 1 SD, and that the test frequencies are somewhat different. The SNR rates protectors for specific types of noise environments, with different ratings for high-frequency (H), mid-frequency (M), and low-frequency (L) spectra. The SLC_{80} value is used to assign a classification to the tested HPD. For example, class 1 is valid for use up to 90 dBA, class 2 to 95 dBA, and so on (Williams, 2012).

Acoustics of HPD

The application of the laws of acoustics as applied to HPDs is similar to those found in the realm of hearing aid acoustics, classroom acoustics, music acoustics, or the larger area of architectural acoustics. For the purposes of HPD, these laws can be described as (1) wavelength phenomena, (2) Helmholtz/volume-related phenomena, and (3) mass and density characteristics. Wavelength-related characteristics can be seen in the degree of attenuation across the frequency spectrum whereas Helmholtz/volume-related characteristics tend to be relegated to a rather narrow spectral region, such as at a resonance. Like wavelength phenomena, mass and density characteristics can be observed over a wide range of frequencies.

All vibrations in air, whether noise, speech, or music, exhibit compressions and rarefactions of the air molecules. The degree of vibration of the movement of the air molecules is related to the amplitude of the vibration. And HPD serves to reduce the amplitude of the molecular vibrations. Because of the three acoustic features mentioned above, this sound reduction is not necessarily uniform across the frequency spectrum.

WAVELENGTH-ASSOCIATED PHENOMENA

With HPDs wavelength phenomena are related to the physical dimensions of the obstruction—longer low-frequency wavelengths do not acoustically “see” the obstruction as well as the shorter high-frequency wavelengths. A HPD, whether it is an earmuff, an earplug, or any other obstruction in the room or in the ear, will therefore provide less attenuation for the lower frequency sounds than for the higher frequency sounds. HPDs are inherently poor at attenuating the longer wavelength, low-frequency sounds and are inherently better at attenuating the shorter wavelength, high-frequency sounds.

This same line of reasoning explains why the attenuation characteristics of audiometric sound booths provide greater attenuation for higher frequency sounds than lower frequency ones. Because of the density and diameter of the sound booth walls, greater attenuations can be provided than head-worn HPDs which are relatively light. Figure 32.5 shows the attenuation characteristics of a well-fit earmuff-style HPD exhibiting the attenuation differences across the frequency range, as well as the attenuation provided by a commercially available audiometric sound booth.

Understandably, the attenuation characteristics of many HPDs that are the result of wavelength phenomena can be problematic. There can be significant low-frequency energy in an industrial noise spectrum, yet this is where HPDs provide the least amount of hearing protection. And with the greater degree of high-frequency sound attenuation many speech cues that contribute significantly to speech intelligibility can be lost. To a certain extent, it is understandable

FIGURE 32.5 Attenuations of an earmuff-style HPD [dark gray] as well as the attenuation of a commercially available audiometric test booth [light gray] for comparison purposes.

that many industrial workers prefer to remove their HPDs when trying to communicate, thereby reducing their effectiveness. Unless specifically modified, HPDs can also have limited acceptability with listening to and playing of music: the lower frequency fundamental notes may be quite audible, but the higher frequency harmonic structure can be lost.

HELMHOLTZ/VOLUME-ASSOCIATED PHENOMENA

Unlike wavelength-associated phenomena which affect a wide range of frequencies, albeit greater in the upper range, Helmholtz/volume-associated phenomena tend to be restricted to a narrow range of frequencies. Resonant chambers can be created within a HPD that either offsets the attenuation (as a resonance) or adds to the attenuation (as a side branch resonator). These additional chambers, depending on their size and location, can significantly alter the attenuation characteristics of HPDs. As will be discussed in a later section, these resonances can be used to minimize the amount of attenuation in the higher frequency region, thereby creating a HPD with a more uniform (or frequency-independent) attenuation characteristic.

MASS AND DENSITY CHARACTERISTICS

As discussed above, the greater the density and the mass of the HPD, the greater the overall attenuation. HPDs made of cotton will have less overall attenuation than those made of polymeric foam or silicon. From an ergonomic perspective, there is a natural upper limit to the mass of the HPD since this may cause discomfort over an extended wearing period.

Earmuffs and Earplugs

There are two major categories of HPDs: Earmuffs that fit over the ear and earplugs that fit into the ear canal. Both

are similar in that they both provide obstruction of sound resulting in attenuation of the noise or music to a level that is less damaging. Earmuffs can have greater mass and density and therefore can provide more overall attenuation than earplugs, especially in the mid- to lower frequency range; nonetheless, well-fitted, deeply seated earplugs can still provide near-maximum amounts of attenuation.

Earmuff-style HPDs, because of their larger size, can incorporate a wider range of acoustic and electronic options such as two-way communication system. However, both earmuffs and earplugs can incorporate many acoustic modifications that can significantly alter their attenuation characteristics. Some of these will be discussed under the heading of uniform attenuation HPDs.

One essential difference between the two styles is that the earmuff-type HPDs do not destroy the natural ear canal resonance which occurs at approximately 2,700 Hz. The attenuation of this type of HPD is therefore given by the attenuation of the earmuff, offset by the natural 15- to 20-dB amplification caused by an unoccluded ear canal. In contrast, earplugs that are located in the ear canal do not have this offset. The ear canal resonance does not offset the attenuation because it has been interrupted by the insertion of an earplug, much like an occluding hearing aid can result in an insertion loss. A schematic of the ear canal is given in Figure 32.6 showing the quarter wavelength standing wave that corresponds to the 2,700-Hz resonance. If there is an obstruction in the lateral end (marked B) where the earplug HPD is situated then this natural resonance will be interrupted, thereby resulting in more relative attenuation at 2,700 Hz than with an earmuff HPD. Obstructions located near the medial end (marked A) will result in minimal attenuations.

FIGURE 32.6 A schematic of the ear canal showing the quarter wavelength standing wave that corresponds to the 2,700-Hz resonance. If there is an obstruction in the lateral end [marked A] where the earplug HPD is situated then this natural resonance will be interrupted, thereby resulting in more relative attenuation at 2,700 Hz than with an earmuff HPD [which is positioned closer to position A]. [Used with permission. Courtesy of the Musicians' Clinics of Canada.]

Subsequently, if one were to normalize the attenuation characteristics of an earmuff HPD and an earplug HPD, there would be less relative attenuation in the 2,700-Hz region with earmuffs versus earplugs.

Maximum Attenuations

As the air-conduction pathway is maximally disrupted by HPDs, the bone-conduction pathway sets a ceiling for maximum attenuation. This ceiling imposed by sound traveling via bone conduction is frequency specific; for instance, maximum attenuation at 2,000 Hz is roughly 40 dB (Berger et al., 2003). This has implications for the fitting and assessment of HPD and may influence the method of HPD evaluation.

Poor HPD Fittings

Like anything that is added to the human body, there may be a poor fit. This may be inherent in the design of the HPD (noncustom fit) or related to how it is worn by the worker or musician. Because of the acoustic characteristics of HPDs workers may partially lift, or loosen the HPD off, or from their ear(s) in an attempt to improve communication with their worker colleagues. This will certainly improve the speech intelligibility since there will be improved audibility of the higher frequency consonant sounds.

The drawback of this removal is the creation of a slit leak or venting route in the HPD. This has the same effect as venting does for hearing aids: There will be less low-frequency attenuation for the HPD. Since many forms of occupational noise have significant energy in the lower frequency region, this partial removal may be quite detrimental to the long-term hearing of the worker. Low-frequency sound will enter the ear directly through the vent, bypassing the HPD. In addition, the existence of a vent (intentional or otherwise) may have deleterious effects on the other “tuned” acoustics in the HPD. One solution to the problem of a worker intentionally removing the HPD for improved communication would be the use of an electronic two-way communication system.

In a musical venue where there may only be intense high-frequency sound energy (such as being downwind of a cymbal), the intentional use of a vent in a HPD can be quite useful. These modified (and usually custom-made) vented/tuned earplug HPDs can be designed to provide minimal attenuation below 1,000 Hz (Chasin, 2006).

A common form of “unintentional” venting of earmuff HPDs is seen as the result of eye protection. Many protective goggles and other eye-wear can cause unintentional slit leaks where the arm of the eye-wear meets the cuff of the earmuff HPD. Protective eye-wear can be designed with very small, almost thread-like arms that will not significantly compromise the attenuation characteristics of the HPDs.

Uniform Frequency (“Flat”) Attenuators

As noted previously, solid earplugs inserted into the ear canal disrupt the normal ear canal resonance. When maximum attenuation is necessary, such as in very high noise situations, this disruption is beneficial, as it results in the greatest attenuation in the frequency range where the ear canal would amplify the most dangerous sounds. However, maximum attenuation is often not a desired outcome of HPDs. When hearing auditory signals is important for safety (e.g., hearing a back-up alarm on a forklift), too much sound isolation increases risk for industrial accidents. When individuals need to communicate verbally, loss of ear canal resonance has a disproportionate impact on reduction in speech intelligibility; some of the most important speech cues are between 2,000 and 3,000 Hz. Mishearing a verbal command can also increase risk of accidents. These are some reasons earplugs are not inserted properly; workers may feel they need better situational awareness, and reducing low-frequency attenuation is in fact safer (not for their hearing, but for the rest of their body).

When the potentially hazardous sound is being produced purposely (such as music), rather than as an unwanted by-product of using machinery (such as drilling), earplugs that reduce normal acoustic cues make HPD unusable. Further, there are acoustic properties of music, such as the relative sound level between the first, second, and third harmonics of a musical note, that contribute significantly to positive attributes of the music, such as pitch and timbre. These properties are partly what make a piano sound like a piano, a clarinet sound like a clarinet, and a guitar sound like a guitar; the same musical note (for instance, A above middle C) played on different instruments is immediately distinguishable as being played by those different instruments. Musicians listen across the frequency range to monitor the quality of their performance, and introducing distortions (such as less attenuation in low frequencies and more attenuation in high frequencies, thus changing the relative level differences between a fundamental and harmonics) interferes with the musician’s ability to perform. In the musician’s competitive world, where consistent, perfect performance is a prerequisite for steady income, anything that interferes with performance is unacceptable.

One approach to improve acceptance of HPD in musicians are custom-fitted earplugs that are intended to provide a modest amount of uniform attenuation across a wide range of frequencies. The earliest forms of uniform attenuating earplug, intended for use by musicians, were Musicians Earplugs™ (MEPs) (Etymotic Research, Elk Grove Village, IL). Production of MEPs began when a need for improved acceptability of HPD was established with the Chicago Symphony Orchestra (Royster et al., 1991). These earplugs, by design, reduce sound levels by an intended 9,

15, or 25 dB (ER9, ER15, and ER25, respectively) and are composed of two components: The filter (which designates the amount of sound reduction—9, 15, or 25 dB down) and a “sleeve” which is custom fitted from an earmold impression and made of vinyl, acrylic, or silicone. MEP attenuations of 9 and 15 dB are modest, acknowledging that many musicians have significant sound exposures, but the levels and/or weekly duration may not necessitate higher levels of attenuation for the musician to receive less than a 100% noise dose (Fligor and Wartinger, 2011). Since the advent of the Musicians Earplugs™ in 1988, several other similar flat attenuation HPDs have come onto the marketplace.

Electronic HPD/Communication Systems

As HPDs have increased in sophistication, manufacturers have developed ways to incorporate two new technologies into some devices: Electronic amplification (also known as “level-dependent amplification”) and communication capability. Electronic amplifying earmuffs have either one (monaural) or two (stereo) microphones on the outside of the earmuff cup(s), which amplify ambient sounds when the ambient noise levels are under a predefined threshold (typically around 82 dBA). Once ambient noise levels exceed this level, the electronic amplification circuitry is deactivated, and the earmuff reverts to being a passive device. When ambient levels drop below the threshold, the amplification circuitry reactivates. The benefit of this feature to the HPD user is that the earmuffs do not have to be removed to have a conversation with, or listen to instructions from, a coworker or supervisor. These earmuffs can also improve situational awareness by making it easier for workers to detect important sounds while still wearing their earmuffs. These devices can be especially useful for hearing-impaired workers. For such workers, conventional HPDs essentially represent an additional hearing handicap (e.g., the workers’ hearing loss plus the additional attenuation provided by the HPD), whereas electronic amplifying muffs may actually allow for improved signal detection.

Some earmuffs also have an input jack that allows the user to connect a communications device, for example, a facility radio or mobile phone. These earmuffs give the user the advantage of being able to understand verbal communications clearly, via electronic means, without needing to remove their earmuffs. This can be a major benefit where frequent communications are required in a noisy work environment. Users may also have the added benefit of being able to listen to music through the same input jack. An additional advantage of these devices is that many have built-in volume limiters, meaning the employer can be confident that the exposure level inside the ear cup of the earmuff does not exceed a predefined threshold, providing assurance that no additional risk of NIHL is added through the use of the communications earmuff.

Verification of HPD

The effectiveness of a HPD depends partly on the physical properties of the device and partly on how they are used by the individual. An excellent example of the interplay is the difference between laboratory-measured NRR and the NRR actually achieved in the field of earplugs versus earmuffs. Laboratory NRR of earplugs (with perfect fit ensured by an experimenter) would suggest these HPDs provide better low-frequency attenuation than earmuffs do, but when accounting for real-world performance, earmuffs provide more low-frequency attenuation than earplugs. Whereas it would be expected that custom-fitted plugs (such as MEPs) would have ideal performance both in the lab or in the clinic and in the real world, this is dependent on the plugs being used correctly by the individual. Thus, verification of actual HPD performance is an important component of mitigating risk for NIHL. There are multiple approaches to verification of HPDs, although three methods are currently the most popular: real ear attenuation at threshold (REAT), microphone in real ear (MIRE), and acoustical test fixtures (ATF). Each method has its strengths and weaknesses, and some methods are more appropriate than others for specific types of HPDs (Berger, 2005).

REAL EAR ATTENUATION AT THRESHOLD METHOD

The REAT method is the longest used method and most intuitive. Simply, it requires the user’s hearing to be tested across a specified range of frequencies without earplugs in place, and again with the plugs in place. This method can be conducted via soundfield audiometry or under circumaural earphones (as long as these earphones are large enough that they do not distort the shape of the pinna). Often, 1-dB step sizes are used to narrow the standard deviation in the measure. As noted previously, the REAT method is used to derive the NRR. It is considered the gold-standard method for verifying HPD, although it has its drawbacks. For one, it requires a behavioral response (and so an introduction of subjectivity in the measure) which is a source of variability in the measure. NRR is measured only in adults, whereas REAT measures with sufficiently small variability using pediatric test techniques (conditioned play audiometry or visual reinforcement audiometry) have not been established. Additionally, it is relatively slow and requires appropriate test equipment and a professional capable of performing puretone audiometry; it requires more time than is typically allotted for fitting a person with earplugs or earmuffs and may not be possible (because of equipment limitations) in the field. Finally, level-dependent (e.g., active noise reduction and passive nonlinear) HPDs are designed to provide little to no attenuation at low input levels (such as used when measuring REAT) and so would purposely show a REAT value of zero (or near zero) dB attenuation.

MICROPHONE IN REAL EAR METHOD

The MIRE technique uses a probe microphone placed near the eardrum and is equivalent to real ear measures (REM) in measuring hearing aid output with hearing aid verification equipment. The difference is that REM is intended to document increase in sound reaching the eardrum when the device is in place and functioning (to bring sound into the residual auditory area of the person with hearing loss) whereas the MIRE technique is intended to document the insertion loss (i.e., attenuation) between the diffuse field and the eardrum when the device is in place and functioning. Benefits over REAT include this measure being objective (no subject response required) and it is considerably faster. A principal challenge, however, is the placement of the microphone in the ear canal or through the HPD in a way that does not influence the performance of the HPD. A leak

between the HPD and wall of the ear canal because of the presence of a probe tube introduces a measurement artifact that greatly reduces the amount of low-frequency attenuation. Commercially available MIRE systems have managed this challenge using different techniques, such as inserting microphones through a valve in the HPD. Using hearing aid verification equipment with standard probe tube microphone (outer diameter 0.95 mm), Fligor (in press) applied a water-based lubricant to the surface of the sleeve of MEPs to attempt to limit the influence of slit leak created by any gaps between the ear canal and the sleeve of the HPD. Examples of good-fit ER15 MEP (with relatively uniform “flat” attenuation across measured frequencies) and poorly fit ER15 MEP (with little attenuation below 1,000 Hz) are shown in Figure 32.7 in the right ear and left ear of the same patient. Although it is possible that there was slit-leak artifact in the left HPD measure, this result suggests the patient should

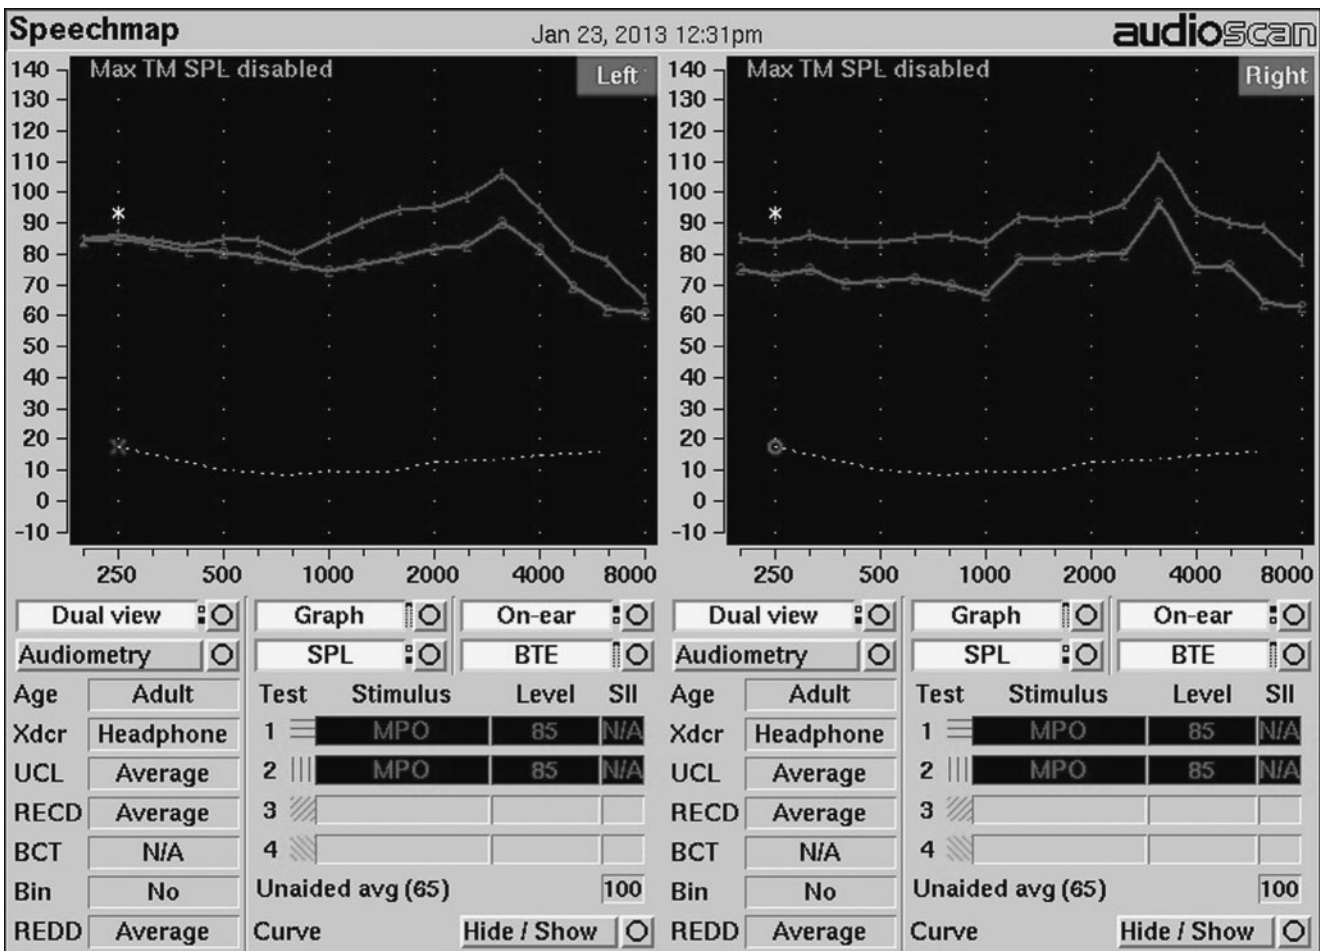

FIGURE 32.7 MIRE measures of right and left ears of patient fitted with ER15 MEPs. The line indicating test 1 (top line) shows the sound level as a function of frequency, as measured near the eardrum by a probe tube microphone to an 85-dB SPL swept tone in the unoccluded condition. Test 2 (lower line) shows the measure repeated with an 85-dB SPL swept tone, but with the left and right ear MEPs in place. There is less low frequency attenuation in the left ear with the MEP than the right ear. This may be due to a slit leak caused by the probe tube microphone.

have REAT measures of that left ER15 MEP and if this lack of low-frequency attenuation persists without the probe microphone in place, the MEP sleeve should be returned to the earmold laboratory and remade for poor fit.

ACOUSTICAL TEST FIXTURE: ATF METHOD

The ATF method involves the use of a mannequin that acts as a surrogate for the human head and ears. The most readily recognized ATF for audiologists is likely Knowles Electronics Mannequin for Acoustic Research (KEMAR). To be an appropriate surrogate, the ear canals, pinnae, head, and so on should be equivalent to the size of the intended user and have characteristics (such as skin simulation) for testing the HPD of interest. A static model ATF lacks the wide variability in the dimensions of adults, and therefore gives data that have limited inference to the real world. An ATF can be used for applications that are unsuitable for use by human subjects, such as measuring nonlinear response of HPD to gunshots and explosions. More sophisticated ATFs can incorporate characteristics of sound transmission through bone conduction to avoid some of the errors with exceeding maximum possible attenuation.

Unresolved Issues with HPDs

AUDIOMETRY, STANDARD THRESHOLD SHIFT, AND REPORTABLE SHIFTS

Arguably, a most effective way to mitigate NIHL risk is to engineer the environment to not exceed safe exposure limits (Figure 32.4). In fact, if noise levels are below 85-dBA TWA, the hearing conservation program need go no further than repeating the noise survey if the work environment changes. Once noise levels equal or exceed 85-dBA TWA, the alternative steps of either changing the worker's schedule so that the exposure time is reduced (administering out the noise) or using HPDs must be instituted. However, these options are problematic and, if not carefully monitored, can be less than effective. How well the alternate methods are working must be assessed. The most certain way to monitor the effectiveness of administrative controls and use of HPD is through periodic hearing testing. Additionally, as per the estimates of excess risk on which the OSHA regulations are based, it is anticipated that up to roughly 25% of workers exposed to 85- to 90-dBA TWA will still develop a handicapping hearing loss. Early identification of high susceptibility to PTS is an effective way for instituting steps in avoiding the development of material hearing loss. Therefore, OSHA requires that all workers with noise exposure at or above the action level have routine hearing tests. The hearing testing program includes baseline testing, annual retests (with appropriate analysis to monitor for changes in hearing), worker training, and follow-up procedures (OSHA, 1983).

A licensed professional must administer the audiometric testing program. Current regulations stipulate that the

professional must be an audiologist, otolaryngologist, or other physician. The administrator does not need to be the person who actually conducts the testing. OSHA allows for trained technicians to do the testing, with an administrator who oversees the program, supervises the technicians, reviews employee audiograms, and makes appropriate recommendations and referrals when needed (OSHA, 1983). It must be noted, however, that while OSHA allows for the use of technicians, some states do not. Anyone responsible for a hearing conservation program that uses technicians should review the licensure laws and other applicable statutes of the states in which the hearing testing is being conducted. This is to ensure that they are adhering to state laws. OSHA does not require specific training for technicians but does recommend that the technician be certified by the Council for Accreditation of Occupational Hearing Conservationists (OSHA, 1983).

All hearing tests are puretone threshold procedures. They must include the following frequencies: 500, 1,000, 2,000, 3,000, 4,000, and 6,000 Hz, with each ear tested independently. The testing can be conducted manually or by using an automated audiometer calibrated to ANSI standard S3.6-2010. Steady-state or pulsed puretones may be used. Additionally, the testing must be conducted in a room meeting specified background levels as indicated in Table 32.4 (OSHA, 1983).

There are two basic types of audiograms that must be considered as part of a hearing conservation program. These are the baseline tests and the annual tests. The baseline test is the first test administered or the test results in which the most sensitive hearing thresholds have been obtained. Annual tests are conducted to monitor for changes in hearing. A standard requirement for all tests is that the preceding 14 hours be "noise free." Usually, this is the overnight period prior to the test. It is important that workers be cautioned to avoid noisy recreational activities (e.g., loud music, power

TABLE 32.4

Minimum Allowable Octave Band Sound Pressure Levels for Audiometric Test Rooms Used for Testing in Hearing Conservation Programs

Octave band center frequency [Hz]	500	1,000	2,000	4,000	8,000
Sound pressure level [dB]	40	40	47	57	62

Reprinted from Occupational Safety and Health Administration. [1983] Occupational noise exposure: Hearing Conservation Amendment: final rule. *Fed Reg.* 48, 9738-9785.

tool use, gunfire) during this noise-free period, and use of earplugs should not be a proxy for “quiet.” If noise cannot be avoided, either at home or at work, then the employee should attempt to keep the exposure time to a minimum and must use effective hearing protection while exposed to levels equal to or in excess of 85 dBA (OSHA, 1983).

The initial baseline test must be obtained within 6 months of the employee beginning work in noise that is at or above the action level. An allowance is made for companies that have their hearing testing conducted by a mobile testing service. In those cases, the initial baseline may be obtained up to 1 year following the first exposure at or above the action level, provided the worker uses effective HPDs after the first 6 months in that setting (OSHA, 1983). Obviously, the closer the initial test is to the commencement of that individual being employed in the high-noise setting, the less likely it is that the data will be contaminated.

Standard Threshold Shift

All workers with exposure at or above the action level must be retested at least annually. The results of the annual test are compared to the baseline test. The frequencies used for the comparison are 2,000, 3,000, and 4,000 Hz, with each ear evaluated independently. If the average hearing sensitivity at these frequencies is 10 dB or worse than the average obtained on the baseline audiogram, then a standard threshold shift (STS) has occurred (OSHA, 1983). This apparently straightforward process is complicated slightly by OSHA's allowance of an age adjustment to account for predicted presbycusis. Therefore, a frequency-by-frequency adjustment must be applied to each of the three comparison frequencies based on the workers' age at the time of the baseline; adjustments are also made to the annual audiogram based on the current age. The averages are then calculated, and the comparison for STS is made (OSHA, 1983). As can be seen in Table 32.5,

even though the raw data show a change of greater than 10 dB, the adjusted values may not constitute an STS.

The presence of an STS requires specific action be taken by the company, and it is in these actions that the process becomes rather complex. Under current regulations (29 CFR 1904.10, effective January 1, 2004), a shift needs to be recorded if the average age-corrected change in hearing at 2,000, 3,000, and 4,000 Hz is equal to or in excess of 10 dB *and* the total average hearing loss at those frequencies in the same ear equals or exceeds 25-dB hearing threshold level (HTL) (without age correction) (OSHA, 2006).

OSHA recognizes that some shifts in hearing may be temporary because of medical conditions, TTS, lapses in attention during the test, or simple day-to-day fluctuations in hearing. For a basic STS, there is an allowance that the shift needs to be confirmed before specific action is taken. The confirmation retest must take place within 30 days of the company becoming aware of the shift. Often, the company is aware of the shift on the day the audiogram is conducted, and the retest deadline is based on that date. However, there may be times when the determination of shift is delayed, such as when an outside agency conducts the test. Under those circumstances, the retest deadline may, in fact, be more than 30 days after the test that first showed the shift. If the retest confirms the shift, the employee's company must then notify the worker of the change in hearing. Notification must be in writing. If the company decides not to use the retest option, then the company must notify the employee of the shift within 21 days of the date on which the company first became aware of the shift (OSHA, 1983).

All STSs are presumed to be because of work-related noise exposure unless a physician or other licensed health-care worker determines that the shift is due to causes other than occupational noise exposure or that work-related noise did not have a significant role in the shift (OSHA, 2006). Additional steps must be taken unless this shift is determined

TABLE 32.5

When Is a Significant Change in Hearing not a Standard Threshold Shift?^a

		Frequency (Hz)			
		2,000	3,000	4,000	Average
Annual test	Hearing @ 58 years	30	35	40	35
	Presbycusis adjustment	12	22	31	
	Adjusted threshold	18	13	9	13.3
Baseline test	Hearing @ 23 years	5	10	10	8.3
	Presbycusis adjustment	3	4	6	
	Adjusted threshold	2	6	4	4

Actual change in hearing: $35 - 8.3 = 26.7$ dB. Corrected change in hearing: $13.3 - 4 = 9.3$ dB.

^aUsing the OSHA correction for presbycusis, this worker, who began work with normal hearing through 4,000 Hz and who is now developing a high-frequency hearing loss, would not be identified as having had a significant change in hearing.

medically to be nonwork-related or not to have been exacerbated by workplace noise. If the worker has exposure of less than 90-dBA TWA and is not currently wearing hearing protection, hearing protection must be fitted and the worker must be trained in the care and use of that protection. If the worker is currently using hearing protection, then he or she must be refitted with equipment providing additional attenuation, if needed, and retrained in the appropriate use and care of hearing protection. In either case, HPD use must be sufficient to reduce the exposure to less than 85-dBA TWA under the HPD. If there are signs that additional testing would be audiologically appropriate, then an audiologic referral is needed. If there are signs of a medical problem, either because of or made worse by HPD use, then otologic referral is required. Otologic referral is also required for suspected medical problems unrelated to hearing protection use (OSHA, 1983).

For workers whose exposures are less than 90-dBA TWA, if a subsequent hearing test shows that an STS is not persistent, then the employee must be notified of the new results, and hearing protection use may be discontinued (OSHA, 1983).

Reportable Shift

STSs equal to or greater than 25 dB require additional action. These reportable shifts must be recorded by the employer on the OSHA Illness/Injury Log as soon as they are first identified (OSHA, 1986). These shifts are recorded in the category of occupational illness. Similar to the basic STS, discussed earlier, the company has a retest option to confirm the 25-dB shift, but the rules are different than for a basic (10-dB) STS. When the shift equals or exceeds 25 dB, the retest to confirm or refute a reportable shift must be done within 30 days of the *date of the annual audiogram* on which the shift was noted. This is different than the retest for a basic STS, which has to occur within 30 days of the company *becoming aware* of the shift. If the retest fails to confirm the reportable shift or if a subsequent medical evaluation indicates the reportable shift is because of nonwork-related causes, then the Illness/Injury Log may be amended to reflect those findings. If the retest confirms the shift or if the retest option is not used, then the same follow-up procedures discussed earlier for a basic retest apply; that is, the worker must be notified in writing within 21 days, and the appropriate actions regarding hearing protection must be implemented.

Whenever an STS has occurred, the professional in charge of the hearing conservation program can revise the baseline audiogram to reflect current levels. This revised baseline audiogram serves as the basis for future comparisons to determine the occurrence of a new basic STS (OSHA, 1983). The rationale for this is as follows. If a worker shows a persistent STS, then each subsequent annual test can be expected to show the same STS relative to the initial test.

By continually referring back to the initial test, future basic STSs may not be identified easily. Revision of the baseline also avoids overreferral for additional attention. However, annual comparisons for reportable shift (≥ 25 -dB shift) should always be made relative to the *initial* test results. If comparison is not made to the initial results, a reportable shift could be missed. For example, worker Smith develops a 15-dB shift after 10 years of work. This basic STS is confirmed by retest. Worker Smith is notified of the change, and the baseline is revised. Ten years later, worker Smith develops another 15-dB basic STS (compared to the revised baseline). Unless comparison is made of the current test to the initial test, the 30-dB cumulative shift might be missed, and the company would be in violation of the OSHA regulations for failure to record the cumulative change.

Finally, if a worker shows a significant improvement in hearing, then revision of the baseline is also warranted (OSHA, 1983). For instance, some workers present with medical problems during their first test. Once those problems have been treated, hearing may improve significantly. Without a revision of the baseline following an improvement in hearing thresholds, any future noise-induced STS could go unnoticed, and initiation of (more) effective hearing protection could be delayed.

FOOD FOR THOUGHT

Given that our current models of hearing loss risk are based on exposures measured in dBA, and given that we cannot ethically repeat studies of unprotected noise-exposed workers with measurement made in dBC, what can potentially be done to resolve this historical possible measurement error? Is the use of the dBA scale actually an error?

What is the relationship between TTS and PTS? If there is no relationship between the two phenomena why do researchers use TTS as a measure and implicitly assume that this has some ramifications for PTS?

What would be the ramifications for industry and employers if OSHA chose to replace the existing PEL (established in 1972) with the NIOSH REL (established in 1998)?

What are some possible approaches to reducing the daily noise exposure of a flight deck technician on an aircraft carrier when engineering noise controls have already been implemented, the worker is wearing hearing protection, and exposures are still exceeding the PEL?

What is the relative societal noise burden from portable listening devices? Are headphones really a significant source of NIHL?

What exposure levels are most appropriate for application to young people? Estimates of excess risk are based on maximum exposure duration of 40 years. A teenager who is exposed recreationally will have many more than 40 years of potential exposure. Should exposures, then, not exceed 75-dBA TWA with 3-dB exchange rate?

How should an employer apply rules of a hearing conservation program to workers with hearing loss who use hearing aids? Such workers might need hearing aids for communication and situation awareness, but hearing aids (especially those with vents in the earmold/hearing aid shell) typically cannot provide attenuation of ambient sound and might amplify hazardous sound further. How can employers provide reasonable accommodation for these workers while still following regulatory hearing conservation program requirements?

ACKNOWLEDGMENTS

We acknowledge the many contributions by Dr. James Feuerstein from edition 6 of this chapter. We also acknowledge Homira Osman for her considerable editorial contributions in the preparation of this chapter.

Nonorganic Hearing Loss

Frederick N. Martin and John Greer Clark

INTRODUCTION

Not every patient seen in the audiology clinic is fully cooperative during the hearing evaluation. This lack of cooperation may be because the patient (a) does not understand the test procedure, (b) is poorly motivated, (c) is physically or emotionally incapable of appropriate responses, (d) wishes to conceal a handicap, (e) is deliberately feigning or exaggerating a hearing loss for personal gain or exemption, or (f) suffers from some degree of psychologic disturbance. This chapter will describe some of the concepts underlying false or exaggerated hearing test results and the motivation for this behavior. It will also present some audiometric and nonaudiometric procedures that aid in the detection of inaccuracies and in the determination of a patient's true hearing thresholds.

Many terms have been used to describe a hearing loss that appears greater than can be explained on the basis of pathology in the auditory system. The most popularly used terms in the literature today are "nonorganic hearing loss," "pseudohypacusis," and "functional hearing loss." Such terms as "psychogenic hearing loss" and "malingering" imply the motivation behind the behavior, may be oversimplifications, and certainly may not be describing the same phenomena. In as much as clinicians typically do not know whether an exaggerated auditory threshold is the result of conscious or unconscious motivation, it seems appropriate to use generic terms. The term "pseudohypacusis" is popular but often thought to be a "mouthful." An older term, "hysterical deafness," is based on a Freudian concept of conversion neurosis and is rarely used. Since the word "hysterical" derives from the Greek "hystera" (womb), the term is actually pejorative and its use is inappropriate for this reason as well. In this chapter, "nonorganic hearing loss" will be used to describe responses obtained on hearing-threshold examinations that are above the patient's true organic thresholds.

If one thinks of a hearing loss which is due to physical impairment in the auditory system as being "organic," then the term nonorganic is immediately clear. Many individuals with nonorganic hearing loss have nonorganic aspects superimposed on an organic hearing loss. Audiologists must remember that their primary function is to determine the extent of the organic component rather than to reveal the

precise reason for spurious test results. As discussed later, a secondary responsibility when working with nonorganic patients, especially with pediatrics, is to help ensure that any psychologic underpinnings that may exist are addressed by the appropriate professionals.

NONORGANIC HEARING LOSS IN ADULTS

A number of factors may encourage some persons either to feign a hearing loss that does not exist or to exaggerate a true hearing loss. One of these factors is financial gain. Certainly, a significant amount of stress around the world is attributable to economics and the economic upheavals in more recent years have only exacerbated this. The very threat of the loss of income may drive some individuals to acts of "questionable honesty" that they might not otherwise consider.

Other factors that may contribute to nonorganic hearing loss are psychosocial and include the wish to avoid undesirable situations. There may be many other gains that the individual believes are afforded to hearing-disabled persons, including excuses for lack of success, advancement in position, poor marital situation, and so on (Peck, 2011).

The number of persons with nonorganic hearing loss may be increasing since the implementation of federal laws regarding hearing safety in the workplace. Some state laws regarding noise in industry are even more stringent than federal legislation. The promise of financial reward is bound to be a factor precipitating nonorganic hearing loss in workers who are in danger of incurring noise-induced hearing loss. Barelli and Ruder (1970) gathered data on 162 medicolegal patients and found that 24% of the 116 workers applying for compensation proved to have symptoms of nonorganic hearing loss. There is little reason to suspect the percentage may be significantly different today.

Studies suggest that those with nonorganic hearing loss have been found to score lower than those without hearing complaints on measures of socioeconomic status and verbal intelligence. They have also been shown to have a greater degree of clinically significant emotional disturbance, tendencies toward hypochondria, more frequent complaints of tinnitus, and a greater reliance on denial mechanisms. Such

patients appear to have a diminished sense of confidence in their abilities to meet the needs of everyday life and may feel a sense of gain by appearing to have a hearing loss.

There is disagreement over whether some nonorganic hearing loss may be psychogenic at all or whether all exaggerated hearing thresholds are deliberately and consciously manifested with an eye toward personal gain. There are certainly studies (i.e., Gleason, 1958) that suggest that those with nonorganic hearing loss might be influenced by psychodynamic factors but not necessarily psychiatrically ill. Some may be emotionally immature or neurotic and may express psychosomatic complaints or exhibit deviant social behavior. It is possible that in many cases of nonorganic hearing loss, the problem is on an unconscious level to gain a favored goal or to explain to society that the patient is blameless for inadequate social behavior. From this point of view, exaggerated hearing loss may be one symptom of a personality disturbance.

Katz (1980) cautions that certain neurologic problems can appear to be nonorganic in nature. For example, one patient who initially responded on puretone evaluation between 40 and 70 dB HL, and eventually at levels of 20 dB HL, responded immediately at 15 dB HL to spondees. This patient was neither a malingerer nor psychogenic. Rather he was a volunteer for a study because he was terminally ill with a tumor of the corpus callosum. He did not claim to have difficulty with hearing, nor did he exhibit any difficulty in communication. Peck (2011) similarly cautions that patients with what has been dubbed *obscure auditory dysfunction* (Saunders and Haggard, 1989) may be viewed by clinicians as exaggerating the extent of hearing difficulties reported. Certainly, the hearing complaints of these patients in the presence of normal audiometrics are a valid concern and are most likely tied to latent auditory processing difficulties.

The question arises, “Why hearing loss?” Why does the patient with nonorganic hearing loss select this disorder rather than back pain, headache, whiplash, or some other more conventional malady? It certainly is possible that some incident in the lives of these patients has focused their attention on hearing. The incident may have been an ear infection, physical trauma, noise exposure, or tinnitus or hearing loss in a relative or close friend. For whatever reason, this incident is the first step toward future nonorganic hearing loss.

Nonorganic Hearing Loss in Children

A number of case reports of nonorganic hearing loss in children appear in the literature dating back to 1959 when Dixon and Newby (1959) reported on 40 children between the ages of 6 and 18 years with nonorganic hearing loss. Despite claimed hearing losses, 39 of these children were able to follow normal conversational speech with little difficulty. Similar findings have subsequently been reported.

Most experienced audiologists can report evaluating children with marked exaggeration of hearing thresholds for puretones in the presence of normal speech recognition thresholds (SRTs).

There are also cases of apparent malingering with psychologic undertones. For example, Bailey and Martin (1961) reported on a boy with normal hearing sensitivity who manifested a great many nonorganic symptoms. After the audiometric examination he admitted a deliberate attempt to create the impression that he had a hearing loss. He claimed he did this so that he could be admitted to the state residential school for the deaf where his parents taught and his sister and girlfriend were students. Investigation into this boy’s background revealed that he was a poor student in a high school for normal-hearing students. Hallewell et al. (1966) described a 13-year-old boy with a severe bilateral hearing loss who revealed essentially normal hearing sensitivity under hypnosis.

Cases of presumed psychogenic hearing loss in children have also been reported. Lumio et al. (1969) described three sisters whose hearing losses all appeared to develop over a period of a few months. Two of the three girls also had complaints of visual problems and were fitted with eyeglasses. All three apparently had their hearing return to normal in 1 day during a visit with their aunt. When the hearing returned the visual disorders also disappeared. These authors reported that the nonorganic hearing loss was due to family conflicts. They believed that it was probable that the hearing loss of the youngest child was entirely unconscious, but the other two may have been deliberately simulated.

Investigators have reported, and clinicians frequently have witnessed, cases in which children with normal intelligence, but with a history of poor academic performance, have exhibited significant nonorganic hearing loss. It is likely in such cases that the attention paid to the children failing an initial school hearing test for whatever reason subsequently encouraged them, consciously or unconsciously, to feign a hearing loss on subsequent examinations. Certainly nonorganic behaviors must be detected as early as possible before children realize that there are secondary gains to be enjoyed from a hearing disorder.

Austen and Lynch (2004) point out the obvious, that a dichotomy between acts of deliberate falsification (malingering) and those of unconscious motivation is an oversimplification of what may be a complex human dynamic. They proposed another term, *factitious behavior*, and formulated a new nomenclature for the categorization of nonorganic hearing loss. There is a detailed set of recommendations and the reader is referred to this publication for greater specificity than can be addressed in this chapter.

As noted, sometimes children who inadvertently fail school screening tests become the object of a great deal of attention. It is frequently recommended that professionals avoid recommendations for preferential seating, special classes, hearing therapy, and hearing aids until the extent

of the hearing problem is defined by proper audiologic diagnosis. Identification audiometry is a significant tool for discovering school children with hearing disorders. There is certainly some reason to fear that a child may fail a school test despite normal hearing because of such factors as noisy acoustic environment, improper testing technique, insufficient motivation, or poorly calibrated equipment. If attention is attracted to this inadvertent failure, the child may get the notion that a hearing loss provides a variety of secondary gains, such as excuse for poor school performance. The end result may be referral to an otologic or audiologic clinic for further evaluation of hearing. Ultimately, such cases may be more easily resolved if behaviors of nonorganic hearing loss were uncovered before referrals are made. Nonorganic hearing loss in children appears to occur with sufficient frequency to cause concern. Psarommatis et al. (2009) believe that nonorganic hearing loss is the most frequent underlying etiology of sudden hearing losses in children. Whether the notion of simulating a hearing loss comes out of a school screening failure or from some conscious or unconscious need, it must be recognized as early as possible by the audiologist to avoid a variety of unfortunate circumstances. Performance or supervision of hearing tests on young children by an audiologist, rather than a technician, may serve to avert what may later develop into serious psychological or educational difficulties.

INDICATIONS OF NONORGANIC HEARING LOSS

The Nontest Situation

Frequently, the source of referral will suggest the possibility of nonorganic hearing loss. For example, when an individual is referred by an attorney after an accident that has resulted in a client's sudden loss of hearing, it is only natural to suspect that nonorganic behavior may play a role in test results. This is also true of veterans referred for hearing tests, the results of which decide the amount of their monthly pensions. Disability compensation to veterans with service-connected hearing losses constitutes a significant portion of the many millions of dollars paid annually to beneficiaries of the Department of Veterans Affairs (VA) in the United States in an effort to compensate them for their disability.

It must be emphasized that the majority of patients referred for such examinations are cooperative and well meaning; however, the VA population consists of a higher-risk group for nonorganic hearing loss than self-referred or physician-referred patients. Nonorganic hearing loss must be on the minds of clinical audiologists or they may miss some of the symptoms that indicate its presence.

A case history is always of value, but it is particularly useful in compensation cases. It is obviously beneficial for examining audiologists to take history statements themselves, so that they can observe not only the responses given to ques-

tions, but also the manner in which these responses are offered. The patient may claim an over-reliance on lipreading, may ask for inappropriate repetitions of words, or constantly readjust a hearing aid. It is usual for hard-of-hearing patients to be relatively taciturn about their hearing problems, whereas exaggerated or contradictory statements of difficulty or discomfort, vague descriptions of hearing problems, and the volunteering of unasked-for supplementary information may be symptomatic of nonorganic hearing loss.

In patients with nonorganic hearing loss, exaggerated actions and maneuvers to watch every movement of the speaker's lips, or turning toward the talker with hand cupped over the ear, ostensibly to amplify sound, is sometimes observed. As a rule, hard-of-hearing adults face the talker with whom they are conversing, but their attentive postures are not nearly so tortuous as described above. Not all patients who intend to exaggerate their hearing thresholds create such caricatures, and even patients who do should not be condemned as having nonorganic hearing loss on the basis of such evidence alone.

The Test Situation

During the hearing examination, the patient with nonorganic hearing loss is frequently inconsistent in test responses. A certain amount of variability is to be expected of any individual; however, when the magnitude of this variability exceeds 10 dB for any threshold measurement one must consider the possibility of nonorganic behavior. With the exception of some unusual conditions it can be expected that the cooperative patient will give consistent audiometric readings.

Two types of patient error are frequently seen in the clinical testing of puretone thresholds. These are false-positive and false-negative responses. When the subject does not respond at levels at or slightly above true thresholds, this constitutes a false-negative response. False-negative responses are characteristic of nonorganic hearing loss. Frequently, the highly responsive patient will give false-positive responses, signaling that a tone was heard when none was presented at or above threshold. False-positive responses, although sometimes annoying, are characteristic of a conscientious responder.

It has long been noted that the patient with nonorganic hearing loss does not offer false-positive responses during silent periods on puretone tests. Thus, one simple check for nonorganic behavior is simply to allow silent intervals of a minute or so from time to time. A false alarm is more likely to indicate that the patient is trying to cooperate and believes that a tone was introduced. In the absence of cognitive or physical impairment, extremely slow and deliberate responses may be indicative of a nonorganic problem because most patients with organic hearing losses respond relatively quickly to the signal, particularly at levels above threshold.

The Audiometric Configuration

A number of authors have suggested that an audiometric pattern emerges that is consistent with nonorganic hearing loss. Some have described this pattern as a relatively flat audiogram showing an equal amount of hearing loss across frequencies. Others have suggested that the “saucer-shaped audiogram” similar to a supraliminal equal loudness contour is the typical curve illustrating nonorganic behavior although these saucer-shaped audiograms can certainly occur in true organic hearing losses. This configuration may actually be fairly infrequent in nonorganic hearing loss and the saucer audiogram seems to have limited use in identifying nonorganic hearing loss.

Because the patient with nonorganic hearing loss may attempt to give responses that are of equal loudness at all frequencies, ignorance of the manner in which loudness grows with respect to intensity at different frequencies does suggest that the result should be a saucer-shaped audiogram. The logic of this is apparently not borne out in fact. It would appear that there is no typical puretone configuration associated with nonorganic hearing loss.

Test-Retest Reliability

One indication of nonorganic behavior is the lack of consistency on repeated measures. Counseling the patient about inaccuracies may encourage more accurate responses; however, if this counseling is done in a belligerent way it can hardly be expected to increase cooperation. Sometimes a brief explanation of the test discrepancies encourages improved patient cooperation. By withholding any allegations of guilt on the part of the patient the audiologist can assume personal responsibility for not having conveyed the instructions properly. This provides a graceful way out for many patients, even if they are highly committed to nonorganic loss. Clinicians have long recognized that some children can be coaxed into “listening harder,” thereby improving results on puretone tests.

Although these suggestions are usually useful when working with civilian populations, exceptions exist when testing military personnel. When counseling and cajoling fail to eliminate symptoms of nonorganic hearing loss, direct confrontation has been made. Military patients have been told that exaggeration of thresholds is a violation of the Universal Code of Military Justice (in the United States) and therefore a court-martial offense. Personal communication with audiologists working in military installations reveals that such methods may be very effective indeed in altering patient behavior. Veterans with service-connected hearing losses may have their pensions interrupted until examining audiologists are satisfied with test results. It is not known, however, whether this kind of open confrontation may have serious psychologic effects on some patients. It can certainly be offensive if inappropriately used. A personal view is that

the risk of psychologic trauma in even a very small percentage of cases should be considered carefully before such aggressive tactics are used. A more prudent approach may be more time-consuming but may also be safer.

The Shadow Curve

It may seem advantageous to a patient feigning a hearing loss to claim that loss in only one ear. Appearing to have one normal ear is convenient because individuals need not worry about being “tripped up” in conversation by responding to a sound that is below their admitted thresholds. In this way all hearing can appear to occur in the “good ear” and the claim can be made that hearing is nonexistent in the “bad ear.” Normal activities can be carried on for the unilaterally hearing-impaired individual without any special speechreading abilities.

It is generally agreed that a patient with a profound hearing loss in one ear will hear a test tone in the opposite ear by bone conduction if the signal is raised to a sufficient level during a threshold test. For an air-conduction signal the levels required for contralateralization range from 40 to 70 dB when supra-aural earphones are used, depending on frequency and generally above 70 dB for all frequencies when insert receivers are used. The interaural attenuation, the loss of sound energy because of contralateralization, is much less for bone conduction than for air conduction. With the vibrator placed on the mastoid process there is virtually no interaural attenuation. Therefore, if a person truly has no hearing for air conduction or bone conduction in one ear, the audiogram taken from the bad ear would suggest a moderate unilateral conductive loss. Unless masking is applied to the better ear a “shadow curve” should be expected.

The naive patient with nonorganic hearing loss may give responses indicating no hearing in one ear and very good hearing in the other ear. The lack of contralateral response, especially by bone conduction, is a very clear symptom of unilateral nonorganic hearing loss and offers a good reason why all patients should be tested initially without masking, even if it appears obvious at the outset of testing that masking will be required later in the examination.

SRT and Puretone Average Disagreement

The SRT is generally expected to compare favorably with the average of the lowest two of the three thresholds obtained at 500, 1,000, and 2,000 Hz. Lack of agreement between the puretone average (PTA) and the SRT in the absence of explanations such as slope of the audiogram or poor word recognition is symptomatic of nonorganic hearing loss. Carhart (1952) was probably the first to report that in confirmed cases of nonorganic hearing loss the SRT is *lower* (better) than the PTA with this SRT/PTA discrepancy present in the majority of patients with nonorganic hearing loss. Ventry

and Chaiklin (1965) reported that the SRT–PTA discrepancy identified 70% of their patients with confirmed nonorganic hearing loss; in each case the SRT proved to be more than 10 dB lower than the PTA. The lack of SRT–PTA agreement is often the first major sign of nonorganic hearing loss.

It is impossible to know the precise strategies patients use if they wish to deceive examiners on hearing tests. For one thing, simply asking them their methods would only result in rebuke and, since nonorganic hearing loss is, in many cases, intrinsically deceitful behavior, an honest response would hardly be forthcoming. Martin et al. (2001) paid normal-hearing adults to feign hearing loss for puretones and motivated them by compensating them with more money as their actions became more convincing. Following a series of puretone tests they were simply asked to describe the strategies they used. Most said that they initially responded randomly and then set a sort of loudness metric in their minds and tried to repeat it during retesting, or at different frequencies. After they had taken the test for a short while and realized that a set procedure was being used they began to establish consistency by counting the number of tones, which were initially presented at 30 dB HL and then increased in 5-dB increments. Assuming that this methodology holds true for patients with actual nonorganic hearing loss an obvious procedure would be to vary from an established technique and present tones at random intensities.

In attempting to remember the loudness of a supra-threshold signal previously responded to, one might easily become confused between puretone and spondaic word levels. Very little research has been carried out to explain why the discrepancy generally favors the SRT. It might be that the loudness of speech is primarily associated with its low-frequency components. According to the equal loudness contours, the low frequencies grow more rapidly in loudness than tones in the speech frequencies. This speculation is supported by the work of McLennan and Martin (1976), who concluded that when puretones of different frequencies are compared in loudness against a speech signal, the difference between them is a function of the flattening of the loudness contours. Certainly one could theorize that the difference between the sensations of loudness for speech and puretones may be related to their different sound pressure level references but this theory has its limitations.

SPECIAL TESTS FOR NONORGANIC HEARING LOSS

One responsibility that audiologists bear is to determine the organic hearing thresholds for all of their patients, including those with nonorganic hearing loss although in some cases this may be more readily achieved through behavioral means after the potential underlying motivators for the exhibited nonorganic behavior have been addressed. It is not simply a matter of gathering evidence against the patient to prove nonorganic behavior. This is sometimes necessary, but the

unmasking of nonorganic cases should not be an end in itself. Although it is easier to make a diagnosis on cooperative patients in terms of their hearing thresholds, a lack of cooperation does not justify disinterest in the patient's true hearing status. There are tests that qualify or prove the presence of nonorganic hearing loss, those that approximate the true threshold, and those that actually quantify the patient's threshold without voluntary cooperation.

QUALITATIVE TESTS FOR NONORGANIC HEARING LOSS

Acoustic Immittance Measurements

Among the many valuable contributions that immittance testing brings to our profession is the detection of nonorganic hearing loss. The acoustic reflex threshold is the immittance measurement that is of greatest value in the diagnosis of nonorganic hearing loss. The elicitation of this reflex at a low sensation level (SL) (60 dB or less above the voluntary threshold) has been construed to suggest the presence of a cochlear lesion. However, if the SL (the difference in decibels between the acoustic reflex threshold and the voluntary puretone threshold) is extremely low (5 dB or less) it is difficult to accept on the basis of organic pathology. There have even been reports of nonorganic patients who demonstrated acoustic reflexes that were better (lower) than voluntary thresholds. If the audiologist is certain that no artifact contaminates the readings, the suggestion that the acoustic reflex may be achieved by a tone that cannot be heard must be rejected, and a diagnosis of nonorganic hearing loss may be made.

More than merely identifying nonorganic hearing loss, acoustic reflex measurements may be useful in the actual estimation of thresholds. Jerger et al. (1974) describe a procedure in which the middle-ear muscle reflex thresholds for puretones are compared to those for wideband noise and low- and high-frequency filtered wideband noise. The procedure, which is referred to as SPAR (sensitivity prediction from the acoustic reflex), approximates the degree of hearing loss, if any, as well as the general audiometric configuration. This procedure has been shown to estimate thresholds in a large number of cases with a high degree of specificity. It certainly appears that this method may have use in estimating the thresholds of patients with nonorganic hearing loss.

There is no way to know how many patients with nonorganic hearing loss appear to give results reflective of a conductive hearing loss, although we have never seen this. Of course, the middle-ear muscle reflex measurement cannot be used in cases with nonorganic components overlying even mild conductive losses, since contralateral reflexes are absent in both ears when even one ear has a conductive disorder. Tympanometry is an objective method that may be used to suggest middle-ear disorders, in such cases.

The elaborateness of middle-ear measurements, including the instructions for the patient to be quiet and immobile, may have the effect of discouraging nonorganic behavior if this test is performed early in the diagnostic battery. It is often good practice to perform middle-ear measurements as the first test on adults and cooperative children. They are asked to sit quietly and are told that the measurements made will reveal a great deal about their hearing. We have no hesitancy in recommending this approach in general and believe it can be a useful deterrent to nonorganic hearing loss.

Stenger Test

Probably the best way to test for unilateral nonorganic hearing loss is by use of the Stenger test. The Stenger principle states that when two tones of the same frequency are introduced simultaneously into both ears, only the louder tone will be perceived.

Since its introduction as a tuning fork test over a century ago, the Stenger test has been modified many times. If unilateral nonorganic hearing loss is suspected, the Stenger test may be performed quickly as a screening procedure. This is most easily done by introducing a tone of a desired frequency into the better ear at a level 10 dB above the threshold and into the poorer ear at a level 10 dB below the admitted threshold. If the loss in the poor ear is genuine, the patient will be unaware of any signal in that ear and will respond to the tone in the good ear readily, because at 10 dB above threshold it should be easily heard. Such a response is termed a negative Stenger, indicating that the poorer ear threshold is probably correct.

If patients do not admit hearing in the bad ear, and are unaware of the tone in the good ear, they simply do not respond. This is a positive Stenger, which proves that the threshold for the “poorer” ear is better than the response given by the individual. A positive Stenger is the interpretation because the tone is actually above the true threshold in the “bad” ear and precludes hearing the tone in the good ear.

The screening procedure described above rapidly identifies the presence or absence of unilateral nonorganic hearing loss if there is a difference in admitted threshold between the ears of at least 20 dB. The test is most likely to be positive in nonorganic cases with large interaural differences (exceeding 40 dB) or large nonorganic components in the “poorer” ear.

A positive result on the Stenger test does not identify the true organic hearing threshold. To obtain threshold information the Stenger test can also be performed by seeking the *minimum contralateral interference levels* (MCIL). The procedure is as follows: The tone is presented to the good ear at 10 dB SL. There should be a response from the patient. A tone is then presented to the bad ear at 0 dB HL, simultaneously with the tone at 10 dB SL in the good ear. If a response is obtained the level is raised 5 dB in the *bad*

ear, keeping the level the same in the good ear. The level is continuously raised in 5-dB steps until the subject fails to respond. Because the tone is still above threshold in the good ear the lack of response must mean that the tone has been heard loudly enough in the bad ear so that the patient experiences the Stenger effect and is no longer aware of a tone in the good ear. Being unwilling to react to tones in the bad ear, patients simply stop responding. The lowest hearing level of the tone in the bad ear producing this effect is the MCIL and should be within 20 dB of the true threshold. An alert patient feigning a hearing loss may “catch on” to what the clinician is doing unless, from time to time, the tone in the good ear is presented without competition from the bad ear.

The Stenger test is equally effective with either an ascending or descending approach with interference levels generally averaging around 14 dB. The result is a close approximation of hearing levels for the “poorer” ear in cases of unilateral nonorganic hearing loss. Monro and Martin (1977) found that the Stenger test, using the screening method, was virtually unbeatable on normal-hearing subjects feigning unilateral hearing losses. Martin and Shipp (1982), using a similar research method, found that as sophistication and practice with the Stenger test are increased, patients are less likely to be confused by low contralateral interference levels. Although the Stenger test, like most tests, has certain shortcomings, most clinicians regard it as an efficient test for quick identification of unilateral nonorganic hearing loss. The only equipment required for the test is a two-channel, puretone audiometer. To be sure, if the test is performed by an inexperienced clinician a series of patterns of tone introductions may betray the intentions of the test to an alert patient. The majority of respondents on a survey of audiometric practices (Martin et al., 1998a) named the Stenger as their most popular test for nonorganic hearing loss, which is difficult to understand since unilateral cases are far and away in the minority.

Modified Stenger Test

A modification of the puretone Stenger test allows completion of the test with spondaic words. The Stenger principle holds for speech stimuli if words, like spondees, are presented via both channels of a speech audiometer simultaneously. All of the criteria for application of the puretone Stenger test apply to the modified version, that is, there should be at least a 20-dB difference between the SRTs of the right and left ears, and the greater the interaural difference and the closer to normal one ear hears the better the test works. A two-channel audiometer is used with either monitored live voice or prerecorded presentation.

Subjects are instructed to simply repeat every spondee they hear. The words are presented 10 dB above the better ear SRT and 10 dB below the poorer ear SRT. If the patient continues to repeat the words the modified Stenger is

considered to be negative, providing no evidence of nonorganic hearing loss. If the patient does not repeat the spondees under these conditions, then the screening test has failed and the MCIL should be sought.

To determine the MCIL, the sensation level of 10 dB should be maintained in the better ear. The hearing level dial controlling the intensity at the poorer ear should be set to the lowest limit of the audiometer. Each time a spondee is presented and repeated by the patient, the level in the poorer ear should be raised 5 dB. The lowest hearing level dial setting in the poorer ear at which the patient stops repeating two or more spondees correctly is considered to be the MCIL and is above the threshold for that ear. The precise threshold cannot be known, but MCILs have been noted as low as 15 dB above the SRT of the poorer ear. If the MCIL is as low as 30 dB HL it may be assumed that hearing for speech is normal.

Experienced clinicians can manipulate the modified Stenger in a variety of ways. The speech itself can be less formal than spondaic words and may consist of a series of instructions or questions requiring verbal responses from the patient. The signal to the better ear may be randomly deleted on the chance that patients may be “on to” the test and may be repeating words they hear in their poorer ears, but will not admit to because they believe that words are also above threshold in their better ears even though they do not hear them. To paraphrase an old saw, “experience is the mother of invention.”

Martin and Shipp (1982) found that sophistication with the speech Stenger test resulted in higher MCILs, which can lead the unsuspecting clinician to accept an exaggerated SRT as correct. Because there is no way to control for any knowledge about the modified Stenger that a patient brings to the examination, the alert clinician is wary of contamination of test results that such knowledge may cause.

Ascending–Descending (A-D) Methods

The use of both an ascending and descending approach to puretone threshold measurements has long been recommended as a rapid and simple procedure. A greater than 10-dB difference between these two measurements suggests a nonorganic problem because the two thresholds should be identical. Personal use of this procedure indicates that this difference is often as large as 30 dB for patients with nonorganic hearing loss. For these patients, the ascending method generally reveals lower (better) thresholds than the descending approach. The comparative ascending/descending threshold test is quick and easy to perform with the simplest puretone audiometer and serves as the basis for the BADGE test (Békésy ascending–descending gap evaluation: Hood et al., 1964). This test has been found to be an excellent screening tool for nonorganic hearing loss. Martin et al. (2000) used a combination of stimuli in the develop-

ment of a screening procedure for nonorganic hearing loss. Using a standard diagnostic audiometer they developed a procedure very much like the BADGE but used standard instead of Békésy audiometry. They compared ascending and descending approaches using tones that were continuously on (CON), pulsing on and off with a standard off time (SOT) as past investigations had used, and pulsing with a lengthened off time (LOT). The CON-SOT-LOT test was described as being rapid and accurate in the detection of nonorganic hearing loss. Subsequent clinical use has borne this out.

The Swinging Story Test and the Varying Intensity Story Test

For some time, a procedure has been available to identify the presence of unilateral nonorganic hearing loss. The test requires the use of a two-channel speech audiometer. A story is read to a patient with portions directed above the threshold of the normal ear (e.g., 10 dB above the SRT) through one channel, other portions below the threshold of the “poorer ear” (e.g., 10 dB below the SRT), and portions through both channels simultaneously.

For this “swinging” test to work, the story must be presented rapidly, including rapid switching from channel 1 to channel 2 to both channels. Although this can be done using monitored live voice, an easier method is to use a prerecording. A calibration tone recorded on each channel allows for adjustment of the volume units (VU) meters before the test begins.

On completion of the recording the patient is simply asked to repeat the story. Repetition of information directed to (and presumably heard in) the good ear or both ears is to be expected. Any remarks from the *bad ear* column must have been heard below the patient’s admitted threshold for speech and prove that the threshold for that ear has been exaggerated. All that can be determined from a positive result is that hearing is better in the poorer ear than what the patient has volunteered, providing evidence of nonorganic hearing loss.

One of the advantages of a modification of the swinging story test is that the theme changes when the *bad ear* column is included or excluded, adding to the complexity of the challenge to the patient with nonorganic hearing loss. Because the patient must concentrate on the story and commit it to memory, it is less likely that the individual will be able to remember which material was presented to the *bad ear*.

There is not much evidence that the swinging story test has been very popular. A major revision of this test is called the Varying Intensity Story Test (VIST) (Martin et al., 1998b). Two main advantages to the VIST are that it can be used in one or both ears (not limiting it to unilateral cases) and that it comes close, in many cases, to approximating the auditory threshold for speech.

To perform the VIST, patients are advised that they will hear a story one time (see Table 33.1), following which they will be asked to respond to a series of 10 written questions. Part I of the story (see above) is presented at 10 dB SL and Part II is presented at 30 to 50 dB below the admitted SRT. The test is considered to be positive if questions resulting from information supplied only from Part II are answered correctly. The interpretation is that the SRT can be no poorer than the level used for Part II. The VIST was shown to work well on subjects simulating nonorganic hearing loss but it remains to be verified on true nonorganic cases.

Low-Level Speech Recognition Testing

Most audiologists tend to perform speech recognition testing at 30 to 40 dB above the SRT. A better approach is to ensure audibility of the speech signal through most of the frequency range to ensure that scores reflect maximum performance levels which often necessitate somewhat higher intensities. Some clinicians routinely do performance-intensity functions for speech recognition scores but these are usually reserved for special cases, such as for determination of site of lesion. Normally, low word recognition scores are expected at low sensation levels. The data in Table 33.2 are adapted from Hopkinson (1978) and suggest approximate word recognition scores that would be attained by normal-hearing individuals at given sensation levels.

It is frequently observed that unusually high word recognition scores can be obtained on patients with non-

organic hearing loss at levels slightly above their admitted thresholds. High scores certainly suggest normal hearing for speech.

Pulse-Count Methods

Some tests may be carried out by presenting a number of puretone pulses in rapid succession and asking the patient to count and recall the numbers of pulses that were heard. The intensity of the tones may be varied above and below the admitted threshold of the tone in one ear (Ross, 1964) or above the threshold in one ear and below the threshold in the other ear (Nagel, 1964). If the originally obtained thresholds are valid the patient should have no difficulty in counting the pulses. Inconsistency should occur only if

TABLE 33.2

Approximate Word Recognition Scores at Given Sensation Levels for Normal Hearing Individuals

Sensation Level [dB]	Word Recognition Score [%]
5	25
10	50
20	75
28	88
32	92
40	100

all the tone pulses are above threshold and the patient has to sort out the number of louder ones from the number of softer ones. This can be very difficult to do. A major advantage to this test is that it can be carried out quickly using any kind of puretone audiometer.

The Yes–No Test

Frank (1976) described a test for nonorganic hearing loss that would seem too simple to work; nevertheless, it often does. The test is intended for children but has occasionally been useful with naive adults. The patient is simply told to say “yes” when a tone is heard and “no” when a tone is not heard. The tone is presented at the lowest limit of the audiometer and increased in intensity in 5-dB steps. Some patients, in an attempt to convince the examiner of poor hearing, will say “no” to tones that are heard below the level selected to be “threshold.” Of course, a “no” response that is time-locked with the introduction of a tone is clear evidence that the tone was heard, barring occasional false-positive responses.

QUANTITATIVE TESTS FOR NONORGANIC HEARING LOSS

Despite the considerable interest that has been generated and the appeal of the previously mentioned tests, none so far has provided the most sought after information. They lack the ability to provide the true threshold of audibility in patients who will not or cannot cooperate fully. For measures of more accurate estimates of the actual puretone thresholds, our profession has tended to turn to electrophysiological procedures.

Auditory-Evoked Potentials

Measurement of auditory-evoked potentials (AEP) has long been considered a “crucial test” in the diagnosis of nonorganic hearing loss as results obtained from this technique and from voluntary puretone testing generally agree within 10 dB. The early evoked potentials, the auditory brainstem response (ABR), have proven to be more reliable than the auditory middle latency responses or the auditory late responses in detecting nonorganic hearing loss. Hall (2007) has suggested that a current recommendation for frequency-specific estimation of hearing levels with nonorganic patients is the use of the auditory steady-state response (ASSR) combined with otoacoustic emissions (OAEs). Discrepancies between ASSR thresholds and both ABR and behavioral thresholds have been reported. As such, although ASSR is an important diagnostic tool for evaluating nonorganic hearing loss, it should be interpreted with caution.

Otoacoustic Emissions

Since their introduction into clinical audiology practice, evoked otoacoustic emissions (EOAEs) have increased in popularity and they serve as an important tool in the diagnosis of auditory lesion site, as well as in estimating hearing sensitivity in noncooperative patients (Dhar and Hall, 2011). OAEs, especially transient-evoked otoacoustic emissions (TEOAEs), have been shown to be of value in cases of nonorganic hearing loss.

EOAEs may reveal that hearing is normal or near normal in patients feigning a hearing loss, but may be of little or no value for those with actual hearing levels greater than about 40 dB HL, who wish the audiologist to believe that hearing is poorer than that. The fact that the adult patient with nonorganic hearing loss is probably aware that some measures of hearing sensitivity are possible without patient cooperation may encourage individuals who arrive at the audiology clinic with plans to falsify test results to become more cooperative when they are prepared for EOAE or AEP tests. This deterrent may be of greater value than the test itself.

Puretone Delayed Auditory Feedback (DAF)

General dissatisfaction has been expressed with speech DAF because it does not reveal the true threshold of the patient with nonorganic hearing loss. Over 50 years ago a procedure was described that uses the delayed feedback notion with puretones and which can be administered to patients who appear unwilling or unable to give accurate readings on threshold audiometry (Ruhm and Cooper, 1964).

During puretone DAF testing, the patient is asked to tap out a continuous pattern, such as four taps, pause, two taps, pause, and so on. The electromagnetic key on which the patient taps is shielded from the individual’s visual field. After the patient has demonstrated the ability to maintain the tapping pattern and rhythm, an audiometer circuit is added so that for each tap a tone pulse is introduced into an earphone worn by the patient. The tone has a duration of 50 ms at maximum amplitude but is delayed by 200 ms from the time the key is tapped. If the tone is audible, its presence causes the subject to vary tapping behavior in several ways, such as a loss of rate or rhythm, the number of taps, or an increase of finger pressure on the key.

It has been demonstrated that changes occur in tapping performance at sensation levels as low as 5 dB and are independent of test tone frequency and manual fatigue (Ruhm and Cooper, 1964). Once a subject has demonstrated key-tapping ability, any alterations seen after introduction of a delayed puretone must be interpreted as meaning that the tone was heard.

Not all researchers have found the 5-dB SL change in tapping performance using puretone DAF. Alberti (1970) found that tapping rhythms were disturbed in general at

5 to 15 dB above threshold, but has observed variations as great as 40 dB SL. He reported that some subjects are difficult to test with this procedure because they either cannot or will not establish a tapping rhythm. At times patients appear to fail to understand the instructions and at other times complain that their fingers are too stiff to tap the key.

Two studies (Martin and Shipp, 1982; Monro and Martin, 1977) show puretone DAF to be extremely resistant to effects of previous test knowledge and practice with tones at low sensation levels. The puretone DAF procedure is considerably less time-consuming than many of the electrophysiological methods and has been found to be accurate, reliable, and simple (Robinson and Kasden, 1973). Despite these advantages, puretone DAF is not generally used and commercial devices are not available for this procedure.

OBSOLETE PROCEDURES

There are several procedures that were developed for the diagnosis of nonorganic hearing loss whose days of popularity have come and gone. Some of these tests were more useful than others, but they have all, more or less, been replaced (Martin et al., 1998a). They are briefly discussed here because of their historical significance.

The *Doerfler–Stewart* test (1946) was designed to detect bilateral nonorganic hearing loss by presenting successive levels of noise and spondaic words through both channels of a speech audiometer. Although cooperative patients continue to repeat spondees even with noise levels slightly above threshold, patients who exaggerate their thresholds for both the speech and noise become confused. Probably because of its failure to produce quantitative data, the *Doerfler–Stewart* test is rarely used today.

Speakers monitor their vocal intensity primarily by means of auditory feedback. When masking is applied to their ears and their thresholds are raised, it is normal for people to speak more loudly in an effort to monitor their voices. This is called the Lombard voice reflex. Theoretically, there should be no change in vocal intensity unless the noise is well above the speaker's threshold, masking the normal auditory feedback. This was the principle of the *Lombard Test*, which has fallen into disfavor because it does not quantify the degree of nonorganic hearing loss present and many false-positive results were observed.

The phenomenon of *delayed speech feedback* has been known for some years. When a subject speaks into the microphone of a recording device and that signal is amplified and played back through earphones, the result is simultaneous auditory feedback and is not unlike what most of us experience as we monitor our voices auditorily. When the feedback is mechanically or electronically delayed by approximately 200 ms, the result is a change in vocal rate and intensity. The major problem with the delayed speech feedback test was that it does not come close to identifying auditory threshold.

In *Békésy audiometry* the locus of auditory lesion is determined by comparison of the threshold tracings obtained with continuous and periodically interrupted tones. Patients with nonorganic hearing loss were reported to manifest a distinct Békésy pattern (Jerger and Herer, 1961) with the tracings for interrupted tones showing poorer hearing than for continuous tones. Several modifications to this test, primarily tied to changes in the off time of the pulsed signal, strengthened its value. To add greater difficulty in Békésy tracings for patients with nonorganic hearing loss, Hood et al. (1964) developed a technique called BADGE. Comparisons are made of auditory thresholds that are approached from high- and low-intensity starting levels, thereby confusing patients who choose to exaggerate their thresholds. Békésy audiometry has not been practiced very much in recent years in large measure because of the extended time it takes for this procedure.

Once the most popular test for nonorganic hearing loss, and formerly required on virtually all veterans seeking compensation for hearing loss, is *electrodermal audiometry* (EDA). The abandonment of EDA is due, in part, to the use of noxious stimuli (electric shocks) as the unconditioned stimuli that were paired with puretones or speech as the conditioned stimuli. According to the model, once conditioning was established by pairing conditioned and unconditioned stimuli, the unconditioned response (drop in electrical skin resistance) to the unconditioned stimulus (shock) would be seen in addition to a conditioned response in reaction to the tone or speech alone. In part, because of the discomfort and possible liabilities involved with this procedure and the concern on the part of some audiologists regarding the validity of EDA, it has fallen into virtual disuse. There are also some tragic stories about misdiagnoses in children.

TEST SEQUENCE

During routine audiometry the precise order in which tests are done probably does not have a significant effect on results. However, patients with nonorganic hearing loss probably attempt to set a level above threshold as a reference for consistent suprathreshold responses. For this reason threshold tests should be performed before suprathreshold tests.

The following test order has proved useful in examining patients with suspected nonorganic hearing loss: (a) Immittance measures; (b) OAE; (c) SRT, including the modified Stenger test in unilateral cases; (d) air-conduction thresholds, including the Stenger test if indicated; (e) word recognition tests at low sensation levels; (f) bone-conduction thresholds; and (g) ABR or ASSR.

TINNITUS

Tinnitus, a term taken from the Latin “tinnire” meaning “to ring,” has become a major health issue. Among all the claims

to the Department of Veterans Affairs (in the United States) for service-connected compensation the most common is for tinnitus. Certainly, the majority of these VA claims are honest and truthful. Nevertheless, for those whose aim is to gain or increase pension benefit, tinnitus may be a tempting way to acquire compensation by exaggerating or fabricating this symptom.

Most tinnitus sufferers also experience hearing loss, which is now the second-most common claim to the VA. The degree of hearing loss can be determined through audiometric testing. However, for purposes of recompense, a system for evaluation of tinnitus is necessary. At this time, there are no objective tests to substantiate tinnitus complaints (e.g., Byun et al., 2010). Therefore, assessment of tinnitus is mainly based on reports by the claimant. For members of the military and veterans, the degree of disability is determined by completion of a questionnaire. If the problem is determined to be recurrent, the usual compensation is a 10% disability. This percentage may be different in other countries.

Since tinnitus is a growing problem there is a great need for research to lead to better assessment measures. As surely as it is important to determine when tinnitus claims are feigned or intensified, it may be even more important to find ways to fairly compensate individuals who truly suffer from this vexing symptom.

COUNSELING NONORGANIC PATIENTS

Counseling sessions should be carried out after all audiologic evaluations. Counseling the individual with nonorganic hearing loss is naturally more difficult than counseling patients with an organic hearing disorder. Peck (2011) notes that nonorganic hearing loss should be viewed as a possible symptom of an underlying psychosocial problem. If the audiologist is able to get the patient to admit true organic thresholds the underlying problem may persist. Whereas adults more often present nonorganic hearing loss for financial gain, this is unlikely the motivation for children.

Children may be told only that their hearing appears to be normal (if this is believed to be the case) despite audiometric findings to the contrary. Parents should be cautioned not to discuss their children's difficulties in their presence or to provide any secondary rewards that may accompany a hearing loss. The audiologist should question the child and/or the parent on potential difficulties or disturbances that may have led the child to seek attention by feigning hearing loss. Raised concerns should be investigated further through referral to the school psychologist. It should be explained to the parent that consultation with the school counselor can help identify issues that may have led to the hearing test failure, so the child and the family can address these concerns together. The resultant supportive therapy from such

referrals is often the most efficacious treatment for the child with nonorganic hearing loss (Andaz, Heyworth, & Rowe, 1995). Parents should be encouraged to see their children not as deceitful, but as resourceful. It is the clever child who can create circumstances that provide some psychological support when confronting significant life stressors (Clark, 2002).

Adults with nonorganic hearing loss may simply have to be told that a diagnosis of the extent of the hearing disorder cannot be made because inconsistencies in response preclude accurate analysis. Peck (2011) suggests relaying to patients that some people coming in for a hearing test seem preoccupied with other concerns that seem to interfere with listening during the test. Asking the patient if that seems applicable may help to uncover underlying issues that should be addressed by a mental health professional. More in-depth questioning might be offered by asking if the patient is troubled by anything in particular with friends or at home or on the job. Guidelines for the audiologist broaching mental health referrals are given elsewhere (Clark and English, 2014). In general, if a referral for psychological evaluation or guidance is indicated, a referral should be made with confidence stating that the audiologist believes it may be beneficial to talk with an expert in dealing with difficult life situations. It is at this juncture that audiology must be practiced as more of an art than a science.

DISCUSSION

In the vast majority of cases, the detection of nonorganic hearing loss is not a difficult task for the alert clinician. The more challenging responsibility of the audiologist is to determine the patient's organic thresholds of hearing, however the difficulty of this task increases as the cooperation of the patient decreases. Some patients with nonorganic hearing loss are overtly hostile and unwilling to modify their test behavior even after counseling.

It is not likely that a single approach to diagnosis and resolution of nonorganic hearing loss is forthcoming, although there are certain points on which we should all agree. For example, it is far better to discourage exaggeration of hearing thresholds at the outset of testing than to detect and try to correct these exaggerations later. Once nonorganic hearing loss is observed, the audiologist is faced with the responsibility of determining the true organic thresholds. Tests that may aid in deterring elevated responses include all the electrophysiological and electroacoustic procedures. In our opinion, acoustic immittance measurements and OAEs should be accomplished initially in all routine audiologic assessments, thereby discouraging some nonorganic hearing loss. The Stenger test is quick and easy to perform, where applicable, and like immittance testing and OAEs allows the patient to realize that the examiner has methods of determining puretone thresholds, even without patient cooperation.

Great care must be taken in writing reports about patients with suspected nonorganic hearing loss. It must be borne in mind that once individuals have been diagnosed as “malingerer,” “uncooperative,” or “functional,” their reputations and prestige may be damaged. To label a patient in such ways is a grave matter because it implies deliberate falsification. Such labels are difficult to expunge and may be tragically unjust. The only way an audiologist can be absolutely certain that a patient with nonorganic hearing loss is truly a malingerer is for the patient to admit to the intent, and most experienced audiologists would probably agree that such admissions are rare indeed. Value judgments are not within the purview of the audiologist and should be avoided.

CONTROVERSIAL ISSUES

Few subjects in the profession of audiology are as open to disagreement as the issue of nonorganic hearing loss. One of the most contentious is probably the terminology that should be used which was discussed earlier. Another would certainly be the believed causes of this condition.

Since the early days of the profession of audiology, there was a belief that the cause of individuals feigning or exaggerating hearing loss could be broken down into two major categories. First, there were those pretending to have a hearing loss (or other medical condition) for personal gain or freedom from an obligation. This deliberate action is called malingering (the prefix meaning bad, wrong, or improper). In other words, this is a hearing loss that is just made up in its entirety or exaggerated. It is a pejorative term that has doubtlessly caused much consternation and litigation over the many years of its use. It is the view of these authors that this is a term that should never be used verbally or in a report unless the patient admits to deliberate falsification, which, over our combined clinical experience of more than 80 years, has never been experienced.

Second, as far as etiology is concerned, the “other” cause was believed to be of a psychologic or psychiatric nature. It was believed by some that there are patients with normal or near-normal hearing who could not hear because unconsciously they did not want to hear. By its nature this would be a hearing loss with no discernible organic cause. There have been case studies of such unconscious behavior published over the years suggesting this to be true in some instances, but this is far from conclusive. In truth the whole matter of nonorganic hearing loss is complex and multivariate. Every case is different and such factors as education, age, occupation and life experience have complex influences that exist on a long continuum. Decisions made about the handling of patients with nonorganic hearing loss are very much influenced by the philosophy of the audiologist. There are still clinicians who believe that all those exhibiting nonorganic hearing loss are simply liars, and others who believe that the behavior is entirely unconscious.

FOOD FOR THOUGHT

1. Given that studies suggest that those with nonorganic hearing loss tend to have a greater degree of clinically significant emotional disturbance, tendencies toward hypochondria, and a greater reliance on denial mechanisms, should the audiologist refer these patients for mental health services following determination of hearing status? How might you determine who might benefit from a consultation with a professional counselor?
2. Do you agree with the authors' recommended test sequence for suspected nonorganic hearing loss and if not what would you do differently and why? Do you believe that the audiological test sequence should be standard for all patients?
 - 3a. You have tested an eleven-year-old boy whose results are clearly indicative of nonorganic hearing loss. While your standard test results have not demonstrated frequency-specific normal hearing thresholds, you are confident that the hearing is within the normal range in both ears. What are the advantages to pursuing testing further to gain clear documentation of normal hearing? What are the disadvantages to doing this?
 - 3b. In question 3a no specific tests for nonorganic hearing loss were utilized. Under what circumstances would you perform such tests, name those you would use and the order in which you would apply them.
 - 3c. List the usual signs of nonorganic hearing loss. Include patient behaviors, anomalies on routine tests, history, and sources of referral.
 - 3d. What might you say to a patient for whom you believe a professional counselor should be brought into the picture? Be prepared for lack of acceptance and even hostility from the patient and/or the significant others who might accompany him or her.

Hearing Loss in the Elderly: A New Look at an Old Problem

Barbara E. Weinstein

DEMOGRAPHICS OF AGING AND HEARING LOSS

We are living during historic times. The demographics of aging have changed dramatically with the coming of age of the “baby boomers” who began to turn 65 in 2011. Worldwide, the older population is growing at a dramatic rate; the world’s 65-and-older population is projected to triple by midcentury, from 516 million in 2009 to 1.53 billion in 2050. The growth rate for the population of persons of 65 years of age is expected to outpace that for the total population rather dramatically, such that by 2040 it will be one in five. The older population is getting older with the most dramatic growth among those over 85 years of age, namely the “oldest-old.” By 2030, people aged 85 or over, will nearly double the number in 2002. Although the number of people aged 75 and over who are employed is relatively small they had the most dramatic gain in employment—increasing by close to 170% from 1977 to 2007. Increasingly, job growth for older workers is most dramatic in the service sector, where audition is imperative for effective communication and transaction of business.

Hearing Loss and Comorbidities

It is notable that older adults with hearing loss have the increased burden of medical comorbidities relating to aging with more than 50% of older adults having three or more chronic diseases (i.e., multimorbidities). According to a recent report by Crews and Campbell (2004) individuals with hearing loss, vision loss, and dual sensory loss have an increased likelihood of presenting with comorbid conditions ranging from falls to hypertension to cardiovascular disease. Age is the most common risk factor for vision and hearing impairment in older adults and it follows that many older adults present with dual sensory impairments. Age-adjusted rates of hearing and visual impairment were significantly higher in men than women.

Using data from the National Health and Nutrition Examination Survey (NHANES), Bainbridge, Hoffman and Cowie (2008) compared hearing levels of adults with and without a diagnosis of diabetes. At all decades (1920s through 1960s), individuals with diabetes presented with

poorer hearing threshold levels across frequencies than did those without diabetes and the difference appeared to be greatest in the higher frequencies. McMahon et al. (2008) found that smoking and diabetes were significantly associated with an increased odds of hearing loss confirming a probable link to age-related hearing loss (ARHL). Diabetes mellitus is associated with hearing impairment and cochlear microvascular dysfunction may be at the root of the association (Helzner et al., 2011).

A number of investigators have recently explored the link between memory, hearing, and cognitive function. Memory impairment and hearing impairment are considered common aspects of aging. In fact, using a sample from the Third NHANES, Li et al. (2006) found that self-reported functional hearing impairment and memory impairment were prevalent, but not comorbid in their sample of adults 65 years of age and older. According to newly emerging data, hearing loss is independently associated with an increased risk of cognitive decline over time with significant associations between greater hearing loss and poorer cognitive function (Lin et al., 2013). Using participants in the Baltimore Longitudinal Study, Lin et al. (2011) conducted a prospective study of 639 adults ranging in age from 36 to 90 years to determine the degree to which hearing impairment is associated with incident all-cause senile dementia and Alzheimer disease. All participants underwent audiometric testing and cognitive testing overtime. The risk of incident dementia increased with severity of hearing loss with adults who had moderate hearing loss were more likely than those with normal hearing to develop dementia and adults with severe hearing loss were at greatest risk.

Social isolation and loneliness, which are correlates of hearing loss and susceptibility to falls, may be possible factors mediating the link between hearing loss and cognitive decline (Cacioppo and Hawkey, 2009; Cacioppo et al., 2010; Lin et al., 2013). Weinstein and Ventry (1982) conducted one of the first audiologic studies on social isolation, demonstrating a stronger link between subjective social isolation, hearing handicap, and hearing loss than between objective social isolation and audiometric variables. We now know that there is also a link among social isolation, self-reported hearing difficulties, and depression. It is notable that individuals with visual impairment are susceptible to

falls and are at risk for activity limitations and consequent social isolation. Older adults with both vision and hearing loss were more likely than those without to have sustained a fall, and accordingly reported fewer social engagements and increased difficulty with activities of daily living. As impaired hearing is associated with greater risk for falls and possible attendant injuries, people with hearing impairment may have more mobility limitations than people without hearing impairment adding to the potential for decreased social engagement (Karpa et al., 2010; Viljanen et al., 2009). Viljanen et al. (2009) explored the relation between walking difficulty and hearing impairment in a female sample. In this study, participants underwent baseline hearing tests and tests of maximal walking speed and walking endurance. They were also asked to self-rate their walking difficulties. At the 3-year follow-up, participants were asked to once again self-rate their walking difficulties. It was of interest that at baseline women with hearing impairment had two times the risk of having major difficulties walking 2 km than those without hearing impairment. Interestingly, participants with hearing impairment were more likely than those without hearing impairment to develop walking difficulties at follow-up. Viljanen et al. (2009) speculated that hearing impairment correlates with mobility as a result of such factors as impaired postural balance and greater risk of falls. Alternatively, it may well be that impaired hearing places greater demand on attention sharing, thereby making mobility more of a challenge. It is important to note that in this sample, the overwhelming majority of people with hearing impairment had mild hearing loss and were not hearing aid users. The fact that people lacking in social connections and reporting frequent feelings of loneliness (i.e., persons with hearing impairment and persons prone to falls) tend to suffer higher rates of cognitive decline, depression, morbidity, and mortality may explain, in part, the link (Cornwell and Waite, 2009).

Helzner et al. (2011) explored the relationship between hearing impairment and cerebrovascular disease (CVD). It was of interest that risk factors for CVD, such as higher levels of triglycerides and history of smoking (in men), higher BMI (in women), and higher resting heart rate, tended to be associated with poorer puretone hearing levels, whereas clinical CVD did not seem to bear any relationship to hearing impairment. Helzner et al. (2011) speculated that insufficient cochlear blood supply may disrupt the chemical balance of endolymph, which in turn can affect the electrical activity of the hair cells and may compromise the activation of the auditory nerve. The authors concluded that “prevention of CVD and its contributing factors has the potential to slow the progression of age-related hearing loss” (Helzner et al., 2011, p. 978).

There are a number of modifiable and nonmodifiable risk factors for ARHL. The nonmodifiable factors include age, genetic predisposition, race, and gender (Yamasoba et al., 2013). The modifiable risk factors include noise,

smoking, ototoxicity, and multiple health comorbidities including CVD, cardiovascular disease, diabetes, and cognitive decline. When present in older adults with chronic conditions ranging from CVD to diabetes and falls, hearing loss is likely to increase the burden of these conditions and at times can exacerbate or be exacerbated by these medical conditions. Hence, audiologists should work with primary care professionals to develop early intervention protocols to reduce the potential burden of hearing loss in persons with multimorbidity.

THE AGING AUDITORY MECHANISM

The field of “otogerontology” has made significant strides in documenting the anatomic, physiological, and audiological changes within the peripheral and central auditory mechanisms. Current thinking is that the auditory system is an integrated one involving an interplay among its many components including the ear and the brain (Weinstein, 2013). More recent thinking is that poor output from the peripheral auditory system, due in part to age-related changes, reduces the quality of the input to the central auditory system and ultimately the communication challenges associated with ARHL. For some, the central locus may underlie the age-related declines in auditory temporal processing key to speech understanding, whereas for others, it may well be the cognitive changes associated with age-related changes in portions of the brain. The lack of uniformity may help to explain the individual differences in speech understanding in challenging acoustic environments which is the hallmark of ARHL. Presbycusis is the term traditionally used when referring to hearing loss in older people (Gates and Mills, 2005).

Although noteworthy, age-related changes in the periphery, including the outer and middle ears, have few implications for communication ability. There is a loss of elasticity and strength in the pinna and external auditory canal. The sebaceous and cerumen glands in the cartilaginous portion lose some of their secretory ability. The decrease in fat leads to significant changes in the skin lining the canal. Changes in the physical properties of the skin, including dryness and dehydration, make the canal prone to trauma and breakdown. Cerumen becomes more concentrated, hard, and impacted due, in part, to inadequate epithelial migration (Weinstein, 2013). The bony canal is especially susceptible to trauma from attempts at cerumen removal because the skin covering is very thin (0.2 mm in thickness). The shape and age-related changes within the ear canal may have implications when making earmold impressions for hearing aids located completely in the ear canal and will influence hearing aid fittings especially with some of the newer deep insertion hearing aids (Weinstein, 2013).

Cerumen impaction can occur in the outer ear because of increased activity of cerumen glands in the cartilaginous portion, physical obstruction because of a hearing aid,

frequent use of cotton-tipped swabs, or the production of drier and less viscous cerumen. Combined with the presence of thicker and longer hair follicles oriented toward the tympanic membrane, the latter condition leads to a higher rate of impaction among older adults. One of the most common reasons for physician visits is accumulation of cerumen because of failure of the self-cleaning mechanism. A common reason for a primary care visit is accumulation of excessive cerumen. Cerumen impaction is present in approximately one-third of older adults, with estimates being quite high among nursing home residents. Developmentally delayed adults, people with intellectual challenges and cognitive impairments, are prone to impacted cerumen (Roland et al., 2008).

The site of conversion of mechanical energy to an electrophysiological signal, the inner ear is composed of several functional components that are vulnerable to the effects of aging. These components are sensory, neural, vascular, metabolic, supporting, synaptic, and/or mechanical (Weinstein, 2013). The most critical risk factor for the auditory sense organ is age yet genetic susceptibility and noise exposure play a role, as well (Lin, Thorpe, Gordon-Salant, Ferrucci, 2011). Although the organ of Corti is most susceptible to age-related changes, structural and chemical changes occur throughout the peripheral and central auditory systems (Tremblay and Ross, 2007). Age-related atrophy ultimately interferes with the transduction process integral to the reception of sound. Knowledge of changes in the aging cochlea is based primarily on histopathologic studies of human temporal bones and more recently on animal models using a variety of animals (Frisina et al., 2009; Schuknecht, 1955; Schuknecht and Gacek, 1993).

The primary histopathologic changes in the organ of Corti include sensory cell degeneration along with loss of supporting cells including Deiters, pillars, and Hensen cells. In general, loss of hair cells begins in the extreme basal end where it is most severe with the outer hair cells degenerating first. Degeneration of the outer row of outer hair cells is often more severe than in the other rows. Decrease in hair cell population is greatest in persons over 70 years of age. It is important to note that outer and inner hair cells tend to degenerate independently. It is now well accepted that degeneration of outer hair cells may in fact be due in large part to noise trauma in addition to age. Loss of nerve fibers in one or more turns of the cochlea has been noted without severe hair cell loss. The loss of inner or outer hair cells is not a prerequisite for age-related pathology of ganglion cells; however, inner hair cell loss is almost always associated with ganglion cell loss. Hence, shrinkage of afferent nerve fibers and their cell bodies, even with inner hair cells present, is a classic finding associated with aging. There is a relationship between amount and location of ganglion cell loss and puretone thresholds. Hearing loss first occurs once the neural unit population falls below the number required for processing acoustic energy (Suzuka and Schuknecht, 1988).

In contrast, speech recognition ability cannot be predicted from spiral ganglion cell population.

Recently, a number of neuronal changes have been documented with increasing age. Age-related changes have been noted to affect neural synchrony which is associated with reduced amplitude of the action potential, decreased neural inhibition (Casparly et al., 2005), and longer neural recovery time (Walton et al., 1998). In addition, there is a reduced number of neurons in the auditory nuclei, synaptic changes between inner hair cells and the auditory nerve, and changes in the level of inhibitory neurotransmitters (Casparly et al., 2005; Clinard et al., 2010; Weinstein, 2013). The neural representation of sounds is altered in the aged central auditory nervous system and there is an age-related loss of acoustic nerve activity with both contributing to the processing problems experienced by many older adults especially in the temporal domain (Frisina and Walton, 2006). It is now well accepted that the consequences of the changes in the peripheral auditory system are seen throughout the central auditory system including the cochlear nucleus, the inferior colliculus (IC), medial geniculate body, and the primary auditory cortex. Specifically, auditory deprivation in the periphery disrupts the tonotopic organization in the midbrain and cortex. There is central auditory reorganization because of neural plasticity in which intact regions of the tonotopic map adjacent to the impaired regions tend to become responsive (Tremblay and Kraus, 2002). Stated differently, reorganization of the auditory cortex and the central auditory system is widespread because of peripheral and central changes which take place with aging.

Although Schuknecht's 1950s histologic technique was crude by today's standards, his work did result in the classification of presbycusis into several distinct types including sensory, neural, metabolic, cochlear conductive, mixed, central, and indeterminate (Gates and Mills, 2005). Difficult to distinguish histologically and clinically from acoustic trauma, the audiometric pattern associated with sensory presbycusis is typical of noise-induced hearing loss. Based on data accumulated using distortion product otoacoustic emissions (OAEs) and audiograms, sensory presbycusis may not be as prevalent in older adults as once theorized (Gates et al., 2002). In fact, sensory presbycusis appears to have more to do with long-term exposure to environmental toxicities such as noise, than with age, *per se*.

A consistent pathologic change associated with neural presbycusis is degeneration of the population of neural units. Neuronal loss tends to diffuse, involving all three turns of the cochlea. Neuronal loss in the periphery, which may begin at any age, is often accompanied by loss of neurons in the ventral and dorsal cochlear nuclei. As the deleterious effects of aging are typically first seen in highly metabolic tissue in the body, it is not surprising that the most prominent feature of ARHL is atrophy of stria vascularis, an area very high in metabolic activity (Schmiedt, 2010). Current thinking is that age-related strial degeneration reduces the

endolymphatic potential (EP), which in turn is responsible for reduced activity in the inner hair cells. The latter changes translate into reduced activity in the auditory nerve and loss of neural synchrony (Ison et al., 2010; Tun et al., 2012). Specifically, according to data accumulated using animal models, there is a direct correlation between strial degeneration and EP voltage and when strial degeneration exceeds 50%, EP values drop rather substantially (Gates and Mills, 2005). The change in the EP with age has given rise to the dead battery theory of presbycusis. Low-frequency hearing loss is typical of persons with strial presbycusis and there is a heritability factor associated with strial presbycusis, which appears to be more pronounced in women (Gates and Mills, 2005). Age-related degeneration of stria vascularis is the most common feature ARHL (Gates and Mills, 2005).

Cochlear conductive presbycusis is associated with changes in the physical properties of the cochlea such as loss of elasticity of the basilar membrane, which affects its mechanical response. Schmiedt (2010) suggested that mechanical presbycusis may merely be an extreme case of metabolic presbycusis, as from animal models we know that a very low EP is associated with a mild, flat audiogram with hearing loss greater in the low frequencies. Mixed presbycusis is characterized by the involvement of two or more of the four classic types of presbycusis. For example, the combination of sensory and strial presbycusis might present as an abrupt high-frequency hearing loss superimposed on a flat audiogram, whereas sensory and cochlear conductive presbycusis might emerge as an abrupt high-frequency loss superimposed on a descending puretone audiogram (Schuknecht and Gacek, 1993). Intermediate presbycusis, described by Schuknecht and Gacek (1993), is characterized by the presence of submicroscopic alterations in structures of the cochlea that control cell metabolism, a decrease in the number of synapses on hair cells, and chemical changes in endolymph. Audiograms associated with presbycusis of this variety are primarily flat or mildly descending, without consistent or distinct pathologic correlates. Thus, presbycusis has variable forms of clinical expression and is not necessarily represented by a single pattern. Despite the audiometric patterns often seen clinically, it is impossible to identify the type of presbycusis from the audiogram.

The aging process impacts the central nervous system in general and the central auditory system in particular. Neuronal age-related atrophy is characterized by an overall loss of neurons; a change in neuron size (i.e., shrinkage); a decrease in size of the cell body, nucleus, or nucleolus; and a decrease in dendritic arborization along with a diminution or disappearance of dendrites and a lengthening of dendrites (Shankar, 2010). Additional functional changes in the auditory nervous system include changes in dendritic morphology, alterations in neurotransmitter receptors and in electrophysiological properties, and glycine inhibition and loss of glycine receptors (Shankar, 2010). The frequency of spontaneous excitatory postsynaptic currents is reduced

while there is interference with the electrical firing pattern characteristic of neurons involved in information processing (Shankar, 2010). The loss of auditory nerve function with age is evident in the changes in the action potential of the auditory nerve in which the input–output functions of the compound action potential are shallow in older animals as compared to younger animals (Gates and Mills, 2005).

According to Gates and Mills (2005), the asynchronous activity in the auditory nerve associated with aging may derive from a combination of factors including the nature of the synapse between the inner hair cells and individual auditory nerve fibers, primary degeneration of spiral ganglion cells, and a reduced EP. It appears that age-related changes in asynchronous activity of the auditory nerve combined with age-related changes in the central auditory nervous system explain the decline in temporal resolving abilities so prevalent in older adults (Gates and Mills, 2005).

According to functional and neurochemical studies using animal models, age-related changes in neural recovery may be attributable to an imbalance in inhibition and excitation critical for normal cellular function and slow peripheral deafferentation (i.e., incomplete afferent connections) may trigger decrements in inhibitory neurotransmission (Canlon et al., 2010; Caspary, Schatterman and Hughes, 2005; Eddins and Hall, 2010). The reduced amplitude of the action potential recording in aging ears is likely indicative of poorly synchronized neural activity in the auditory nerve which translates into abnormal function in the auditory brainstem as reflected in auditory brainstem studies (Gates and Mills, 2005). Alterations in synaptic processing, decline in inhibitory neurotransmitters such as GABA, and age-related disruptions in temporal processing associated with changes in the auditory nerve and central auditory pathways likely contribute to the speech understanding difficulties in background noise which are the hallmarks of ARHL (Frisina and Walton, 2005).

Using animal models, we now have an improved understanding of the nature of age-related changes in the central auditory nervous system. It appears that the primary aging changes in the dorsal cochlear nucleus are driven by the rapid loss of cochlear input (aka peripherally induced central effects) (Frisina and Walton, 2006). Further, there appear to be disruptions of synapses from ascending auditory nerve fibers in older animals as they make contact with cochlear nucleus neuron, along with a slight decrease in the number of nerve fibers within the lateral lemniscus and the IC (Frisina and Walton, 2006). It seems that there is an age-related downregulation of GABAergic inhibition throughout the auditory central nervous system, which may account for the age-related changes in the strength of central synapses (Caspary et al., 2008). According to Caspary et al. (2008) there is a selective loss of normal adult inhibitory neurotransmission with age which likely contributes to the loss of sensory function typical of older adults. Similarly, there are age-related declines in glycine receptors in the cochlear nucleus

which hampers glycinergic transmission critical to auditory processing (Canlon et al., 2010). Additionally, there are age-related changes in glutamate receptors which affect synaptic transmission in the cochlear nucleus, yet there does not appear to be age-related changes in the GABA receptors (i.e., a primary inhibitory neurotransmitter which decreases the neuron's action potential) in the cochlear nucleus (Canlon et al., 2010). There is a reduction in glycine levels in the cochlear nucleus with increasing age which alters the response properties of cells within the CN (Casparly et al., 2008). Interestingly, SOC studies in animals show age-related changes in potassium channels and calcium binding proteins in cells of origin in the descending pathway from the SOC to the cochlea (Zettel et al., 2007). According to Gleich et al. (2004) the size of glycine and GABA neurons in the high-frequency limb of the lateral superior olive is significantly reduced in older gerbils. The IC shows significant age-related changes in GABA neurotransmission (Casparly, Schatteman and Hughes, 2005). It appears that the degraded and decreased acoustic input associated with age-related changes in the auditory periphery is associated with a selective down regulation of normal adult inhibitory GABAergic function in the IC (Casparly et al., 2008). Notably, there is a decrease in the number of GABA-immunoreactive neurons, a decrease in GABA release, and a decreased concentration of GABA in the IC (Canlon et al., 2010). Further, decreased acoustic input from the auditory periphery is associated with significant changes in GABA neurotransmission in the normal adult IC (Casparly et al., 2008). In rats the IC shows significant age-related changes related to GABA neurotransmission and a loss of GABA-immunoreactive synaptic endings, as well (Turner and Casparly, 2005). The effects of age on the IC include reductions in the number of GABA-immunoreactive neurons, the concentration of GABA, GABA release, and GABA receptor binding (Leventhal et al., 2003). Similarly, there are deficiencies in glutamate function with age (Canlon et al., 2010). Reductions in the latter neurotransmitter have implications for neurotransmitter function in the IC likely affecting auditory processing. Finally, animal studies suggest that aging may be associated with a deficit in neural recovery at the level of the IC. According to Canlon et al. (2010), some of the above changes in the IC are typical of those seen in neural presbycusis and may explain deficits in intensity and temporal coding in older adults.

Brody (1955) was among the first investigators to identify age-related changes in the temporal lobe of the aging brain. Using a limited number of brains, Brody (1955) found that the magnitude of cell loss was greatest in the superior temporal gyrus. Notably, there was an almost one-to-one correlation between age and cell loss. He also noted a decrease in the thickness of the superior temporal gyrus with increasing age that was not apparent in other cortical regions. Subsequently, Scheibel et al. (1975) studied the superior temporal cortex and noted a loss of dendrites and cell death in older patients. According to animal

studies, auditory deprivation from the periphery disrupts the tonotopic organization of the central auditory nervous system. Recent research confirms that the primary auditory cortex undergoes age-related plastic changes, similar to that observed at lower levels of the auditory pathway (Casparly et al., 2008). Age-related changes in the GABA enzyme levels have been found in the primary auditory cortex of rats and it is likely that in humans a loss of normal GABA transmission contributes to difficulty in temporal coding (Canlon et al., 2010). Age-related changes in the brain, including the prefrontal cortex, have profound implications for the communication challenges confronting older adults.

GERIATRIC SYNDROMES ASSOCIATED WITH HEARING LOSS IN OLDER ADULTS

In addition to age-related degeneration, a number of other factors explain the hearing loss experienced by older adults. These include excessive exposure to occupational or recreational noise, genetic factors, acoustic neuroma, trauma, metabolic disease such as diabetes, vascular disease, infections, autoimmune disease, and drug exposure. Because of polypharmacy in older adults, adverse reactions from ototoxic agents may result from drug–disease interactions or drug–drug interactions. The cochlea is especially susceptible to ototoxicity because medication is retained for a longer period and in a higher concentration in the inner ear fluids than in any other body tissue or fluid, especially in individuals with liver or kidney dysfunction. Older adults are at particular risk for aminoglycoside ototoxicity when they have an existing loss of auditory function associated with the aging process (Weinstein, 2013).

Cardiovascular disease (CVD) is widespread among older adults. Cardiovascular insufficiency compromises the blood supply to organs throughout the body. Helzner et al. (2005) found that individuals with CVD had a 56% higher risk of hearing loss. Low-frequency thresholds appear to be more closely correlated to CVD than high-frequency thresholds, suggesting a possible vascular or metabolic link (Gates et al., 1993; Helzner et al., 2005). Helzner et al. (2011) noted that such risk factors as higher levels of triglycerides and history of smoking in men, higher body mass index in women, and higher resting heart rate in men and women were related to poorer hearing. The likelihood of hearing loss and its progression is higher in older adults with a diagnosis of diabetes than in those without the diagnosis (Mitchell et al., 2009). Another condition rising in prevalence among older adults is cognitive decline and data on its association with hearing impairment are compelling.

Cognitive impairment is associated with lower hearing levels and with faster declines in peripheral hearing sensitivity (Kiely et al., 2012; Lin, 2011). Lin et al. (2013) found that persons with hearing loss at baseline demonstrate more dramatic decline in cognitive status than did

individuals with normal hearing. Further, over the 6-year follow-up period, individuals with hearing loss were initially at increased risk of developing cognitive impairment than were those with normal hearing, with persons with more significant hearing losses at greatest risk.

Depression is among the most prevalent affective disorders in older adults. MacDonald (2011) explored the relationship between hearing loss and depression in a sample of adults 65 years of age and older. Scores on the Hearing Handicap Inventory for the Elderly were significantly associated with scores on the depression scale on the Center for Epidemiological Studies-Depression (CES-D) Scale. Interestingly, the actual hearing loss scores accounted for a smaller proportion of the variance on the CES-D. Similarly, in a sample of older adults from Japan, Saito et al. (2010) found that scores on the HHIE-S were an independent predictor of scores on the Geriatric Depression Scale (GDS). Gopinath et al. (2012) reported that having a measured hearing impairment at baseline dramatically increased the likelihood of developing a self-reported hearing handicap over time (Weinstein, 1986). Furthermore, after adjusting for age, and other factors, older adults with a self-perceived hearing handicap had a greater chance of reporting depressive symptoms. Similarly, after adjusting for age, smoking, stroke, visual impairment, and walking disability as compared to persons without a self-reported hearing handicap, those with significant self-reported hearing handicap on the HHIE-S had significantly lower mean physical component and mental composite scores on the SF-36, a scale that quantifies dimensions of health and well-being.

Zuniga et al. (2012) explored the relation between hearing level and saccular, utricular, and semicircular canal function in a sample of older adults 70 years of age and older. High-frequency hearing loss was associated with reduced saccular function, yet not with utricular or semicircular canal function. Age and noise exposure were significantly associated with cochlear and saccular dysfunction. This finding may explain, in part, why older people with chronic dizziness or imbalance are two to three times more likely to fall in comparison with older people who do not experience these problems. Karpa et al. (2010) underscored the importance of the links between hearing loss and functional decline, physical decline, cognitive impairment, low self-rated health, and mortality. They reasoned that the association between hearing impairment and difficulty in walking may be attributable to fear of falling, impaired balance associated with decreased vestibular function in older adults, and/or decline in physical and social activity associated with hearing loss. Furthermore, hearing impairment may increase the odds of cardiovascular death perhaps because these individuals are socially isolated, do not visit their doctors regularly, and are less inclined to take preventive steps such as exercise and diet. Interestingly, a recent report using data from the 2005 to 2006 and 2009 to 2010 NHANES revealed that in fact, for adults age 70 years and over, hearing

loss is independently associated with hospitalizations and poorer self-rated health (Genther, Frick, Betz et al., 2013). They too speculated that pathways through which hearing loss may increase the burden of disease may be through the relationship with social isolation and cognitive decline.

In conclusion, age-related changes within the auditory system are associated with many geriatric syndromes. The connections are linked either directly or indirectly to reduced independence, reductions in quality of life, increased mortality risk, social isolation, and disability in walking which are notable in selected individuals with hearing loss. Despite the fact that hearing loss is a chronic problem and is a leading cause of disease burden, it continues to go unrecognized and untreated in the majority of older adults.

AUDIOLOGIC FINDINGS

Puretone Thresholds

Age-related changes throughout the peripheral and central auditory systems are associated with decrements in hearing for puretones, speech understanding, and deficits in cognitive processing. Age and frequency effects emerge in cross-sectional and longitudinal studies of hearing loss with differences in prevalence estimates that may be associated with differing definitions of hearing impairment (e.g., three-frequency vs. four-frequency puretone average, 15 or 25 dB HL as cutoff) and lack of consistency in use of better or poorer ear to define hearing status. Despite the latter, there is general agreement regarding configuration and frequency specificity of hearing loss. Recent population-based studies on hearing loss in community-based older adults confirm that age-related hearing has several distinct features. Air-conduction thresholds became poorer with increasing frequency and puretone hearing sensitivity tends to decline with increasing age, with the greatest loss in the frequencies above 1,000 Hz. Further, the hearing loss tends to be bilateral, symmetrical, and sensory/neural in origin. The decline in high-frequency sensitivity appears to be greater in males, whereas the decline in low-frequency thresholds tends to be greatest in females of comparable age. Hearing loss configuration in the higher frequency tends to be sharply sloping in males and gradually sloping in females (Gordon-Salant, 2005). The average hearing loss in older males can be described as mild to moderately severe, bilateral, and sensory/neural with a sharply sloping configuration. Older women tend to present with a mild to moderate, gradually sloping, bilateral symmetrical, sensory/neural hearing loss. Among residents of nursing facilities, the sensory/neural hearing loss tends to be more severe than that of community-based individuals, in large part because of the older age of residents (Weinstein, 2013).

In addition to gender, race influences hearing status of older adults. (Lin, Thorpe, Gordon-Salant, Ferrucci, 2011) reported that the black race may be a protective factor

against developing hearing loss in that prevalence of hearing loss among black women and men over 70 years of age is dramatically lower (i.e., 45%) than in white (67%) participants. Prevalence of hearing loss is slightly higher among black men (43%) than among black women (40%), with white males having the highest prevalence (72%). Notable is that whites have a 63% greater likelihood than blacks of having a hearing loss. Finally, genetic factors have an impact on puretone hearing levels, as well. McMahon et al. (2008) explored the role of family history in hearing loss. Prevalence of hearing loss in their sample of 2,669 adults was higher in men (39%) than in women (29%). The majority (68%) of participants had mild hearing loss. Forty-seven percent of participants reported a family history of hearing loss. Most notable was that the majority (63%) of people reporting a family history of hearing loss were female. Severity of hearing loss was linked to familial history with 64% of participants who had moderate to severe hearing loss reporting a positive family history, as compared to 53% with mild hearing loss and 45% without hearing loss. Among those with moderate hearing loss, family history was on the mother's side. In addition, siblings in this cohort were more likely to have a hearing loss. This work suggests a strong association between presbycusis and family history with the relationship greater among females and their mothers than that found in males.

Speech Understanding

Older adults have more difficulty understanding speech in noisy environments, when people speak quickly, when the speaker has a foreign accent, in reverberant conditions, when there are multiple talkers, when the message is complex, and when there is reduced contextual information. Loss of peripheral hearing sensitivity, decline in cognitive abilities, age-related changes within the eighth nerve, auditory brainstem pathways, and auditory cortex are hallmarks of ARHL. Additionally, lack of neural inhibition and decrease in excitatory synchronization translate into degradation of the neural code throughout the central auditory nervous system (Tun et al., 2012).

There are large individual differences in speech understanding among those over 60 years of age with multiple probable etiologies. Results of a systematic review recently completed by Humes et al. (2012) shed additional light on the several hypotheses which have been suggested to explain the mechanisms underlying the central auditory processing (CAP) problems experienced by older adults, including the peripheral hypothesis, the central auditory hypothesis, and the cognitive hypothesis. In the peripheral hypothesis, the auditory periphery is implicated; in the central auditory hypothesis, the auditory portion of the central nervous system from the cochlear nucleus to the primary auditory cortex is implicated; and in the cognitive hypothesis, age-related changes in cognitive processing resources such as

working memory, attention, and executive function appear to underlie the speech processing difficulties many older adults experience (Humes et al., 2012; Tun et al., 2012). It is abundantly clear that the CAP problems typical of persons with ARHL cannot be isolated nor can they be attributable solely to one of the above mechanisms. A brief overview of each is included below.

Peripheral (e.g., cochlear changes) hypothesis. This hypothesis holds that speech recognition difficulties are attributable to individual differences in the encoding of sound by the outer ear through the inner ear and eighth nerve (Humes et al., 2012). The peripheral component is reflected in the frequency-specific sensitivity loss revealed by the audiogram, most notable in the high frequencies. The peripheral hypothesis has been further subdivided into two versions. One version suggests that simple changes in audibility, in which sound energy falls below an individual's audible region, account for the speech understanding problems characterizing older adults. The other version suggests that reduced physiological processing associated with age-related changes in the cochlea creates distortions beyond loss of hearing sensitivity. Sources of distortion may be due to changes in peripheral encoding mechanisms including loss of spectral and temporal resolution and loss of intensity discrimination. Decreased frequency selectivity and reduced intensity discrimination are manifest by increased frequency difference limens, poor intensity resolution, and increased intensity difference limens.

Central auditory hypothesis. This hypothesis implicates age-related changes in auditory structures in the central nervous auditory system including the IC (Humes et al., 2012). There are two possible explanations for the central auditory hypothesis including the more direct, namely the central effect of biological aging (CEBA), or the indirect mechanism, namely the central effect of peripheral pathology (CEPP). In the case of the former, peripheral hearing is normal and the speech communication deficits are attributable to deficits in the central auditory mechanism from the cochlear nucleus through the auditory pathways (Humes et al., 2012). In contrast, in the case of CEPP, the speech understanding deficit is due to the fact that central auditory changes may be induced by the peripheral pathology (Humes et al., 2012). Speech-based measures are typically used to assess central auditory function; however, performance is undoubtedly influenced by cognitive function.

Cognitive hypothesis. This hypothesis implicates higher centers in the auditory pathways as a source of individual variations in cognitive abilities and declines in cognitive performance. Cortical functions subsumed under these areas include information processing, storage, and retrieval. These cortical processes underlie performance on speech understanding tasks, and it follows that individual

differences in speech understanding performance may be attributable to deficits in one or more of these areas. It is noteworthy that cognitive deficits are not confined to the auditory modality. Indeed, short-term memory deficits may emerge on tasks involving both auditory and visual presentations of stimuli. The most notable changes in cognitive performance that influence speech understanding include attentional deficits, age-related reductions in the speed of perceptual and mental processing, and deficits in working memory and in executive function. Executive control processes that include such concepts as inhibition, working memory, and attentional capacity are responsible for the ability to plan, assemble, coordinate, and sequence operations integral to speech understanding which is a highly complex task. According to Kalluri and Humes (2012) given the role of cognitive processing in auditory function, audiologist should consider using dichotic tests, for example, to screen for central/cognitive function as decisions regarding choice of technologies recommended to older adults (e.g., hearing aids, FM systems) must be informed by these changes.

The information above indicates that many older adults experience significant difficulty understanding speech in less than optimal listening situations and the etiology is likely multifactorial. That is, peripheral, central, and cognitive factors likely interact in a variety of ways to explain the auditory processing difficulties which are characteristic of ARHL. The large individual differences in processing problems underscore the importance of screening cognitive function, assessing speech understanding in noise or reverberant conditions, and using results from targeted testing to inform recommendations which in many cases must go beyond traditional hearing aids. In addition to incorporating objective tests which are influenced by peripheral, central, and cognitive factors, self-report measures of communication function should be included as responses reflect the quality of life implications of speech processing deficits. Similarly, given the fact that lifelong experiences of playing music and software-based brain fitness programs tend to have a positive effect on speech understanding in noise, audiologists should inquire about these experiences and should discuss the potential beneficial effects of cognitive and perceptual training. Finally, audiologists should work with older adults with ARHL to assist them in learning how to use top-down processing skills to supplement deficits in bottom-up processing of the auditory signal (Pichora-Fuller and Levitt, 2012).

PSYCHOSOCIAL CONSEQUENCES OF HEARING IMPAIRMENT

Literature that has emerged over the past 10 years has demonstrated conclusively that untreated hearing loss has detri-

mental effects on psychosocial well-being, communication, affect, cognitive status, and functional health status. In fact, the myth that hearing loss is harmless has been debunked, and it is becoming increasingly clear that, if untreated, hearing loss can be costly to the individual in terms of relations with family members, social engagement, mortality, and productivity at work. The increased listening effort and fatigue associated with communicating in noisy and reverberant rooms contributes to the burden of hearing loss and the desire on the part of older adults with ARHL to gradually withdraw from social activities. When hearing loss goes undetected, the burden on the individual and society is enormous. ARHL is associated with perceived social isolation, which in turn is a predictor of adverse physical and mental health outcomes (Cornwell and Waite, 2009; Weinstein and Ventry, 1982). It is notable that persons with more chronic conditions become more functionally impaired sooner than do persons with fewer chronic conditions.

To further understand its adverse effects, it is important to understand that hearing loss and attendant communication deficits occur in the context of other geriatric syndromes including cognitive impairment, falls, and depression, contributing to disability which is a growing public health concern (Rosso et al., 2013). To explain, disability is defined as difficulty in performing activities of daily living such as dressing or eating, because of an existing physical or mental health limitation. Interestingly, according to results from the Women's Health Initiative, an observational study of community-based women over 65 years of age, 75% of the participants with five or more geriatric syndromes at baseline suffered from dizziness, hearing impairment, visual impairment, or urinary incontinence (Rosso et al., 2013). Women with five or more geriatric syndromes were six times more likely to develop incident disability than were those with no geriatric syndromes at baseline. The fact that presence of geriatric syndromes such as hearing loss is predictive of developing disabilities is significant in that the negative effects of hearing loss are potentially preventable with early identification and targeted interventions.

Dalton et al. (2003) conducted a population-based study of the relationship between hearing impairment and selected quality of life variables in a large sample of adults between the ages of 53 and 97 years old. More than half of the subjects had a hearing impairment, which was mild in 28% and moderate to severe in 24% of subjects. The quality of life indicators associated with hearing loss were social functioning, mental health, and physical functional status. The adverse effects of untreated hearing impairment appear to be a global phenomenon. Wu et al. (2004) evaluated the psychosocial consequences of self-perceived handicap in a sample of 63 older adults ranging in age from 62 to 90 years attending a geriatric medicine clinic in Singapore. In their study of subjects with self-reported hearing difficulty and a failed puretone screening, 70% of respondents indicated that

they would be happier if their hearing were normal, 40% indicated that difficulty hearing made them feel frustrated, and 43% admitted to feeling sad because of their hearing handicap. Interestingly, the federal government in Australia is designing a comprehensive approach to managing ARHL because “as a cause of burden of disease, hearing impairment is the second highest disability for every Australian man” (Smith et al., 2005, p. 2).

Gerontologists have long studied social isolation and have identified a number of indicators, all associated with poorer health. The link between hearing impairment and subjective social isolation is typically ignored by gerontologists but given its link to depression and cognitive impairment it is likely that hearing loss may explain some of the variability across indicators of social isolation which include having a small social network, low participation in social activities, a perceived lack of social support, and feelings of loneliness (Cornwell and Waite, 2009). It is of interest that older adults who perceive high levels of social support tend to have better coping strategies, greater self-esteem, and sense of control, whereas those who are socially disconnected tend to have poorer physical and mental health outcomes (Cornwell and Waite, 2009). The costs of social disconnectedness to society, the individual, and family members are high. Audiologists could potentially play a role in reducing the burden of selected conditions such as cognitive decline and social isolation if we focus research and clinical interventions on demonstrating that use of hearing assistive technologies including hearing aids is effective treatment for older adults with age-related hearing difficulties who value social engagement and connectedness.

To summarize, poor hearing is associated with perceived difficulties across a wide variety of activities that relate to managing everyday life. ARHL is predictive of increased functional, physical, and psychosocial impairments, as well as poorer health-related quality of life. There is a high degree of individual variability in the reactions of older adults to hearing loss, ranging from complete acceptance and positive personal adjustment to feelings of displacement, anger, and withdrawal. For this reason, it is important to qualitatively and quantitatively assess each patient to determine how hearing impairment affects them, their activity level, and their relations, with friends and family.

A DIAGNOSTIC AND MANAGEMENT PROTOCOL

It is clear from research and clinical experience that older adults require a diagnostic and management protocol which is client centered and unique to their needs. The protocol proposed below is based on several premises taken from the geriatric literature on patient-centered care, coupled

with the American Academy of Audiology Guideline for the Audiologic Management of Adult Hearing Impairment.

Premise 1. The objectives of the initial audiologic assessment with an elderly client should be to (1) understand the client’s experience with hearing loss (aka the patient journey), that is, the communication difficulties the individual is having from their perspective and that of a communication partner; (2) gain an understanding of the hearing status and speech understanding under a variety of conditions and at differing signal-to-noise ratios (SNRs) using reliable and valid measures; (3) understand the client’s stage of readiness and motivation to embrace some form of targeted intervention; and finally, (4) determine candidacy for the most appropriate hearing solution(s), be it personal sound amplifiers, hearing aids, hearing assistance technologies (HATs), speech communication training, and/or some form of counseling. Eliciting and understanding the patient’s perspective or narrative—concerns, ideas, expectations, illness experience, needs, feelings, and functioning—is key to the assessment process (Epstein et al., 2005).

Premise 2. Clinical measures of hearing are inadequate predictors of the difficulties older adults face in carrying out routine activities in their natural environments, accordingly routine assessment protocols are limited in their ability to enable audiologists to understand the complex auditory processing difficulties that are hallmarks of ARHL. Stated differently, audiologists must incorporate measures into the test battery which tap into age-related declines in auditory temporal and binaural processing and aspects of cognitive processing including working memory and speed of processing. Objective tests should be designed to uncover the listening difficulties the individual is experiencing, such as difficulty in the presence of noise, and reverberant conditions and to determine listening strategies being used (e.g., does the individual take advantage of visual cues when communicating?). Self-report data should be incorporated and used as an adjunct to objective and multifactorial speech testing as responses which often reflect personality variables are predictive of candidacy for intervention and outcomes from intervention. Finally, the importance of a test battery approach cannot be overemphasized, especially since many older adults will have difficulty understanding speech in group situations, in noise, and in reverberant conditions despite relatively mild hearing loss.

Premise 3. We should rethink our conceptualization of interventions for the hearing impaired and insure that the “patient experience” drives our recommendations. We must keep in mind that cognitive function will influence choice of intervention and outcomes and we must remain cognizant of the interaction between peripheral sensory

function and cognition when designing intervention strategies. We can best serve the needs of our older clients by providing customized solutions to their various communication challenges. Using decision aids which present the many options available will engage the patient as a partner and can ensure that they are made aware of the numerous approaches to improving the communication difficulties and outcomes associated with options presented. Technologies which include personal sound amplifiers, hearing aids, remote microphone technology, situation-specific HAT, and/or computer-based auditory training to improve auditory, cognitive, and speech processing are some of the many options available. The philosophy behind the choice of intervention should be our desire to “foster the effective and efficient trading of bottom-up processing based on the signal and top-down processing based on knowledge” (Pichora-Fuller and Levitt, 2012, p. 355). Important intervention outcomes to be cited should include independence, safety, improved quality of life, stress-free and natural listening, improved relations, and reduced burden of illness. We should insure that every person who walks into our office leaves with some form of solution to the communication challenges being voiced especially when purchase of hearing aids has been postponed. To reiterate, solutions can range from listing and reviewing necessary communication strategies, advice on hearing protection to promote hearing health, use of mobile apps on smartphones, and discussions about the value of personal sound amplifier products (PSAPs) for selected uses to some form of computer-based auditory and speech comprehension training. Using the principles listed above, the audiologic evaluation for older adults should include the intake and the evaluation. More information about counseling regarding recommendations and follow-up can be found on the Point at <http://thepoint.lww.com>.

Step 1: The Intake and Needs Assessment

The purpose of the intake is to obtain a comprehensive history that encompasses medical and nonmedical aspects of the hearing loss. To best promote quality of care, the traditional case history should focus on the etiology and evolution of the hearing loss and geriatric syndromes that may be relevant especially those typically associated with hearing loss including diabetes, kidney disease, and CVD. Smoking history, family history, hearing aid use history, and history of noise exposure are important considerations, as well. A multifaceted needs assessment which provides a feel for the patient journey and the impact of the hearing loss on the individual and the family is an integral part of the intake. During the initial encounter keep in mind what is important: What does it mean to this person to have this impairment at this time in his or her life, with spouse and

8. HHCIR (Hearing Health Care Intervention Readiness) Questionnaire

children, in the person’s environment, and peer group? Table 34.1 lists some questionnaires to consider for a communication needs assessment. Responses will inform testing protocols and can serve as the basis for counseling and decision-making regarding next steps in the process including treatment options. Further as Tun et al. (2012) suggest, self-report measures yield information about lifestyle and quality of life, and at times you can get at ease of listening which is so relevant especially when communication partners are concerned. Table 34.2 includes a very recent modification of the Hearing Handicap Inventory, namely the Hearing Health Care Intervention Readiness Questionnaire (HHCIR), which is currently undergoing reliability and validity testing. This questionnaire includes questions on social engagement and readiness plus questions about activity limitations/participation restrictions. Given the link between social engagement and cognitive function and social isolation and hearing loss it is important to ask directly about the issue of social connectedness. People who consider themselves to be lonely and isolated are at risk for disability and should be referred to their physician and of course recommendations for hearing assistance if appropriate. Finally, at the intake, audiologists might consider routinely administering a screening form for mental status such as the Montreal Cognitive Assessment (MoCA) or Mini-Mental Status Evaluation (MMSE), for depression using the Patient Health Questionnaire (PHQ), and for vision using the Snellen Visual Acuity Eye Chart.

Information from these screening instruments is important given the interplay among hearing impairment, cognitive function, depression, and visual status. At times referral to a geriatric specialist or primary care physician may be appropriate as partnering with these professionals

Hearing Health Care Intervention Readiness Questionnaire^a

Hearing Health Care Intervention Readiness [HHCIR]

© Barbara Weinstein, 2012

Instructions: The purpose of this questionnaire is to identify any problems you are having communicating with others and to help determine your readiness to pursue a hearing healthcare intervention. Please circle either *the most appropriate response* to each question. If you hearing aids, please answer the way you hear when using the hearing aids, if you are not experiencing any hearing difficulties, please mark NA for each item.

Item		4	2	0	NA
H-1	Does a hearing problem cause you difficulty when listening to the television or to the radio?	Yes	Sometimes	No	
R-1	How important is it for you to have less difficulty when listening to the television or radio?	Very	Somewhat	Not very	
H-2	Does a hearing problem cause you difficulty when visiting with friends, relatives, or neighbors?	Yes	Sometimes	No	
R-2	How important is it for you to experience less difficulty when visiting with friends, relatives, or neighbors?	Very	Somewhat	Not very	
H-3	Does a hearing problem interfere with your ability to hear environmental sounds such as the telephone ringing or car horns honking?	Yes	Sometimes	No	
H-4	Does a hearing problem cause you to feel frustrated when communicating with friends, coworkers, or members of your family?	Yes	Sometimes	No	
R-3	How important is it for you to feel less frustrated when communicating with friends, coworkers, or members of your family?	Very	Somewhat	Not very	
SI-1	Do you experience feelings of loneliness or not belonging due to your hearing loss?	Yes	Sometimes	No	
SI-2	Do you perceive yourself to be isolated from friends and/or family members due to your hearing loss?	Yes	Sometimes	No	
SE-1	How confident are you that you would follow the recommendations of a hearing healthcare professional (e.g., undergo a hearing evaluation, use hearing aids, use a hearing assistance technology, participate in a communication program)?	Very	Somewhat	Not very

can help achieve desired health outcomes. Our value as a doctoring profession by serving as an important partner in the healthcare maze may be elevated if physicians see how treatment of hearing loss may reduce some of the burden associated with treating persons with multimorbidity including reducing possible disability and some of the high cost of medical care associated with the prolonged life of older adults.

Step 2: The Evaluation

The purpose of the evaluation is to determine hearing status including type and severity of hearing loss and speech understanding/auditory processing ability in a variety of listening situations using material which are

ecologically valid (e.g., sentence materials). Puretone air- and bone-conduction testing across octave and interoctave frequencies is the first part of the evaluation. Next, it is important to assess speech understanding ability using valid real-life listening materials, presentation levels, and situations. Given the individual variability inherent across persons with ARHL, speech understanding should be evaluated using open-set sentence materials presented under different conditions such as (1) with and without visual cues; (2) with and without competing noise at various SNRs; and (3) using degraded speech to uncover the temporal processing declines which are characteristic of ARHL (Tun et al., 2012). Adequate time at the end of the testing should remain during the session to discuss patient preferences relative to their journey and the

results and of course intervention options using decision aids.

HEARING SCREENING

Hearing screening has been a health promotion activity engaged in by audiologists to promote early identification of hearing loss and intervention with hearing aids. Historically, compliance with traditional screening programs conducted by audiologists has been quite low, because only a small proportion of individuals undergoing hearing screenings actually follow through with the recommendations to undergo hearing tests and then consider purchasing a hearing instrument. With the benefit of a series of epidemiologic studies we now know that the most successful screening programs are those which target and identify individuals at risk, who are interested in and motivated to change their behavior. These are the individuals who are most likely to benefit from intervention. Hearing screening is worthwhile if it leads to relief of distress or to improvement in the functions of daily living, and if it is highly acceptable to patients this improves compliance with therapeutic recommendations (Mitchell and Coyne, 2010).

Because hearing loss accompanies many geriatric syndromes and management of hearing loss could potentially reduce disability, primary care physicians, potentially the future gatekeepers of hearing health care for Medicare beneficiaries, should be involved in screening older adults for hearing difficulties. To explain, the primary care physician has considerable influence over their patient's actions pertaining to health matters. If a physician recommends a hearing test and possible treatment, the likelihood that the patient will comply is typically higher than when the referral is initiated by an audiologist. Screening of older adults with multimorbidity may be acceptable to physicians if they understand that uncovering and treating hearing loss may reduce some of the burden of geriatric syndromes which are associated with disability, mortality, increased hospitalizations, and social isolation. If physicians do not routinely engage in preventive activities, then they should consider a hearing screening under the following conditions: (1) If a family member reports a concern about hearing/understanding; (2) if selected chronic conditions place the patient at risk for hearing loss; (3) if the patient takes ototoxic medications; or (4) if the patient smokes or has a history of noise exposure. If the patient is known to be depressed or to have a cognitive impairment, it would behoove the physician to conduct a hearing screening, as it may be that untreated hearing loss is a contributing factor (Weinstein, 2013).

The target population for hearing screening programs should be individuals at risk for the health condition likely to benefit in terms of projected life-span, self-efficacy, outcome expectations, and cost-benefit considerations. For

hearing health promotion activities to be successful they should be integrated and coordinated across providers and settings, and protocols should be functional in scope rather than disease based, including tailored and multicomponent interventions. Additional keys to success include a protocol that is brief, is easy to administer, is acceptable to both the healthcare provider and the patient, accurately discriminates across varying levels of function, and includes follow-up mechanisms and community resources that are in place to handle referrals and monitor adherence. One final key ingredient of successful programs is distribution of educational materials (Weinstein, 2013). Patient education materials are important because studies suggest a relationship between health literacy and rates of chronic health conditions. In short, individuals with inadequate health literacy have significantly higher rates of certain chronic conditions including arthritis and hypertension as compared with those with adequate literacy (Wolf, Gazmararian, and Baker, 2005). Hearing screening is a good target condition for screening as individuals are living longer and will have hearing loss as they live out their lives.

The physician screening program should be multicomponent including screening for hearing impairment and an otoscopic examination because of the high prevalence of impacted cerumen in older adults. The Welch Allyn Audioscope™, a handheld otoscope with a built-in audiometer, is well accepted as a reliable and valid alternative to a portable screening audiometer (Yueh et al., 2010). A self-report questionnaire, such as the Hearing Handicap Inventory, which is reliable and valid should be included as well, as scores are predictive of candidacy for and outcomes with intervention. Physicians conducting hearing screens should target older adults with multimorbidity. Multimorbidity complicates care and is associated with adverse consequences, including disability, high symptom burden, poorer quality of life, and higher rates of adverse effects of treatment or interventions (Tinetti et al., 2012). Finally, targeted referrals based on consideration of the patient's life expectancy and medical status are key elements. Therefore, in the case of a patient with compromised health status because of multiple comorbidities and a shortened life expectancy who failed the puretone screening, the physician might recommend communication strategies and use of a small personal amplifier such as the pocket-talker in small groups and when watching television. Use of this system will insure that the patient continues to communicate with family members and their physicians and importantly remains connected. In contrast, a person in good health with a life expectancy in excess of 10 years might be referred to an audiologist for a hearing test and consideration of hearing aids (Weinstein, 2013). Audiologists are essential to the success of physician screening initiatives, and part of their role is providing the physician with literature to be distributed to the patient that will promote a patient-clinician partnership, which is

critical to successful outcomes. The physician must know how to recognize patients who are hearing impaired, how to communicate with the hearing impaired, how to discuss options that are appropriate, and how to give advice that will guide the patient's actions. The physician must tell older patients that age is not a limiting factor for the hearing impaired to benefit from hearing aids and available HATs (Weinstein, 2013). It is incumbent on audiologists to educate doctors regarding the improvements in quality of care and life which could result from management of a geriatric syndrome, such as hearing loss, the effects of which are treatable with a variety of nonmedical interventions. Another point to emphasize is that older adults underreport or fail to report hearing deficits, and that hearing deficits are one of the few geriatric syndromes missed during the traditional medical exam (Weinstein, 2013).

It is important to underscore that the goal of a hearing screening is to identify those persons with hearing impairment who will pursue and benefit from intervention as hearing screening is only cost effective when compliance is high and outcomes are tangible and beneficial. It is important to emphasize that physicians are likely to screen for hearing loss if they are made aware that untreated hearing impairment can be detrimental placing some older adults at risk for disability which in the long term is costly to the individual and society. It is also imperative that physicians understand that the ability of the patient to understand during physician encounters is vital to achieving patient-centered care, which is a guiding principle of care of older adults with multiple geriatric syndromes (American Geriatrics Society (AGS) Expert Panel, 2012). In fact, an important conclusion from the AGS Expert Panel on the Care of Older Adults with Multimorbidity is as follows: "inadequate communication skills and educational materials are also barriers to the care of older adults with multimorbidity. Because conversations about prognosis and preferences can often be difficult for clinicians, training of all healthcare team members must address communication skills" (AGS, 2012, p. 20). Finally, audiologists should be aware of the isolating effects of hearing impairment given the link between social disconnectedness, mortality, and morbidity.

FUTURE TRENDS

Audiologists are well versed in all things related to hearing and are strong proponents for hearing aids which work for many but are not embraced by the majority of persons with communication difficulties despite the sophisticated signal processing available today. In my view, audiologists should adopt some of the guiding principles of the AGS which emphasize on patient-centered care, in which the healthcare professional elicits and incorporates the preferences of their patient into decision-making for older

adults with multiple chronic conditions (AGS, 2012). Once the patient is informed of the benefits and harms of available treatment options using decision aids or decision trees, the patient's input and their preferences are given considerable weight. Importantly, clinical management decisions are framed within a broader context which includes life expectancy, likelihood of benefitting, functional status, resources, and quality of life (AGS, 2012). Perhaps, this change in philosophy will enable audiologists to truly partner with persons with hearing loss and healthcare professionals to help achieve mutually agreed upon outcomes.

SUMMARY

The aging of the Baby Boomer generation and increased longevity brings with it challenges to which audiologists should be armed to respond, namely a huge increase in the number of older adults in general and those with auditory processing and communication challenges in particular. These individuals will need and want to hear and understand family, friends, coworkers, physicians, and of course when at work or engaged in leisure time activities. In fact social engagement and ease of communication remain priorities in the golden years of one's life. Adults with ARHL must be encouraged to seek out audiology services early so that hearing loss does not interfere with the quality of their prolonged life. My goal in developing this chapter was to arm audiologists with information about hearing loss in older adults that will empower them to effectively identify, evaluate, and manage this growing and important population. Hearing healthcare services for older adults must be delivered with an understanding of the aging process and the biases older adults bring to their health care. A better understanding of aging in general and its impact on the hearing mechanism in particular will hopefully promote the delivery of patient-centered audiology combined with targeted interventions. Availability of HATs, digital hearing aids, cochlear implants, software to promote auditory and cognitive training, PSAPs, and a vast array of strategies to foster improved communication means that persons with hearing loss should leave the office of the audiologist armed with toolkits that will enable them to communicate more effectively.

FOOD FOR THOUGHT

1. Greater hearing loss is independently associated with self-reported falls such that a 25-dB hearing loss is associated with a nearly 3-fold increased odds of reporting a falls (Lin & Ferrucci, 2012). Is the relationship between hearing loss, mobility limitations, and self reported falls evidence enough to convince physicians to routinely screen hearing in older adults who have a history of falls?

2. Given the link between hearing loss and incident dementia, namely that cognitive impairment is associated with lower hearing levels and with faster declines in peripheral hearing sensitivity; should audiologists routinely administer a reliable and valid cognitive screening test (e.g., The Montreal Cognitive Assessment, MoCA) to older adults and make the appropriate referrals when indicated.
3. Hearing loss is independently associated with increased hospitalizations and poorer self-rated health. Does an untreated or unrecognized hearing loss affect transitions in care and adherence with physician recommendations? If so, what role could audiologists play if they served on the patient centered medical home (PCMH) which is a newly emerging team based health care deliver model?

Tinnitus and Hyperacusis

Richard S. Tyler, William Noble, Claudia Coelho,
Eveling Rojas Roncancio, and Hyung Jin Jun

INTRODUCTION

Tinnitus and hyperacusis are two challenging issues in audiology as patients can be desperate, and there are no cures. Nonetheless, several forms of treatment are available, and audiologists should possess a good foundation of hearing loss, hearing measurement, and rehabilitation to provide an accurate evaluation and effective management of tinnitus and hyperacusis. We advocate a flexible approach, as appropriate, that includes collaboration with informed psychologists and physicians.

Tinnitus can be defined as (1) a perception of sound (it must be heard), (2) involuntary (not produced intentionally), and (3) originating in the head (rather, it is not an externally produced sound), whereas hyperacusis does not have a widely accepted definition. Hyperacusis can involve loudness, annoyance, fear, and pain. We have noted that tinnitus is often accompanied by hyperacusis, and many current sound therapy protocols treat tinnitus and hyperacusis in parallel.

TINNITUS

Neurophysiological Causes, Mechanisms, and Models

Virtually anything that produces hearing loss can also produce tinnitus. The most common causes are noise exposure, aging, head injury, and medications. Sometimes, the causes are unknown. Estimates of prevalence vary, in part, because of differences in the definitions used in surveys (see Davis and Rafaie, 2000). The prevalence of tinnitus increases with age and hearing loss, but in particular is influenced by noise exposure. In our clinical experience, many workers in noisy situations report that the onset of tinnitus is gradual. Initially, tinnitus is heard only occasionally during the day or for brief periods after work. Subsequently, the duration of the tinnitus persists until it eventually becomes continuous. Typically (but not always), the onset of tinnitus occurs after the onset of hearing loss (sometimes years afterward). There

are workers who report that tinnitus began after their exposure to noise had ended.

Tinnitus is classified as either sensory/neural or middle ear (Tyler and Babin, 1986). Middle-ear tinnitus is typically related to middle-ear vascular or muscular dysfunction. Sensory/neural tinnitus originates in the cochlear and/or neural auditory pathway. There are likely several different subgroups of tinnitus arising from different mechanisms (Dauman and Tyler, 1992; Tyler et al., 2008a). The mechanism responsible for coding tinnitus can originate in the cochlea, the brainstem, or the central nervous system (Figure 35.1). We believe that the auditory cortex must be active in tinnitus, since that is where sound is “perceived.” This cortical activity could be associated with (1) an increase in spontaneous activity, (2) synchronous spontaneous activity across nerve fibers, and (3) more fibers tuned to the same best frequency (Salvi et al., 2000). As noted by Hallam (1989), other parts of the brain must be involved in patients who are anxious or have emotional reactions to their tinnitus. This includes the autonomic nervous system and the amygdala (Cacace, 2003).

It is curious that other parts of the nervous system can also influence tinnitus. For example, some patients report a change in their tinnitus with eye movements, light touch, or voluntary muscle contraction (Cacace, 2003; Levine, 2001). Others experience pressure around the head that can change tinnitus, or jaw clenching which can produce a high-pitch temporary tonal sound. It is not completely understood how the stimulation of systems outside the auditory pathway changes tinnitus. It is important to distinguish between muscle contraction that changes tinnitus by contracting middle-ear muscles and effects mediated by nonauditory neural pathways.

Some patients with “normal” hearing also report tinnitus. It should be remembered that “normal” hearing is arbitrary. Someone could have an audiometric “notch” of 20 dB hearing level (HL) at 4,000 Hz with 0-dB HL thresholds elsewhere. This likely represents an auditory pathology. Additionally, hearing thresholds are traditionally measured at octave frequencies from 250 to 8,000 Hz, leaving large regions of the cochlea unexamined, including frequencies above 8,000 Hz (see Kujawa and Liberman, 2009).

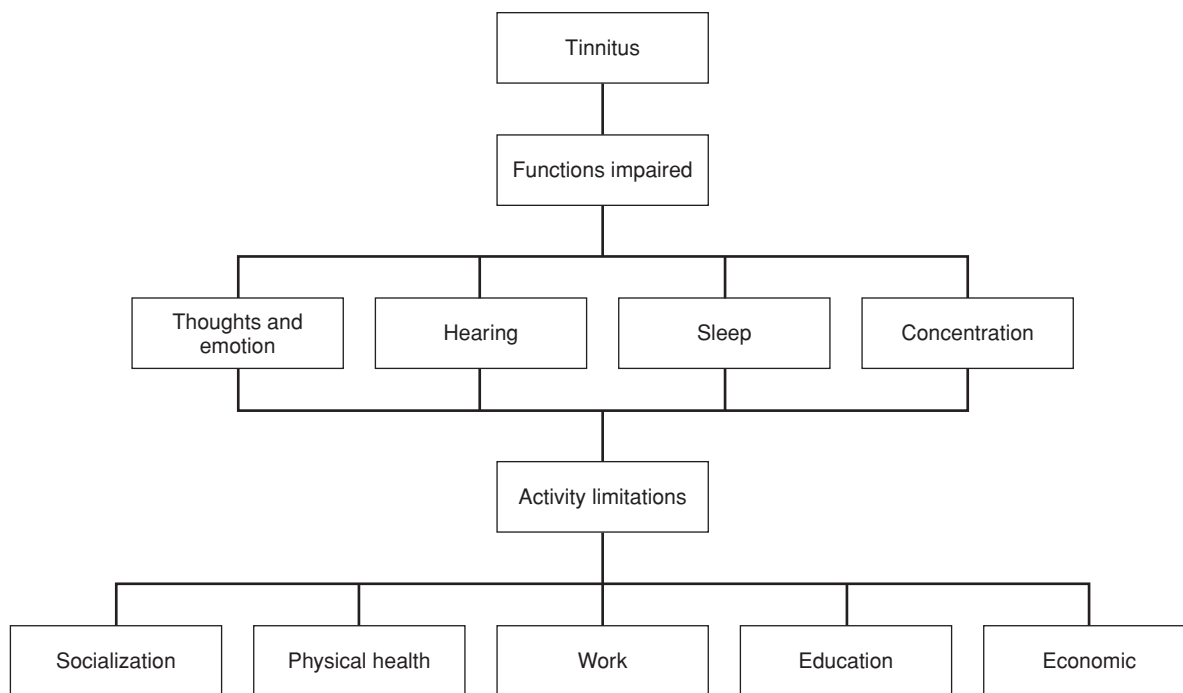

FIGURE 35.1 Domains where tinnitus can have an impact.

Auditory Hallucinations as Tinnitus

When someone reports hearing sounds that are like music or voices, it is important to consider mental illness. Reports of imagined voices or music can occur as part of psychotic illness such as schizophrenia. If there is no record of such illness, but there is evidence of depression, anxiety, or unrealistic thoughts or actions, then these should be addressed with the client and a referral provided to a mental health professional. In the absence of indications of mental illness, one could treat this as with other types of tinnitus. Certainly tinnitus can have a central origin. Patients who present no signs of mental illness and who hear music and voices could benefit from support, reassurance, and the counseling and sound therapy programs described later. It is important not to overreact to the patient's reports.

EVALUATION

Medical

Referral to an otologist is appropriate for pulsatile, sudden onset, worsening tinnitus, asymmetrical signs, and diseases of the auditory system (Perry and Gantz, 2000). A detailed clinical history could offer important clues about etiology and to help select laboratory and radiologic exams that will be required to investigate a particular case. It is often important to know what medications and dietary supplements are in use, diet, alcohol and smoking habits, food allergies, and lactose intolerance. A patient's and family's health history could give important information. Often, a

focus of the evaluation will be on the cardiovascular system and on metabolic disturbances, such as diabetes and hypercholesterolemia. Laboratory examinations (e.g., cholesterol levels, glucose, zinc, screen for ototoxic drugs) and imaging tests (e.g., ultrasound, computed tomography scan, magnetic resonance imaging, magnetic resonance angiography) might be utilized. Generally, physicians are interested in identifying a possible treatable cause.

Middle-ear tinnitus is associated with either abnormal middle-ear blood flow or middle-ear muscle contraction. Some call this "objective" tinnitus, because it can be amplified and heard by the examiner. However, some spontaneous otoacoustic emissions, that are produced in the cochlea, can also be heard. Therefore, we prefer the term middle-ear tinnitus. Otologists may determine whether the tinnitus sensation changes with manipulations of blood flow (by asking patients to perform a brief vigorous exercise or by partially constricting a blood vessel of the neck). These manipulations can change the pulsing sensation. A proportion of these can be addressed surgically. Some vascular tumors also touch the eardrum and can be visually observed. Movements of the eardrum can sometimes be observed visually or with the help of measurements of air pressure in the external canal with tympanometry. Oral cavity examination may demonstrate myoclonic activity (palatal myoclonus).

Tinnitus can sometimes be influenced by movements of the head and neck. Some otologists search for signs of temporomandibular dysfunction which can involve jaw or facial pain or tenderness and difficulty or discomfort in chewing.

Another focus is a search for treatable sensory/neural tinnitus. This includes some forms of sudden hearing loss, Ménière's disease, or a tumor of the auditory nerve. It could be that some forms of tinnitus might be caused by metabolic diseases and deficiencies (e.g., anemia, diabetes, hypercholesterolemia, zinc and vitamin deficiency). Evaluations for these conditions would involve studies of the blood and urine.

Measuring the Tinnitus

The pitch, loudness, and amount of noise necessary to mask tinnitus can be measured to quantify tinnitus, provide assistance for fitting maskers, and monitor changes in tinnitus perception. (Often, this can be reimbursed in the United States when using Current Procedural Terminology (CPT) code 92625: Assessment of Tinnitus.) Patients can usually compare the pitch produced by a puretone to the "most prominent pitch" of their tinnitus (Tyler, 2000). Pitch matching can be highly variable, and an indication of the variability should be reported in the patient chart. Patients can also adjust the intensity of a tone so that it has the same loudness as their tinnitus. Sensation level is not a measure of loudness. The results of a tinnitus loudness match can be reported in dB sensation level (SL), but this level can only be interpreted over time for a particular patient if the hearing threshold at that frequency does not change. An alternative approach is to convert the physical intensity of the sound into the subjective loudness scale based on sones. Sones represent an international standard; 1 sone equals the loudness of a 40-dB sound pressure level (SPL) 1,000 Hz tone (about 49 dB HL) in a normal listener. A sound that has a loudness of 4 sones is four times as loud. Another measure of the magnitude of tinnitus is the amount of noise required to mask the tinnitus, sometimes referred to as the minimum masking level. The noise level (specify the frequency characteristics of the noise, e.g., broadband 250 to 8,000 Hz) is increased until it just masks the tinnitus.

Several things can contribute to the variability of tinnitus measurements. First, one should be aware that the test stimuli can change the tinnitus. This is probably more likely to happen for intense stimuli and when stimuli are presented ipsilaterally to the tinnitus. The ear receiving the stimuli should be reported. Second, in many patients the perception of tinnitus is not constant but varies throughout the day or from day to day. A reasonable approach to this is to make multiple measurements and report each value. The variability of the measurements can be documented by replicating the measures and recording the results of each trial in the patient's chart. For example, we often use the average of three loudness matches, three minimum masking levels, and six pitch matches (because pitch tends to be more variable). In patients with highly variable tinnitus, additional measurements can be made, and the measurements can be repeated at subsequent visits (particularly for a patient whose tinnitus changes).

Measuring the Reaction to the Tinnitus

People's reaction to their tinnitus covers a broad range. Some appear not to be particularly bothered by it, whereas for others, the tinnitus can have a dramatic effect on their lifestyle. The primary impairments can result in difficulties with thoughts and emotions, hearing, sleep, and concentration (Figure 35.1) (Erlandsson, 2000; Noble, 2013; Noble and Tyler, 2007). Sleep disturbance is one of the most common of these impairments (McKenna and Daniel, 2006; Tyler and Baker, 1983) causing some to have difficulty falling asleep, whereas others have difficulty falling back asleep if they wake up in the night.

When determining the impact tinnitus is having on an individual's life, an easy first step is to ask the person to "list all the problems you have that you associate with your tinnitus, starting with the problem that bothers you the most" (Tyler and Baker, 1983). This can be done before the first appointment and can lead to an open discussion of the important problems as perceived by the patient.

Several questionnaires designed to quantify the problems caused by tinnitus are available. These differ based on the scale used. Our experience is a 0 to 100 scale is easy for patients (a familiar decimal scale like dollars), in which a patient will respond 0, 5, 10, 15, . . . 100, which enables a 21-point scale. This provides greater resolution than a 0 to 10 scale. Questionnaires also differ on the scope of questions asked.

Tinnitus Handicap Questionnaire (Kuk et al., 1990) has been widely used to assess the influence of drugs (Coelho et al., 2013), cochlear implants (Pan et al., 2009), and sound therapy approaches (Tyler et al., 2012). Others (Meikle et al., 2012) also include general questions on the quality of life. We believe this can make the questionnaire less sensitive to treatment effects, as the quality of life can be influenced by many factors not directly captured by treating tinnitus. Tyler et al. (2006) developed the Tinnitus Primary Function Questionnaire (2014), shown in Appendix 35.1, which focuses on emotional, hearing, sleep, and concentration difficulties and is sensitive for clinical trials and assists in determining treatment needs. All appendices can be found at the end of the book.

TREATMENTS

There are two basic types of tinnitus treatment strategies: Those designed to reduce or eliminate the physical perception and those designed to change the patient's reaction.

Counseling

There are various counseling approaches: They range from providing information to more engaged collaborative counseling (for a review, see Tyler, 2006). Many of these are based on the work of Hallam (1989) known as tinnitus habituation

therapy. Others include strategies for improved coping, management, and behavioral change (Tyler et al., 1989). Among these are tinnitus activities treatment (Tyler et al., 2006), tinnitus retraining therapy (Jastreboff, 2000), and tinnitus cognitive behavior therapy (Anderson et al., 2002; Henry and Wilson, 2001; Robinson et al., 2008). The aim of these procedures is to provide ways for the person suffering with tinnitus to adjust his or her reactions to the experience.

The goals of these psychologically based therapies often overlap (Tyler et al., 2006). For example, patients can be helped to habituate to their tinnitus by de-emphasizing the fear associated with it. Another approach is to decrease the attention given to the tinnitus, often with the help of background sound. The way a patient thinks about the tinnitus can influence his or her reactions to it. Therefore, some clinicians will help patients consider how they think about their tinnitus. These thoughts can be challenged and revised. Another approach is to assist patients to change their focus away from their tinnitus. This can be facilitated by refocusing on other enjoyable and engaging activities. Having planned activities during which time it is known that the tinnitus is less intrusive can be very helpful.

It is our general view that many patients concerned about tinnitus can adapt to it after the explanation of its origin and its nonthreatening nature (where careful assessment has established that it is not a sign of a more serious medical condition); however, for a substantial number of patients such reassurance is less effective, and a more elaborate intervention is needed. The descriptions in the following sections provide guidance on the sorts of appropriate counseling within the context of general audiology practice. When more elaborate counseling is required, reference to the clinical psychologist is appropriate.

Important attributes of the clinician include

- Ability to listen
- Patience
- Ability to be encouraging to the patient
- Emotional insightfulness
- Self-awareness
- Ability to laugh at the bittersweet aspects of life
- Positive self-esteem
- Ability to talk candidly about depression, anxiety, and other psychologic stressors

At the initial interview, it is helpful to determine if patients are curious, concerned, or distressed about their tinnitus (see Figure 35.2) (Tyler et al., 2008b). Much of the anxiety associated with tinnitus stems from uncertainty regarding its source and consequences. Curious patients typically require only basic information regarding possible causes, mechanisms, prevalence, consequences, and likely outcomes. These patients find that once the mystery of tinnitus is explained to them, their reaction is largely resolved. Concerned patients require more detail and benefit from information regarding things they can do on their own or

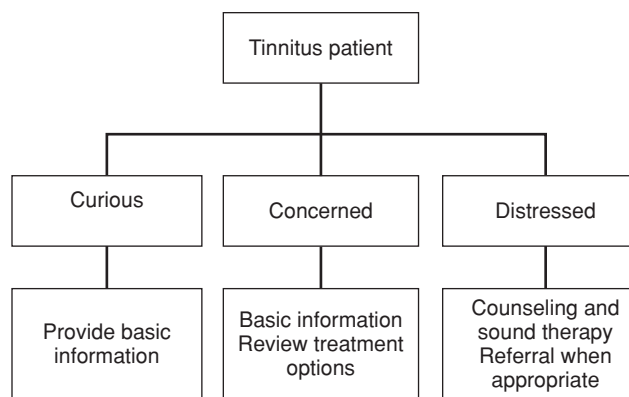

FIGURE 35.2 Broad categories of patients that reflect level of severity and therefore level of treatment needed.

other treatment options. Depending on the level of concern, these patients can require a more formal evaluation that includes the questionnaires and psychoacoustical measurements discussed earlier. Distressed patients require specific tinnitus treatment. Patients with severe anxiety and depression should obtain help from psychologists or psychiatrists. Patients who report suicidal thoughts or self-harm need to be further questioned regarding their intentions, and a referral to clinical psychology or psychiatric services should be made immediately if any concern exists.

Whereas individual counseling approaches will vary, the common elements of successful counseling strategies include the items listed in the following sections.

PROVIDING INFORMATION

Most approaches provide information about hearing, hearing loss, and tinnitus. They usually include the causes, prevalence, and common consequences of tinnitus. For many people, the unknown aspects of tinnitus are the most alarming. They often find this basic information about tinnitus reassuring and may require no further assistance.

THOUGHTS AND EMOTIONS

It is helpful to distinguish the tinnitus itself from the person's reaction to the tinnitus. The way people think and feel about their tinnitus can have a major influence on their reactions. One focus of cognitive behavior therapy, and other counseling strategies, is on challenging a person's thoughts about tinnitus and thereby facilitating changes to the reactions to the tinnitus (Hallam, 1989; Henry and Wilson, 2001).

MEETING THE PERSON'S NEEDS

Some counseling procedures go beyond providing information and attempt to understand and influence the overall emotional well-being of the patient. By necessity, these procedures are collaborative and require more time. Several approaches are available to help individuals understand and

change the emotional consequences of their experience with their tinnitus. Mohr and Hedelund (2006) have developed a person-centered tinnitus therapy (trying to understand how the tinnitus fits into the larger scope of the individual's life).

COPING/MANAGEMENT STRATEGIES

Some counseling approaches include coping/management strategies to help patients understand and change their perceptions about tinnitus and to modify their reactions and behaviors. Activities are planned to determine situations in which tinnitus might be a problem and then to modify their specific situation to reduce these occurrences. For example, patients might report that their tinnitus is worse when they first get home from work. This might be a result of sitting in a quiet room reflecting on the day's activities. An alternative activity might be to go for a walk while listening to music, or physical exercise, such as Tai Chi or yoga, to limber up. Just about any activity that reduces stress can be helpful.

RELAXATION AND IMAGERY PROCEDURES

Some patients benefit from learning specific relaxation or imagery procedures. These can be used when people experience stress, and it can be helpful for them to learn relaxation strategies or to focus attention to other thoughts. Exercises to learn how to redirect attention away from the tinnitus are also employed. For example, in a quiet room, patients can imagine the sound of waves on a deserted beach. Then, they can redirect their attention to their tinnitus—then back to the waves. In a pair of excellent books (one for patients and one for clinicians), Henry and Wilson (2001) lay out programmatic exercises that patients can do on their own or that can be done in cooperation with the clinician.

Sound Therapies

Sound therapies include strategies that use background sounds to reduce the prominence of tinnitus or decrease its loudness or level of annoyance (Folmer et al., 2006; Vernon and Meikle, 2000).

THE USE OF HEARING AIDS

Most patients with tinnitus also have hearing loss. Properly fitted hearing aids should help with communication and often also help with tinnitus by reducing the stress involved with intensive listening and by amplifying low-level background sounds. Hearing aids are often the first component of sound therapy for patients with tinnitus (Kochkin et al., 2011; Searchfield, 2006).

THE USE OF WEARABLE SOUND GENERATORS

Wearable ear-level devices are available that produce low-level noise. Some patients prefer this to listening to their

tinnitus, perhaps because it is more pleasant to listen to or because the devices may decrease the loudness or prominence of their tinnitus. Some patients wear devices while their tinnitus is particularly annoying, whereas others use these devices during all waking hours. These devices look like hearing aids and are worn either behind the ear or in the ear. The noise should be adjusted to a level so that it does not interfere with communication.

The level of the background sound that is suggested varies with different sound therapies. There are two types of masking. Total masking covers tinnitus completely, so the person hears a “shhhhhh” instead of their tinnitus. With partial masking, the noise is set to a level so that both the tinnitus and the noise can be heard. This technique usually reduces the loudness, annoyance, or prominence of the tinnitus. Some protocols suggest that the ideal place for the noise should be at a level that is about equal to the tinnitus, where the tinnitus is just heard through the masking noise and mixes or blends with the tinnitus. Hazel recommended that “the masking sound does not completely cover the tinnitus.” Other protocols focus on a lower level with the noise just in the background. For example, Tyler and Babin (1986, p. 3213) suggested that patients should use the “lowest masker level that provides adequate relief.”

A masking device that is set to a high level might hamper listening to everyday sounds and might also make the tinnitus worse (Folmer et al., 2006). Devices are available that combine a hearing aid and a noise generator in a single unit.

THE USE OF NONWEARABLE SOUND GENERATORS

Many people also find it helpful to use sound in the background around the home or office or while they are going to sleep. Some use common devices, such as a fan, to produce the noise. There are also devices that are produced specifically for the purpose of producing background sounds, such as raindrops on leaves or waves on the shore. Pillows with tiny loudspeakers that connect into other sound devices are available to facilitate sleep. Radios and sound reproduction systems (e.g., MP3 players) have the advantage that they can be set according to preference. It is often helpful to have control of the level.

THE USE OF MUSIC

Most people can enjoy some types of background music, and it is not surprising that many use a soft, light music in the background to help decrease the prominence of their tinnitus. There are now a variety of signals to choose from, including background music and nonrepeating “fractal tones.”

DURATION OF DEVICE USE

How long someone uses a device throughout the day and how many months someone should continue to use the device

can vary across patients. Some patients will use a device only when their tinnitus interferes with an important task, such as reading for work. We never insist that patients have to “avoid silence” because their speech perception is often worse in noise and some will constantly monitor their environment and their tinnitus in this effort. Some will choose not to use the device when communicating with others. In some cases it may be advisable to set the device to a low partial masking level and leave it on all day. This can help the patient forget about it and avoid focusing on the device and their tinnitus throughout the day. Some patients choose to use their noise generators for life, whereas others may choose to use them until they feel like they have attained some control and their reactions to the tinnitus are sufficiently reduced.

Tinnitus Activities Treatment

Our counseling approach has evolved over the years (Tyler and Babin, 1986; Tyler et al., 1989). We continue to prefer the partial masking strategy we recommended in the 1980s, although some patients benefit from total masking. We now call this approach tinnitus activities treatment (Tyler et al., 2006) which contains four separate modules.

THOUGHTS AND EMOTIONS

The way patients understand and think about their tinnitus influences their reactions to it. Providing information in a collaborative fashion to ensure understanding is essential. Key aspects of this area include

- Listening to the patient and addressing issues that are important to him or her
- Providing information about hearing, hearing loss, tinnitus, and role of conscious and subconscious attention
- Understanding the patient’s reactions to unexpected, uncontrollable events
- Suggesting changes in behavior and lifestyle that can facilitate acceptance and habituation

It is important to help patients recognize the difference between the tinnitus itself and their reaction to it. Cognitive therapy separates the tinnitus from the patients’ reactions to it and may provide a sense of control over the impact tinnitus has on their lives.

HEARING AND COMMUNICATION

Tinnitus and hearing loss often occur together, but the patients cannot “hear” their hearing loss, so they project their communication problems on the tinnitus. Reviewing the patient’s hearing loss and its impact on communication may redirect some of the anxiety to an area where treatment is more obvious. In addition to hearing aid information, a review of assertive communication versus passive or aggressive communication styles is useful.

SLEEP

Understanding normal sleep patterns is the first step in gaining control over the problem (McKenna, 2000; McKenna and Daniel, 2006). Other strategies include

- Exploring factors that can affect sleep (e.g., stress, environmental noise, room temperature)
- Arranging the bedroom to promote sleep (e.g., comfortable bedding, remove distracting items from room)
- Avoiding alcohol, smoking, and eating before bedtime
- Using sound to mask tinnitus (e.g., noise generators or soft radio)
- Learning relaxation exercises (e.g., imagery, progressive relaxation)

CONCENTRATION

In our therapy, we discuss the importance of concentration and things that affect our concentration. We review factors in the environment (e.g., lighting, background noise, distractions, and temperature) and personal factors (e.g., being tired, current health status, and other stressors in our lives) that impact our ability to focus our attention for a sustained period of time.

Activities in “attention diversion” (Henry and Wilson, 2001) give patients practice switching attention from one engaging task or stimulus to another. This type of exercise shows people that they can control what sounds, images, or other stimuli they consciously focus their attention on. Repeated practice with this type of activity can help give patients a sense of control over their attention as well as their tinnitus.

Medical Approaches

PHARMACOLOGIC APPROACH

We believe that no medication has been shown to effectively eliminate tinnitus in repeated clinical trials. Furthermore, it is likely that specific subgroups (as yet unidentified) of tinnitus patients benefit from some drugs. Evidence-based pharmacological approaches are limited to the treatment of tinnitus comorbidities such as depression, anxiety, and insomnia with antidepressants, anti-anxiety drugs (anxiolytics), and drugs to facilitate sleep. Potential medications include substances that have an action on blood circulation and viscosity, muscle relaxants, anticonvulsants, steroids, and diuretics. If indicated, they should be used in addition to counseling.

SURGICAL APPROACHES

Some forms of vascular abnormality can be treated by cutting away or restricting blood vessels. With myoclonus, surgical section of the tensor tympani and stapedial tendons can be successful.

In severe cases, cutting the eighth nerve (cochlear neurectomy) has been used, sacrificing hearing in that ear, but unfortunately, this has had only limited success in reducing tinnitus. Some physicians believe that tinnitus is a result of abnormal compression of the eighth nerve by a vessel (called vestibulocochlear compression syndrome) and have performed microvascular decompression operations of the vestibulocochlear nerve in the treatment of unilateral severe tinnitus.

Other Possible Treatments

Several other alternative approaches have been promoted to treat tinnitus. A guiding principle in judging these treatments should be that they have been shown to be effective in well-designed clinical studies that have been replicated. Chasing many different promised, but ineffective cures can be detrimental to the patient's overall emotional state.

Herbal supplements, such as ginkgo, and dietary supplements, such as zinc, magnesium, melatonin, copper, niacin/vitamin B₃, and cobalamin/vitamin B₁₂, have been proposed but there is no systematic evidence of beneficial effect (Coelho et al., 2013), although, some patients might experience some relief. Acupuncture has not been shown to be effective.

Some patients also ask about the potential benefit of changing their eating and drinking habits. Maintaining healthy diets and exercising are good for all of us, but no data indicate that these changes necessarily will improve tinnitus.

Some have suggested that temporomandibular joint dysfunction can cause tinnitus and thus treatment with jaw manipulations can cure tinnitus. It is not obvious to us that this is possible.

Patients will ask about these treatments, and we recommend discussing the principle of documented effectiveness in well-designed replicated studies. We also note that individual differences might be important. Some options can be harmless (such as drinking less coffee), but some alternative treatments do have important risks or side effects, and these should be explained to the patient.

One of the most promising treatments for tinnitus is the use of electricity. Studies have included stimulation of the cochlea (Rubinstein and Tyler, 2004) and brain. Electricity has also been successfully applied to the brain with transcranial magnetic stimulation. Numerous studies have demonstrated the effectiveness of cochlear implants in reducing tinnitus in many patients. Thus, it seems that, in a few years, there will be devices available that reduce tinnitus via electricity. The proportion of patients for whom this will help is not known; the details of the appropriate stimulus parameters are also unknown.

TINNITUS IN CHILDHOOD

Investigating tinnitus in childhood is challenging because of its subjectivity. It is rarely reported spontaneously by children

and seldom routinely explored in pediatric otolaryngologic evaluation. Nonetheless, children do experience tinnitus. Most do not appear to be bothered, but remarkably, those who are bothered report similar suffering as adults (e.g., with emotional concerns, hearing, sleep, concentration), sometimes resulting in problems at school. It should be cautioned about intervention with children when parents were more concerned than the child because this may increase the child's anxiety about the tinnitus. Kentish and Crocker (2006) have designed tinnitus counseling specifically for children.

CONCLUSIONS REGARDING TINNITUS

There are likely many causes and mechanisms of tinnitus, and therefore, many treatments could be potential candidates. It is important to distinguish between the tinnitus and reactions to tinnitus. There are many counseling and sound therapies that likely help patients with their reactions. No medications or other physical treatments have been shown to be effective in well-designed and replicated trials.

HYPERACUSIS

The concept of hyperacusis includes loudness hyperacusis, annoyance hyperacusis, fear hyperacusis, and pain hyperacusis. One can readily imagine that sounds perceived as being very loud could easily become annoying. The anticipation of loud and/or annoying sounds could reasonably lead to the fear of these sounds. However, it is possible for sounds to be annoying or feared without being too loud. Patients also report that some sounds are physically painful, usually those perceived as loud. Occasionally, patients with tinnitus report that some sounds make their tinnitus worse. It is important to separate each of these symptoms, both for the patient and the clinician, to understand the problems carefully, and to offer treatment suggestions.

Neurophysiological Causes, Mechanisms, and Models of Hyperacusis

Anything that causes a sensory/neural hearing loss can likely also cause hyperacusis. Hyperacusis can also occur without identifiable hearing loss.

As a stimulus is increased, the activity of individual nerve fibers increases, and the number of nerve fibers activated increases (and usually its perceived loudness also increases). Moderately intense sounds might result in loudness hyperacusis if

1. greater than normal activity was produced on individual nerve fibers,
2. more nerve fibers were activated than normal, and/or
3. there was greater than normal synchrony across fibers.

Salvi et al. (2000) suggested that tinnitus could result from altered neural connections in the brain following hearing loss. Cortical neurons that previously have received input from damaged frequency-specific nerve fibers are colonized by neighboring regions of the brain, over-representing their representation at the cortex. We suggest that hyperacusis might also be a function of such brain plasticity. Following a peripheral hearing loss, say at 4,000 Hz, nerve fibers in the brain that normally respond to 4,000 Hz begin to respond to other, nearby frequencies, for example, 3,000 Hz. This results in more nerve fibers in the brain responding to 3,000 Hz than would be present normally. If hyperacusis is related to the number of fibers activated, this could account for it as a phenomenon.

Hazell (1987) suggested that hyperacusis might be the result of an “abnormal gain control.” It is as if the brain receives a lack of information after hearing loss and therefore turns up some hypothetical gain control. Although intriguing, there are several problems with this suggestion. First, such a gain control mechanism must not operate on acoustic signals, because the hearing loss is not corrected. Second, our clinical experience is that some individuals without any apparent hearing loss also have hyperacusis. Third, most people with hearing loss do not report hyperacusis. Whenever emotions are involved, for example, in fear hyperacusis, other regions of the brain must also be involved.

EVALUATION OF HYPERACUSIS

Medical

The medical evaluation for hyperacusis parallels that for tinnitus. Some conditions have been associated with hyperacusis, including facial paralysis, head trauma, and metabolic disorders, infections (Lyme disease), and genetic (Williams’ syndrome) abnormalities.

Measuring Hyperacusis

LOUDNESS HYPERACUSIS

Loudness Discomfort Levels

Loudness discomfort levels (LDLs) can be performed with puretones at 500 and 4,000 Hz in each ear. We use the following instructions: “This is a test in which you will be hearing sounds in your right/left ear. We want you to decide when the sound first becomes uncomfortably loud.”

Magnitude Estimation of Loudness

It is possible to present tones and ask for a rating of loudness on a scale from 0 to 100, with 100 being the loudest sound a person can imagine.

Hyperacusis scales have been developed to attempt to differentiate loudness and annoyance and to ascertain

a general idea of the impact of hyperacusis on a patient’s daily activities (see Appendix 35.1). The questionnaire asks individuals to consider several typical events they might encounter in their daily lives. They then separately rate the loudness and the annoyance for the same situations. For example, a patient may rate “telephone ringing in the same room” as 40 out of 100 on the loudness scale (with 100 being unbearably loud), whereas rating it as 85 out of 100 on the annoyance scale (with 100 being unbearably annoying).

ANNOYANCE HYPERACUSIS

As mentioned, a questionnaire is shown in Appendix 35.2 where we attempt to quantify annoyance of sounds. Appendix 35.3 shows a handicap scale that asks patients to respond to statements in terms of their hearing loss, tinnitus, and hyperacusis. The statements include items such as “You avoid shopping” or “You feel depressed” and allow clinicians to separate the impact on function that patients perceive from their hearing loss, tinnitus, and hyperacusis. Another approach we have tried is to have patients rate recorded sounds. For example, we have patients rate recorded sounds of dishes hitting together, a lawn mower, and crowd noise.

Dauman and Bouscau-Faure (2005) developed a multiple activity scale for annoyance hyperacusis, providing 15 situations (e.g., concert, shopping center, work, church, children). Subjects rated from 1 to 10 each of the “relevant” activities, which were averaged for a total score. They also had patients rate annoyance hyperacusis on a scale from 1 to 10.

FEAR HYPERACUSIS

Patients can develop a fear of very specific sounds or categories of sounds (e.g., those containing high frequencies) or of any intense sound. The simplest approach may be to ask the patients to make a list of sounds they fear to determine if a specific pattern exists.

PAIN HYPERACUSIS

Some patients report that listening to some sounds create pain. Often, they are perceived as loud, and these patients typically have fear of these sounds.

TREATMENT FOR HYPERACUSIS

Treatments for hyperacusis are less well developed than for tinnitus. First, a clear distinction needs to be made about whether one is treating loudness, annoyance, fear, or a combination of these problems. The same basic tenets of good counseling mentioned earlier for tinnitus can be applied. Patients also have very different levels of distress associated with their hyperacusis. It is necessary to determine initially

if they are just curious, somewhat concerned, or very distressed.

Counseling

We believe hyperacusis can influence a patient's emotional well-being, hearing, communication, sleep, and concentration. One approach would include a cognitive behavior modification model, thus focusing on response, emotions, and thoughts (Henry and Wilson, 2001). In hyperacusis activities treatment, we include four sections.

The first section is emotional well-being. Patients with hyperacusis are often anxious and distressed about being exposed to intense noise. We provide information about possible mechanisms such as the coding of intensity by the number of nerve fibers and the activity on nerve fibers. We also review how our reactions are influenced by our expectations. If we expect that a visit from a father-in-law will be trouble, we are more likely to react negatively even to reasonable events. If we are expecting a situation to be unbearably loud, that raises our anxiety levels and influences how we react to sound. Some patients might have developed unreasonable expectations, so we provide some instruction on how we are able to change our reactions. It is important to help patients recognize the difference between the loudness of the sound and their reaction to it.

The second section is hearing and communication. Some patients avoid communication situations where they expect there to be intense sounds. Sound therapy to reduce loudness hyperacusis should be able to provide some assistance with this. Others will avoid using hearing aids or use gain settings that are insufficient. Patients can set the maximum output of their hearing aids temporarily to a lower level (Searchfield, 2006) and gradually increase this over time.

The third section is in the area of sleep. Occasionally, patients with fear hyperacusis will report that they do not sleep as well because of the anticipation of an intense sound. Partial masking sound therapy (e.g., playing music throughout the night) can be helpful for some.

The fourth section is that some patients report that they have difficulty concentrating in anticipation of an intense sound. Again, partial masking sound therapy can be helpful.

Sound Therapies

One fundamental issue is whether to protect the ears from moderately intense sounds, for example, with earplugs. Some patients with severe hyperacusis do this on their own. Of course, everyone (including hyperacusis patients) should protect their ears from potentially damaging high-intensity sounds. However, protecting a hyperacusis patient's ears from moderately intense sounds will not cure the patient's hyperacusis. In fact, restricting one's exposure to moderately intense sounds might have a further negative impact.

One can imagine that if it is uncommon to hear a sound at 85 dB SPL, then whenever a sound of this level is perceived, it might result in an overreaction.

There are currently five general sound therapy strategies that we are aware of for hyperacusis. Good evidence to suggest their effectiveness is lacking.

CONTINUOUS LOW-LEVEL BROADBAND NOISE

One approach is to expose the patient to continuous low-level broadband noise. The rationale is that the reduced input resulting from hearing loss is responsible for the hyperacusis. Correcting this reduced input by continuous noise exposure might reduce the hyperacusis. An advantage of this approach is that the noise can be provided during waking hours with wearable noise generators, and the patient does not have to focus on the device or treatments at times during the day. Having a device also provides some control for the patient, so they do not feel helpless. A possible disadvantage is that noise might interfere with speech perception. Formby and Gold (2002) have reported great success in some individuals with loudness hyperacusis (changes in the LDLs >50 dB). Dauman and Bouscau-Faure also used this procedure for annoyance hyperacusis with some positive results; however, they concluded that "noise generators do not provide a rapid solution to the problem" (p. 506) and that annoyance hyperacusis "does not improve as rapidly as usually reported" (p. 509).

SUCCESSIVE APPROXIMATIONS TO HIGH-LEVEL BROADBAND NOISE

A second approach is to allocate select times during the day for noise exposure and to gradually increase the duration and/or level of exposures over time. Another option is for patients to listen to noise for 30 minutes at a soft loudness each night for 2 weeks. For the next 2 weeks, the noise might be increased by a few decibels. For the next 2 weeks, the duration of exposure might be increased by another 30 minutes. The level of the noise can be gradually increased over several weeks. An advantage is that the patient can participate in the strategy for increased exposure. The level should never be uncomfortable, but higher levels can be used because the patient can listen to these levels at times when speech perception is not required.

SUCCESSIVE APPROXIMATIONS TO TROUBLESOME SOUNDS

A third approach that we have used involves recording of specific sounds. These can be selected with the patient and obtained by direct recordings or by prerecorded sound samples. It can be particularly helpful for patients who experience hyperacusis for specific sounds. The patient can then

replay the sounds at times when they are relaxed and at a much reduced (and not annoying) level. The patient can then successively increase the duration and level of listening periods over several weeks. The levels and categories of sounds can successively approximate the troublesome sounds. In parallel, we integrate the exposure of sounds in carefully controlled environments to situations closer and closer to approximating the actual situations resulting in hyperacusis.

PARTIAL MASKING

Partial masking with a continuous background sound can be used to reduce the loudness and prominence of intermittent sounds that might otherwise be annoying. For example, low levels of music can partially mask background annoying traffic noise. Additionally, the low-level music can create a background whereby the patient is less likely to anticipate being disturbed while getting to sleep, sleeping, or concentrating.

GRADUAL INCREASE OF MAXIMUM OUTPUT OF HEARING AID

The maximum output of a hearing aid can be initially lowered to a level where sounds are not perceived as loud (Searchfield, 2006). Then, over several days or weeks, the maximum output can be gradually increased. This successively exposes the patient to sounds perceived as louder. If the patient experiences hyperacusis, the maximum output can be lowered again.

Medication

The use of medication to treat hyperacusis has not been investigated in clinical trials, but interest is high because of the lack of cures.

HYPERACUSIS IN CHILDHOOD

Hyperacusis also occurs in children and is frequently associated with tinnitus and noise exposure. Moderately intense sound from the television, games, and telephone rings can cause some children to cover their ears with their hands. The symptoms can be so severe that activities such as car rides, vacuum cleaning, and lawn mowing are avoided. Generally, the approach we use is similar to our approach for adults. However, it is particularly important to consider the influence of peers, school, and parents.

CONCLUSIONS REGARDING HYPERACUSIS

Hyperacusis can be related to loudness, annoyance, and fear, and it is critical to distinguish the particular problems

involved with individual patients. Counseling to provide information and reassurance and to challenge beliefs about hyperacusis can be very useful. We have identified four different approaches to sound therapy, including the use of continuous low-level noise, the use of successive approximation of troublesome sounds, partial masking to reduce the loudness and/or prominence of sounds, and gradually increasing the maximum output of a hearing aid. These approaches all require controlled investigations. No medications have been shown to be effective.

SOME FINAL THOUGHTS ON TINNITUS AND HYPERACUSIS

Patients with tinnitus and hyperacusis often find themselves receiving little or no help from healthcare professionals. Dismissive responses to their concerns only exacerbate their frustration. This is unfortunate because many can be helped with brief, supportive counseling. Audiologists are in an excellent position with their training in hearing, hearing loss, and counseling to provide important assistance to these patients. The challenge is substantial, but so are the rewards.

Clinically, most patients report (and likely do) benefit from counseling and sound therapy, including hearing aids. Healthcare reimbursement often requires evidence.

Many cases of tinnitus and hyperacusis can be prevented by reducing noise exposure. This can be accomplished by reducing noise levels at the source, using hearing protection, reducing the duration of exposure to noise, and taking “rests” away from the noise. Never miss an opportunity to promote the importance of hearing loss, tinnitus, and hyperacusis prevention.

ACKNOWLEDGMENTS

We wish to acknowledge grant support provided by the American Tinnitus Association and the National Institutes of Health (Grant No. 5R01DC005972). We thank George Haskell and Aditya Bardia for help with an earlier version of this document.

FOOD FOR THOUGHT

1. A war veteran comes in and complains he can't get to sleep at night because of the crickets in his ear. What is your plan?
2. You are asked by a local attorney for your help accessing whether a factory worker has, or has not hearing loss and/or tinnitus. She also wants to know what level of impairment the worker has, and what recommendations you would make to accommodate any work impediments because of his tinnitus. How can you help?

3. A father comes into your clinic worried that his 8 year old daughter cries and covers her ears whenever she has two of her school friends over to play? It occurs when they make a lot of noise, but he states it is really not that noisy. His recollection is that it only occurs with the same two friends. What is your plan of evaluation and what do you tell the father?

Tele-audiology

De Wet Swanepoel

INTRODUCTION

Little James, age 6 weeks, and his parents live in a remote community in northern Ontario, Canada. He has not passed an initial and a follow-up screening, so his parents have brought him to a local clinic for a diagnostic auditory brainstem response (ABR) assessment. Under the supervision of an audiologist, the trained screener connects the electrodes and places the insert earphones. The audiologist is not physically present, but is supervising remotely from a videoconferencing facility in Thunder Bay. Once James is set up, the audiologist remotely controls the computer running the ABR software and evaluates his hearing over the next 40 minutes. Until recently, such an evaluation would involve the expense, time, and inconvenience of parents having to take 2 days off work and travel by air from their remote community to Thunder Bay.

In another part of the world, Mr. Omondi, age 74, is taken by his son to the local mission hospital in his local village in western Kenya. For the past 15 years, he has been isolated from his family and community because of a disabling hearing loss. This is devastating in any society, but arguably worse when one is illiterate and resides in a culture where respect for the elderly and the oral traditions they pass on is central to the social fabric of the society. He has been unable to access audiologic services because none have existed apart from a handful of private clinics in the distant capital city. At the local hospital, a nurse instructs Mr. Omondi and puts on a headset and bone oscillator connected to a diagnostic computer-operated audiometer that runs an automated test sequence. Results are uploaded to a secure centralized server through a 3G cellular network connection. An audiologist in Sweden reviews the findings, interprets the results, and sends a recommendation back through the secure connection. For the first time, Mr. Omondi has his hearing loss diagnosed with the possibility of intervention.

These cases represent the possibilities that information and communication technologies (ICTs) are offering and serve as examples of typical services emerging in many parts of the world. This field of health care is referred to as telehealth or, in audiology, as tele-audiology.

Key challenges facing global health care, including audiologic health care, relate to issues of access, equity,

quality, and cost-effectiveness (World Health Organization (WHO), 2011). In the past two decades, the world has seen exponential growth and development in ICTs that have revolutionized the way in which modern society communicates and exchanges information. These technologies are also impacting and changing modern health services and may provide a cost-effective and sustainable means of providing much-needed audiologic services to those populations identified as having restricted or limited access. The possible benefits may be far reaching, with telehealth able to improve healthcare access, quality of service delivery, effectiveness and efficiency of health care and towards amelioration of the inequitable distribution of health professionals globally (Dharmar et al., 2013; Wootton et al., 2009).

DEFINING TELEMEDICINE, TELEHEALTH, AND eHEALTH

The most commonly used term to describe the use of ICTs in health service delivery has traditionally been the term “telemedicine” (Fatehi and Wootton, 2012). Perhaps reflecting the rapid development and incorporation of new advances in technology, terminology was evolved and expanded over time. The term “telehealth” has been introduced to encompass a broader spectrum of health-related functions, including aspects of education and administration (Fatehi and Wootton, 2012). More recently, the term “eHealth” has been used to include aspects related to data management and processing. Evidence, however, suggests that these terms are used interchangeably by health providers and consumers and are ambiguous in their definition and the concepts to which they refer (Fatehi and Wootton, 2012). As a result of the ambiguity, the WHO (2010) and the American Telemedicine Association (ATA, 2013) have adopted “telemedicine” and “telehealth” as interchangeable concepts. The WHO defines these terms as “The delivery of health care services, where distance is a critical factor, by all health care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation and for the continuing education of health care providers, all in the interest of advancing the health of individuals and their communities” (p 9).

FIGURE 36.1 Illustration of telehealth service-delivery models. ICT, information and communication technology.

Another variation in terminology related to the field has been the use of the prefix “tele” in front of the specific field of healthcare practice, that is, tele-dermatology and tele-psychiatry. Generally, using “tele” has implied the use of ICTs to practice various aspects of these specific healthcare professions. For the purposes of this chapter, the term tele-audiology will be used as a category referring to the practice of audiology using telehealth modalities.

TELEHEALTH SERVICE DELIVERY MODELS

Telehealth is not a field of medicine or health care per se. Rather, it is a means by which existing healthcare needs may be served by using ICT to link healthcare expertise with patients and with other health providers with the ultimate aim of providing better access, efficiency, and cost-effectiveness to healthcare services like audiology. Telehealth may be utilized for educational or clinical purposes.

Providing telehealth services can be classified into two basic models that relate to the timing of the information exchange and the interaction between patient and health professional or between health professional and health professional (WHO, 2010). The first model has been called “store-and-forward” or asynchronous telehealth which involves sharing prerecorded information from one location to another (Figure 36.1). The information may be relayed from a patient site (also called the remote or originating site) to a healthcare provider site (also called the specialist or host site), or between healthcare providers. Importantly, “store-and-forward” telehealth models do not require a healthcare provider to interact with the information in real time. An example may be something as simple as sharing a prerecorded puretone audiogram by e-mail to an expert colleague for an opinion on diagnosis and management. In some cases, a facilitator at the patient site may be present to record the clinical information to be relayed to a healthcare provider or patients might self-monitor or assess and relay this information themselves.

In comparison, “real-time” or synchronous telehealth requires that both individuals (e.g., the healthcare provider and

patient) are simultaneously engaging in information exchange (Figure 36.2). A typical example may be a consultation with a patient using videoconferencing, but it may also include diagnostic assessments by a specialist who remotely controls a computer-operated diagnostic device connected to a patient. Applications will vary and may include expert surveillance or expert presence through audio and/or video facilities of procedures at the patient site (Swanepoel et al., 2010a).

CONSIDERATIONS FOR A TELE-AUDIOLOGY SERVICE

Information and Communication Technologies for Telehealth

Sharing information and communication is foundational to the concept of telehealth. This process is facilitated by the use of ICTs that provide the technology and connectivity for sharing information between different sites (Table 36.1). Technology and connectivity are closely related and often contained in the same concept. For example, a cellular phone

TABLE 36.1

Technologies Typically Facilitating Store-and-Forward (Asynchronous) and Real-time (Synchronous) Telehealth Practice

Store-and-Forward (Asynchronous)	Real Time (Synchronous)
E-mail	Videoconferencing (video and voice)
Facsimile	Voice call (Fixed line, mobile, VoIP, or satellite)
Multimedia message (MMS)	Desktop sharing software (to control device)
Text message	Virtual private network (VPN)
Shared online networks	
Patient online portals	
Web-based eHealth patient service sites	

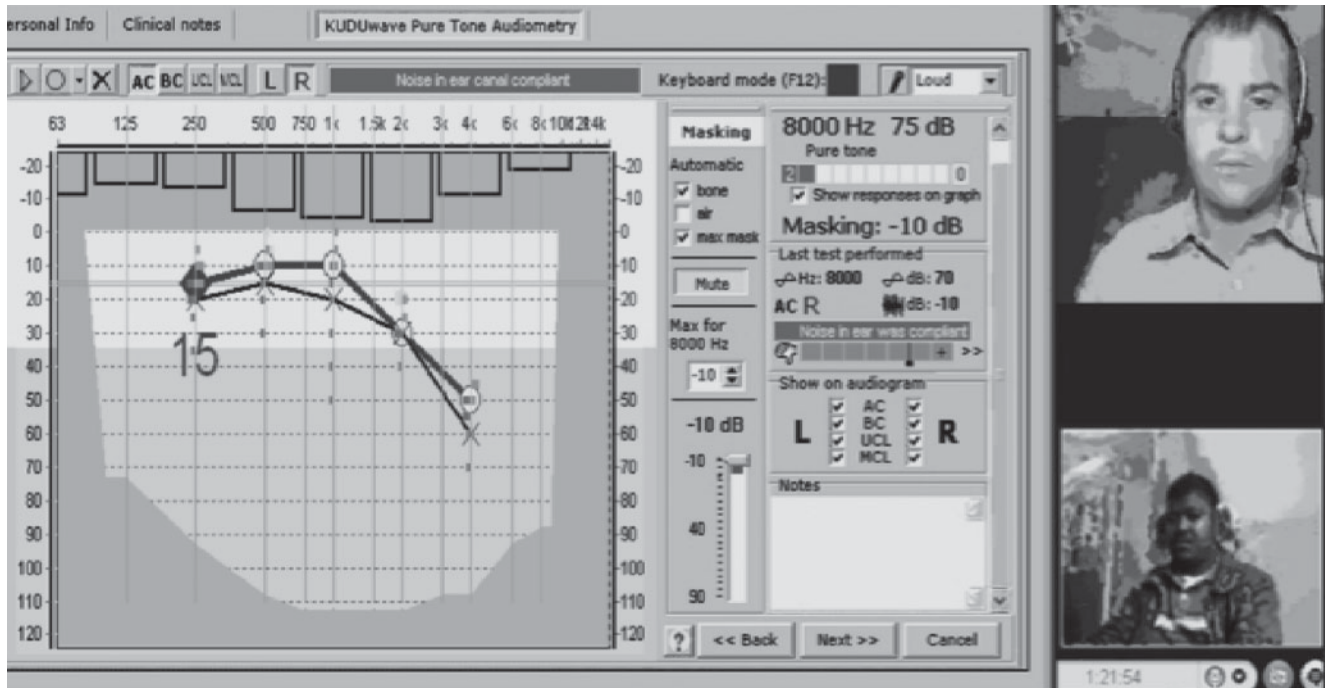

FIGURE 36.2 Remote audiometry test transmitted from Dallas, Texas, to Pretoria, South Africa. The clinician is visualized in the *top right corner* with the patient visualized in the *bottom right corner*. The left and right ear thresholds are visualized on the audiogram on the *left side* of the figure. The test session can be watched at <http://www.youtube.com/watch?v=HDfjuvPODh0>.

is a physical handset (technology) that transmits and receives information using radio signals (connection). A more complex but typical example with overlap of the technology and connectivity concepts is e-mail. The e-mail technology includes the software interface used on a device of some sort (e.g., PC, tablet, or smartphone) and the connection being facilitated through the Internet connection of the particular device (e.g., WiFi; global system for mobile communication or GSM). The technologies that may be used in telehealth may therefore include non-Internet-based technologies such as facsimile, two-way radio or telephone, or Internet-based technologies that may include e-mail, web browsing, file transfer protocol (FTP), shared networks, voice over Internet protocol (VoIP), video traffic for teleconsultation and videoconferencing, and remote desktop sharing software (e.g., TeamViewer). Devices ranging from smartphones and tablets to laptops and personal computers (PCs) usually operate the Internet-based telehealth technologies. Connectivity includes options such as fixed line telephone networks, cellular phone and Internet network, satellite phone and Internet networks, integrated services digital network (ISDN), and digital subscriber line (DSL).

Technologies available for telehealth applications are diverse and continually evolving and developing. Although technologies may be very expensive, there are increasingly more affordable options available. Videoconferencing rooms with advanced equipment, for example, may be cost prohibitive for many healthcare facilities, but free videoconferencing

software (e.g., Skype, ooVoo, Google Hangout) could be used on devices such as laptops, tablets, or smartphones.

Equipment for Telehealth Purposes

Apart from the ICTs required for telehealth services, equipment must be considered. For example, if videoconferencing is being done via a computer, an internal or external webcam and microphone must be used at both sites to capture the video and audio images for transmission.

COMPUTER-OPERATED EQUIPMENT

Computer-operated equipment allows easy sharing of information in a store-and-forward mode, that is by e-mailing a printout of results. Computer-operated equipment equipped with remote desktop sharing software allows the healthcare provider to control onsite equipment in real time for the desired assessments, procedures, or interventions.

DEDICATED TELE-AUDIOLOGY TECHNOLOGIES

The practice of audiology is especially reliant on computer-operated equipment for screening, diagnosis, and intervention (assistive devices), with the potential to be highly compatible with telehealth service provision. However, currently audiologic equipment is usually not made with the intention of using it within a telehealth service-delivery model and therefore may lack some important features

that could add to the reliability and quality of such assessments (Clark and Swanepoel, 2014). For example, when conducting audiometric testing remotely, the audiologists do not know whether the environment is sufficiently quiet or not. Environmental and patient feedback systems may be very useful to incorporate in future equipment as one way of making devices more specifically telehealth enabled (Swanepoel et al., 2010a). A recently developed diagnostic audiometer, specifically developed for telehealth purposes, includes examples of such novel features as live and continuous environmental noise monitoring, lightweight and mobile design with all hardware encased in the earcups and powered from a USB power source, and the ability to record patient responses and response times (Maclennan-Smith et al., 2013; Swanepoel et al., 2010a, 2013b).

AUTOMATION IN TELE-AUDIOLOGY

Other features of audiologic equipment that may be beneficial to telehealth are the automation or semiautomation of equipment-based procedures (Swanepoel et al., 2010a, 2010b). Automation allows for telehealth facilitators to take the necessary measurements and relay them to audiologists for interpretation/management. Advances in computer technology are making automation of audiologic assessment procedures easier, which has led to growing interest in automation (Margolis et al., 2010; Swanepoel et al., 2010b). A recent meta-analysis of automated diagnostic puretone audiometry, for example, revealed that automated audiometry is equally accurate and reliable compared to the gold standard of manual audiometry. The authors did however highlight the shortage of evidence for audiometry with bone conduction, in patients with various degrees and types of hearing loss and difficult-to-test populations (Mahomed et al., 2013).

Telehealth Facilitators

Technology and connectivity, despite being experienced by users as temperamental at times, are often the easy part of a successful telehealth program. A key element required for the success of a program often depends on the support personnel, in particular the telehealth facilitator. Telehealth models may typically utilize nonspecialist personnel, referred to as telehealth facilitators, to facilitate the telehealth encounter linking the health provider and the patient (Swanepoel et al., 2010a). These personnel may vary, such as community healthcare workers, assistants, nurses, primary healthcare physicians, or IT specialists. They are not qualified to make diagnoses or interpretations but with proper training are qualified to facilitate the information exchange for the specific telehealth encounter. These individuals must be thoroughly trained in the required equipment, procedures, protocols, and patient interactions related to the service provided. Regular monitoring and retraining are important.

Often the quality and success of a clinical telehealth service are primarily dependent on the telehealth facilitator.

Patient and Environmental Considerations

Because of the nature of telehealth services, where health professionals are not with the patient in person, additional considerations related to the patient receiving the service and the environment in which the service is provided are required. In fact, some patients and some environments may not be appropriate for provision of telehealth services. In pediatric audiology, for example, it may not be appropriate to conduct visual reinforcement audiometry. The timed behavioral response to the signal may be difficult to follow because of transmission delays in activating the stimulus and in observing the response. Furthermore, video resolution of the patient may likely be insufficient to observe minor behavioral reactions such as eye movements. Table 36.2 provides a summary of patient considerations that may impact telehealth services, which clinicians should keep in mind when considering service provision.

TABLE 36.2

Patient Considerations in Tele-audiology (Summarized from ASHA, 2013a)

Domains	Characteristics
Physical and sensory	Hearing ability Visual ability Manual dexterity Physical endurance
Cognition, behavior, and motivation	Level of cognitive functioning Attention maintenance Ability to sit in front of camera with minimal extraneous movements (to avoid poor image quality) Willingness of patient/family to receive telehealth services
Communication characteristics	Auditory comprehension Literacy Speech intelligibility Cultural/linguistic variables Availability of interpreter
Support resources	Availability of technology Availability of facilitator Ability to follow directions to operate and troubleshoot telehealth technology and transmission (patient/facilitator/family)

TABLE 36.3**Summary of Core Standards Related to Telehealth in Clinical Practice****Administrative Standards***Organizations*

1. Follow standard operating policies and procedures
2. Systematic quality improvement and performance management process
3. Compliance with relevant legislation, regulation, and accreditation requirements
4. Assuring patients are aware of their rights and responsibilities
5. Telehealth integrated into existing operational procedures for obtaining consent
6. Collaborative partnerships aware of applicable legal and regulatory requirements

Health professionals

1. Fully licensed/registered with respective regulatory/licensing bodies where patient is located
2. Aware of credentialing requirements at site where consultant and at site where patient is located
3. Aware of locus of accountability and any/all requirements when practicing in another jurisdiction
4. Cognizant of provider-patient relationship established within the context of telemedicine proceeding with evidence-based, best possible standard of care
5. Necessary education, training/orientation, and ongoing continuing professional development to ensure competencies for safe provision of quality services

Clinical standards

1. Organization and health professionals practicing telehealth aware of own professional discipline standards and those to be upheld via telehealth considering specific context, location, timing, and services
2. Guided by professional discipline and national clinical practice guidelines when practicing via telehealth with consideration of any modifications to specialty-specific clinical practice guidelines for telehealth to meet clinical requirements for discipline

Technical standards

1. Ensure equipment sufficient and functioning to support diagnostic needs
2. Strategies to address environmental elements of care for safe use of equipment
3. Comply with relevant safety laws, regulations, and codes for technology and technical safety
4. Compliant infection control policies and procedures for telehealth practice
5. Policies and procedures to comply with local legislated and regulatory rules for protection of patient health information ensuring physical safety of equipment and electronic security of data
6. Appropriate redundant systems to ensure availability of network for critical connectivity
7. Appropriate redundant clinical video and exam equipment for critical clinical encounters and clinical functions
8. Meet technical standards for safety and efficacy for devices interacting with patient
9. Processes to ensure safety and effectiveness of equipment through ongoing maintenance

Source: Adapted from ATA [2007].

Environmental characteristics are especially important in audiology where most services require ambient noise levels kept to a minimum. Considerations should include quiet rooms with minimal distractions, as well as good lighting and appropriate design to ensure optimal video and audio transmission. Positioning of the patient and placement of equipment in relation to the patient are important variables when videoconferencing is being used (American Speech-Language-Hearing Association (ASHA), 2013a).

Tele-audiology Standards and Guidelines

Professionals and organizations providing health services are required to adhere to administrative, professional, clinical,

and technical standards when practicing via telehealth. A summary of core standards specified by the ATA (2007) can be found in Table 36.3. These serve as general but fundamental requirements across healthcare disciplines providing remote health services, interactive patient encounters, and other electronic communications between patients and health professionals. Discipline-specific guidelines are necessary when considering telehealth for particular patient groups, disorders, and contexts. In audiology, discipline-specific guidelines have been proposed by the ASHA (2013a), the Canadian Association for Speech-Language Pathologists and Audiologists (CASLPA, 2006), and the American Academy of Audiology (AAA, 2008).

These position statements and resolutions on telehealth in audiology endorse and support its use to improve access

to audiologic services. There is agreement that telehealth has the potential to overcome accessibility barriers related to distance, travel costs, weather, mobility, patient schedules, and personnel shortages. At present, tele-audiology is proposed primarily as a way to increase access to care when deemed in the best interest of the patient and not to replace existing services that could be provided through face-to-face services without difficulty. As more research evidence accumulates, the role of tele-audiology is likely to evolve beyond only improving access to care to also improving the efficiency in service delivery and cost efficiency in existing audiologic practice (Swanepoel et al., 2010a).

Current guidelines and resolutions also agree that telehealth service must be equivalent to in-person service provision in scope and nature. Audiologists must also be attentive to patient perceptions and cultural diversity that may result in differences in comfort level with telehealth technology. Furthermore, tele-audiology service should always be provided or supervised by a qualified audiologist. Audiologists must be aware of and accountable to the ethical and clinical standards of their professional regulating or licensing body and abide by these as specified for the state or province. Cross-border or cross-state telehealth service provision introduces important questions on accountability (ASHA, 2013b). At present, some states in the United States require that the professional must be licensed both at the home state and in the state where the patient is being served. There is an increasing number of states with telehealth provisions for audiology, but characterized by widespread variability (ASHA, 2013c). It is also the responsibility of the service provider to ensure adherence to the privacy and security requirements of federal and state regulations when storing and transmitting patient information. Protecting patient information is not a simple or straightforward task and it has been recommended to consult an expert specializing in these issues (ASHA, 2013a).

Reimbursement and insurance coverage for telehealth services has been identified as one of the most important reasons for the slow adoption of telehealth (Bashshur et al., 2013). Advocacy at the state and national level to enact laws removing reimbursement barriers for telehealth services would increase widespread adoption of these services. Increasingly, communities are changing reimbursement regulations to incorporate telehealth services (ASHA, 2013a; Australian Government Department of Health and Aging, 2013; Bashshur et al., 2013). Unfortunately, when reimbursement regulations include telehealth, they often cover only certain types of services such as face-to-face consultations, as opposed to store-and-forward services that are likely to hold more promise for improved time and cost efficiency (Australia Government, 2013). Reimbursement and insurance coverage programs for telehealth services continue to change, and therefore must be verified prior to initiation of the services (ASHA, 2013a). The responsibility of fee reimbursement should be established with patients prior to service delivery (CASLPA, 2006).

WHY TELEHEALTH FOR AUDIOLOGY

Telehealth has been proposed to hold great potential toward improved access, quality, efficiency, and cost-effectiveness of healthcare services particularly for populations who have traditionally been underserved (WHO, 2010). Improved efficiency in competitive healthcare environments because of telehealth services has been demonstrated to result in increased patient services and hospital and professional billing revenue (Dharmar et al., 2013). Telehealth can potentially bridge the general barriers often created by distance, poor travel infrastructure, severe weather, and unequal distribution of healthcare providers in urban and rural settings or even across world regions (Swanepoel et al., 2010a). These potential advantages of telehealth are particularly appealing in the field of global hearing health care where there is a dearth of hearing health professionals who are able to provide audiologic services to an increasing number of persons who require care. In addition to the prevalence of hearing loss and the shortage of hearing healthcare professionals, the advances in technology and rapid expansion in connectivity are opening up new avenues for delivering tele-audiology.

Addressing Current Challenges

INCREASING HEARING LOSS CASELOAD

Recent estimates indicate a global prevalence of just over 10% for permanent bilateral adult hearing loss of 35 dB or greater, which translates to more than half a billion adults affected (Stevens et al., 2013). Excluding milder losses, the WHO (2013) estimates that 328 million adults (hearing losses >40 dB) and 32 million children (hearing losses >30 dB) have a disabling hearing loss. It is not surprising, therefore, that it is the most prevalent chronic disability with 5.3% of the world population suffering from disabling hearing loss.

An important characteristic of global hearing loss prevalence is the fact that it is increasing significantly because of the increase in life expectancy. Since 1990, the average life expectancy has increased from 64 to 68 years of age in 2009 with an increase from 76 to 80 years of age in high-income countries (WHO, 2011). With aging as the most common cause of hearing loss, longer life expectancies globally mean an unmatched growth in hearing loss prevalence in the foreseeable future (Swanepoel et al., 2013a). In countries like the United States, Baby Boomers (born between 1946 and 1964) are now entering the geriatric age categories, and because of longer life expectancies and the disproportionately large numbers in relation to previous generations, there will be unprecedented demands for hearing health services. The growing number of persons with hearing loss globally raises the question of how they will be able to access audiologic

care. Tele-audiology potentially offers a way to provide the growing number of patients with access to services.

SHORTAGE OF AUDIOLOGIC SERVICES

Unfortunately there is a global shortage of ear and hearing health professionals (Fagan and Jacobs, 2009; Goulios and Patuzzi, 2008). As a result, close to 80% of persons with hearing loss globally cannot access hearing healthcare services because they reside in developing countries where hearing healthcare services are often unavailable (Fagan and Jacobs, 2009; Goulios and Patuzzi, 2008; WHO, 2006). In sub-Saharan Africa, for example, many countries have no audiology or ENT services (Fagan and Jacobs, 2009). Of the 46 countries constituting this world region, which comprises almost 1 billion people, only one (South Africa) provides tertiary-level education for audiologists.

A shortage of hearing healthcare services is not only a developing world problem, however. According to estimates in the United States, there is a major capacity shortage in terms of the need for hearing evaluations and the capacity of the current audiologic workforce to deliver these. Estimations indicated that in the year 2000 there was an annual shortfall of 8 million audiograms projected to increase to 15 million by 2050 (Margolis and Morgan, 2008). A more recent analysis of audiologic demand in the United States in relation to current and projected growth rate of new graduates demonstrate a growing mismatch between the demand for audiologic services and capacity to deliver these (Windmill and Freeman, 2013). Estimates indicate that the number of persons entering the profession will have to increase by 50% immediately and attrition rate lowered to 20% to meet the demand. Alternatives, including increased capacity for service delivery through telehealth, are suggested as ways of improving the audiologic service-delivery capacity.

In addition to professional shortages, underserved regions also persist in developed countries including Canada, Australia, and the United States because of traveling distances and geographical and weather obstacles. Utilizing telehealth approaches in hearing health care has been suggested as a means of addressing the availability and distribution of audiologic expertise and increasing the access to audiologic care (Swanepoel et al., 2010a, 2010d).

ENHANCING AUDIOLOGIC EFFICIENCY

Apart from the potential telehealth has for improving access to the growing need for audiologic services, future applications of telehealth may also enhance existing services by improving efficiency with resultant cost-savings for health systems and individuals. Use of asynchronous screening and even diagnostic methods of assessing and monitoring patients may ensure that only those requiring advanced assessments, counseling, or intervention are referred for full audiologic assessments. An example of this is a national

tele-audiology service providing mandated monthly audiologic monitoring for patients with multidrug-resistant tuberculosis receiving ototoxic medications (Bashshur et al., 2013). Many of these patients are in remote rural locations where automated audiometry is facilitated at primary healthcare facilities and results uploaded through cellular networks to a server, allowing remote interpretation and recommendations by audiologists. This saves traveling costs for patients who would otherwise have to attend facilities with an audiologist, which may be hundreds of miles away. Prior to this service, the majority of these patients were not monitored as required because of the travel and cost barriers. In this way, the efficiency of audiologic services is enhanced. Many more such examples could be provided but systematic research documenting enhanced efficiency and cost containment should be prioritized.

Advances in Technology and Expanding Connectivity

The past two decades have seen unprecedented growth in technology. There has been a revolution in the processing capabilities and size of computing equipment such as personal desktop computers. In the past 5 years, a new market of tablet computers, smartphones, and phablets (hybrid phone and tablet) has emerged that is charting new ways of engaging with information. Alongside the hardware developments, the Internet has changed and developed to become the predominant workspace from which devices access, store, and share information. These advances allow new and innovative ways of utilizing technology in hearing health care (Kelly and Minges, 2012). Interfacing with audiologic equipment may be facilitated through tablets and smartphones as opposed to desktop or laptop computers. Novel applications of technologies may also have facilitated automation of audiologic testing in some respects. Recent evidence, for example, has suggested that there is renewed and increasing interest in automated audiometry largely because of the possibilities for efficient, accurate, flexible, user-friendly and reliable functioning offered by newer technologies (Mahomed et al., 2013).

In addition to technologic advances, the rapid improvement and distribution of connectivity is providing an increasing opportunity for implementation of telehealth globally. Connectivity around the world has grown exponentially with one in every three people worldwide having access to the Internet in 2012 (Internet World Stats, 2012). Although Internet penetration in a region like Africa is still reasonably low and bandwidth costs are expensive, the large-scale rollout of cellular networks across Africa and the rest of the world is opening doors through mobile connectivity in the most remote and underserved areas (Kelly and Minges, 2012; Swanepoel et al., 2010a). Growth in the spread of mobile phones globally has been unmatched in the history of technology. In 2012 there were more than

6 billion mobile subscriptions, with 75% of the world's people having access to a mobile phone (Kelly and Minges, 2012). It is estimated that by 2015 there will be more mobile subscriptions than people, with more than 80% from developing countries. This growth in connectivity and in mobile phone technology is already transforming the delivery of healthcare services. It allows access to information and communication sharing with the most underserved areas, which allows for provision of telehealth services.

Continuing advances in technology and connectivity are therefore making tele-audiology a feasible and opportune area of practice and research set to change the way in which audiologists provide services. It is important that the profession of audiology capitalizes on these advances and directs its development to ensure that not only optimal access but also best practice and care is delivered to patients.

TELE-AUDIOLOGY IN PRACTICE

Tele-audiology is becoming increasingly used as part of audiologic service delivery across a variety of applications. Examples are provided within the broad categories of audiologic screening, diagnosis, intervention, and continuing professional development.

Screening

Screening lends itself quite naturally to store-and-forward (asynchronous) telehealth applications with trained non-specialist personnel being able to conduct screenings. In fact, the widespread screening of newborns for hearing loss, although not often termed as such, may be considered a form of asynchronous telehealth. Trained screeners conduct the measurements in hospitals and subsequently upload the results to secure servers, where the data are managed and the necessary follow-up measures are recommended. Although results are not necessarily reviewed remotely, they are still managed as part of an electronic health information system.

In a systematic review of telehealth applications in audiology (Swanepoel and Hall, 2010), several reports of tele-audiology screening applications were identified, including real-time screening of newborns with automated otoacoustic emissions (OAE) and ABR (Krumm et al., 2008). Unsurprisingly, the screening results were similar between remote and onsite screening. Real-time screening of elementary school children with puretone audiometry revealed similar test sensitivity but slightly poorer test specificity values when compared to onsite screening (Lancaster et al., 2008). These applications, however, would seem best mediated through a store-and-forward (asynchronous) telehealth model but these “proof-of-concept” studies support the viability of remote screening.

Another important development for audiologic screening has been the use of a self-screening over the telephone or Internet as a store-and-forward (asynchronous) applica-

tion. This type of screening has the inherent advantage of providing widespread access to hearing screening, which is especially important considering the aging world population, especially the current aging Baby Boomer generation (Swanepoel et al., 2013). It also has important limitations, however, that include a lack of absolute calibration of stimuli and control of environmental variables at the remote test site (ambient noise levels, variable transducer types, etc.). One way to overcome some of these limitations is to use a test that does not require absolute calibration but rather uses a relative signal-to-noise ratio. For this purpose, simple automated speech-in-noise tests have been developed for delivery over the telephone or Internet with normative signal-to-noise ratios to indicate a refer result. In the Netherlands, for example, the national hearing screening service is a triple-digit-in-noise test using an adaptive procedure that can be used reliably over the telephone or computer headset (Smits et al., 2006). In the future, these screening tests will also be available as mobile smartphone applications.

Diagnosis

Conducting diagnostic audiologic test procedures within a telehealth framework requires the sharing of information in a store-and-forward or real-time manner between the patient and audiologic professional sites. The most common form of telehealth practice in audiology is probably something most audiologists have done at some point in time—to ask for a second opinion on a patient or test result. Although not commonly recognized as such, asking for an expert second opinion using an ICT medium such as the telephone or e-mail constitutes a form of real-time or store-and-forward tele-audiology.

In cases where information sharing is from a site without the specialist knowledge of an audiologist, but where there is access to audiologic equipment and ICT, an audiologist may provide services directly in real time or using store-and-forward methods (Table 36.4). Real-time remote services will require the audiologist to engage with the patient and to control the diagnostic test equipment remotely (see section on telehealth equipment). Diagnostic store-and-forward tele-audiology may require some degree of automation to conduct test procedures facilitated by nonspecialist personnel (telehealth facilitator or nurse). Alternatively, the telehealth facilitator should be trained to conduct the specific test procedure but this may not be possible in many cases (e.g., diagnostic puretone and speech audiometry, ABR).

CASE HISTORY

Case histories can be taken quite easily in real time using technologies such as video-conferencing. Store-and-forward methods may also be utilized and could include completion of questionnaires and standardized forms online (e.g., tinnitus and hearing loss handicap inventories) prior to consultations.

TABLE 36.4

Summarizing Applications of Common Diagnostic Audiologic Procedures Using Telehealth

Diagnostic Procedure	Telehealth Modes Applicable	Automation	Populations
Case history	Store-and-forward or real time	Can be automated	All
Video-otoscopy	Store-and-forward	–	All
Tympanometry	Store-and-forward or real time	Automated	All
Acoustic reflexes	Store-and-forward or real time	Automated/ semiautomated	
Puretone audiometry	Store-and-forward or real time	Can be automated	Older children and adults
Speech audiometry	Real time	–	Older children and adults
Otoacoustic emissions	Store-and-forward or real time	Automated	All
Auditory brainstem response	Real time	–	All
Intraoperative monitoring	Real time	–	All
Balance testing	Real time	–	Older children and adults

VIDEO-OTOSCOPY

Video-otoscopy has been used for telehealth purposes to assist in establishing outer and middle-ear status. Video-otoscopic images can be e-mailed or uploaded to online servers for remote interpretation. Studies have confirmed the reliability of this technique in children and adults compared to face-to-face interpretations (Biagio et al., 2013; Patricoski et al., 2003). A recent study demonstrated that a nonspecialist telehealth facilitator could be trained to record video-otoscopy images comparable to an otolaryngologist for remote interpretation (Biagio et al., 2013). A follow-up study on children demonstrated similar findings and was the first to report using brief videoclips as opposed to still images (Biagio et al., in press). Videos have the added advantage of capturing more area of the ear canal and tympanic membrane from various angles and allow remote clinicians to pause and rewind to specific frames for detailed analyses.

IMMITTANCE

Current immittance equipment is largely automated, requiring only an ear canal seal for the test sequence to commence. Nonspecialist personnel could therefore be trained to acquire a tympanogram or even an automated acoustic reflex threshold sequence. If the results are recorded on a computer-based system, the findings may be uploaded directly to a server or e-mailed. Results from older systems that are not computer-based can be printed and faxed, scanned and e-mailed, or even photographed by a smartphone and sent to the remote site for interpretation. Immittance test findings are usually part of a larger test battery of results required for a thorough audiologic or otologic diagnosis.

PURETONE AUDIOMETRY

In a systematic review of telehealth applications in audiology the majority of reports validated the use of puretone

audiometry in real time to remote locations. The evidence demonstrates that diagnostic puretone audiometry can be conducted remotely on patients with the same accuracy as face-to-face testing (Swanepoel and Hall, 2010). Figure 36.2 provides a screenshot of a remote audiometry study conducted between Dallas, Texas, and Pretoria, South Africa (Swanepoel et al., 2010c). To date, no remote diagnostic puretone audiometry assessments have been reported on children apart from puretone audiometry screening on elementary school-aged children. Obvious challenges emerge when considering remote testing using conditioned play and visual reinforcement audiometry on young children. At present, the complete lack of research evidence in this regard leaves the validity of these measures for tele-audiology questionable. Developing alternative approaches and using well-trained facilitators may allow pediatric audiometry to be conducted on younger children but must be supported by validation research.

Automated puretone audiometry can also be used within a store-and-forward telehealth paradigm (Mahomed et al., 2013; Swanepoel et al., 2010b). A nonspecialist trained in setting up patients and providing the necessary instructions may facilitate automated diagnostic audiometry with the results forwarded to remote audiologists for interpretation and recommendations (Swanepoel et al., 2010a). A single report is available on the validity of automated puretone audiometry in children 4 to 8 years of age (Margolis et al., 2011). Findings indicated that automated puretone audiometry is possible in young children but a measure of test quality should be included to identify unreliable test findings. The system used included a validated measure of automated puretone audiometry reliability.

SPEECH AUDIOMETRY

Conducting speech audiometry through telehealth means is complicated because of the requirement to clearly hear patient responses. The audio quality on videoconferencing links may

not always be sufficient to clearly differentiate between similar sounding words. Alternative real-time method may be to have a trained listener at the patient site who can cross-check the patient responses. The only published tele-audiology study on speech audiometry to date used the Hearing-in-Noise-Test (HINT) (Nilsson et al., 1994), and despite possible confounding factors mentioned above, the results of the study were comparable to the face-to-face testing (Ribera 2005). This testing would require very good connectivity with little or no deterioration in audio transmission and no obvious time delay.

Alternative diagnostic speech audiometry test paradigms may be developed using various options such as closed set word lists or touchscreen response options to speech stimuli. It may even be possible to present a number of speech lists to patients with appropriate instruction and make high-quality audio recordings that are uploaded to secure servers where the lists may be scored asynchronously.

AUDITORY-EVOKED RESPONSES

A few validation studies have been reported applying tele-audiology to diagnostic OAE and ABR (Krumm et al., 2007; Swanepoel and Hall, 2010; Towers et al., 2005). OAE and ABR measurements taken remotely were comparable to those measured onsite. These test setups require a facilitator to correctly place probes (OAE) or transducers and electrodes (ABR). Using interactive videoconferencing allows the remote audiologist to instruct and guide the facilitator in preparing the patient for the test procedure. Auditory-evoked potential measures conducted in real time by expert audiologists on patients in underserved areas are appealing tele-audiology applications. This is especially true in light of the shortage of experienced pediatric audiologists and the increase in babies requiring diagnostic ABR testing following newborn hearing screening. Tele-audiology allows pediatric audiologists to assess patients in different counties, states, and even across continents. In Canada, this type of service has been used for several years to test babies in remote or underserved areas (Polovoy, 2008).

INTRAOPERATIVE MONITORING

Intraoperative monitoring by audiologists may include several types of monitoring procedures, including electrocochleography, ABR measures during surgical excision of acoustic schwannomas, and other surgical procedures where the cochlea or neural pathway of the auditory system may be involved. During cochlear implant surgery, intraoperative device testing and patient responses to electrical stimulation are widely practiced. Device checks include determining the integrity of the implant and its electrodes, and responses to electrical stimulation may include stapedial reflex threshold, neural response telemetry, and electrically evoked ABR (Shapiro et al., 2008).

Intraoperative monitoring services for audiologists are characteristically time consuming with traveling involved and preparation and waiting for the surgery. Remote intraoperative monitoring may increase time efficiency of audiologic resources. Technicians can set up the monitoring equipment and link the devices to the Internet, where an audiologist may take control of the equipment from his or her office and conduct and monitor the specific intraoperative monitoring procedures. A study compared onsite audiologic monitoring and remote monitoring during cochlear implant surgery for several patients (Shapiro et al., 2008). These authors conclude that remote intraoperative monitoring during cochlear implant surgery is feasible, time saving, practical, and efficient (Shapiro et al., 2008).

BALANCE ASSESSMENT

One study has reported using telehealth for vestibular assessment. It involved a single case study with a remote consultation for a patient with benign positional vertigo using two-way videoconferencing and the use of cameras to view the patient's eye movements remotely (Virre et al., 1997). Real-time consultations are certainly possible and equipment-based measures could be conducted remotely, but would require a competently trained facilitator to set up patients for assessments and to facilitate some of the physical maneuvers. Caution must be taken to ensure patients are not put at an increased risk of injury because the assessment is conducted remotely.

Intervention

Audiologic intervention covers various practices that may include prescription, fitting and verification of hearing aid and assistive listening devices, cochlear implant mapping, counseling, vestibular rehabilitation, tinnitus treatment, and aural rehabilitation. In some cases, audiologists may also provide early intervention services to children with hearing loss and their families. Telehealth provides unique opportunities to provide many of these services in ways that may be more cost effective, less time consuming, and offering a greater reach to underserved areas (Swanepoel and Hall, 2010).

HEARING AIDS AND ASSISTIVE DEVICES

Since hearing aids are now almost always digital and programmed by computer-operated software to be patient specific the application of telehealth for remote programming is likely a future development. There are different levels, however, at which telehealth may support the continuum of hearing aid selection, fitting, verification, counseling, and troubleshooting. It may be used across all of these aspects or only for one or two. Current reports have only utilized telehealth means for one or two at time (Campos and Ferrari, 2012; Pearce et al., 2009; Wesendahl, 2003).

An important concern with hearing aid fittings conducted through telehealth means is taking the initial earmold impression. Someone who is qualified and sufficiently trained to take an impression without risks to the patient should be used. Telehealth may be used as a quality control measure to supervise remote earmold impressions in real time. Each context must apply the guidelines and prescriptions of the responsible professional bodies in regard to this practice. Using noncustom earmold hearing aids solves a lot of the issues with quality control and risks related to custom earmolds within a telehealth framework. The possibility of completing a fitting shortly after diagnosis is a further advantage of a noncustom earmold. Unfortunately, not all hearing losses can be accommodated with noncustom earmolds but improvements in technology for feedback reduction are expanding the fitting ranges of these devices (McPherson, 2012).

Remote hearing aid fitting, verification, and subsequent outcomes have been demonstrated to be comparable to a control group of adults who received the same services in a face-to-face setup (Campos and Ferrari, 2012). The remote audiologist conducted hearing aid programming, real-ear verification, and patient education using remote desktop sharing software and videoconferencing equipment with the assistance of an onsite facilitator without experience in hearing aid fitting (Campos and Ferrari, 2012). Outcomes were measured a month later using the HINT and the International Outcomes Inventory for Hearing Aids (IOI-HA) (Cox and Alexander, 2002). No significant differences were found between remote and face-to-face consultation time, real-ear measures matching respective targets, and outcomes in relation to hearing aid use in hours, or between HINT results and IOI-HA results. In an earlier study, remote verification of hearing aid fitting was also verified to be comparable to face-to-face real-ear verification procedures (Ferrari and Bernardes-Braga, 2009). A multiple case study report from Australia confirms these applications as practical and beneficial with a series of patients presented that were assisted remotely with hearing aid fittings, including real-ear measures for verifications, hearing aid program changes, informational counseling, and hearing aid troubleshooting (Pearce et al., 2009).

Although no reports are available on using telehealth methods to assist with provision of assistive listening devices such as FM systems, the applications demonstrated for hearing aids presume that these could also be tailored for tele-audiology provision.

COCHLEAR IMPLANTS

Cochlear implants are specialized devices that are implanted and managed by professional teams, usually located in cities where advanced and highly specialized medical and audiologic support is available. This means that after implantation, patients who reside long distances from these cochlear

implant centers of excellence have to travel regularly to have their implant mapped. Tele-audiology offers a way to provide some of these follow-up services at remote sites with the use of desktop sharing software and videoconferencing.

Current telehealth evidence indicates that there is no significant difference between remote and onsite electrode-specific measure including impedance, ECAP thresholds, psychophysical thresholds, and map levels (Hughes et al., 2012; McElveen et al., 2010; Wesarg et al., 2010; Eikelboom et al., 2014). As a result, remote cochlear implant mapping can be done as a replacement for face-to-face mapping service provided adequate onsite personnel and technology support is offered (Hughes et al., 2012; Ramos et al., 2009). Furthermore, the remote session duration was only slightly higher than the face-to-face sessions on average. Significantly poorer speech perception scores were recorded for the remote test session but were attributed to the influence of environmental noise since the remote site did not have a sound booth (Hughes et al., 2012). The measurements did not require a facilitator with specialized knowledge of cochlear implants or audiology, and patients were generally comfortable connecting the programming cables to the processors (Hughes et al., 2010).

Some of the challenges include incompatibilities between different generation software, hardware, and speech processors. Furthermore, the communication with patients during the remote session was challenging at times, especially when the processor was connected directly and the cochlear implant microphone deactivated as a result. Videoconferencing can also be difficult to facilitate effective speech reading if there is some compromise in the connectivity (Hughes et al., 2012).

COUNSELING AND REHABILITATION

Since videoconferencing is able to connect individuals with live audio and video feeds, real-time counseling and rehabilitation can be conducted without the need for expensive equipment. The counseling and rehabilitation can also occur in a store-and-forward paradigm using something as simple as e-mail exchanges between a patient and a professional. The use of an Internet-based counseling program for new hearing aid users through daily e-mail interchanges for 1 month indicated that it was a powerful medium for observing changes in behavior and perception of patients and allowed for timely responses to concerns (Laplante-Levesque et al., 2006). Utilizing an online education program for adult hearing aid users, Thoren et al. (2011) demonstrated that the Internet can be used effectively to reduce residual problems and that online discussion forums could be useful for rehabilitation. In work currently underway, researchers are developing Internet-based rehabilitation methods for adults with hearing loss using a patient-journey model (Manchaiah et al., 2013). If this type of program proves effective, it may offer ways of providing services that are easily accessible in addition to ensuring cost and time savings.

Internet-based treatment has also been investigated extensively for tinnitus patients (Andersson and Kaldo, 2004; Kaldo et al., 2008). The treatment program consisted of a web-based self-help manual that applied cognitive behavioral principles. Patients submitted weekly diaries to follow progress and give feedback. In comparison to conventional cognitive behavioral therapy for the control group, the treatment group improved to a significantly greater extent than the control group but also had a much higher dropout rate (Andersson et al., 2002). In a follow-up nonrandomized clinical trial, the Internet-based treatment demonstrated significant reductions in distress associated with tinnitus that persisted at 3 months follow-up (Kaldo-Sandström et al., 2004). In a follow-up randomized control trial with improvements to the Internet-based therapy, the treatment groups (Internet-based vs. group cognitive therapy) yielded significant positive results with no significant differences on main outcome measures with relatively stable results persisting at 1-year follow-up. The attrition rate was lower than for previous Internet treatments for tinnitus and was almost twice as cost effective as conventional group treatment (Kaldo et al., 2008).

TELE-INTERVENTION

Early intervention services to infants and young children with hearing loss are essential to improve acquisition of developmental milestones, empower families to meet the needs of their child, and minimize the need for special education services (Cason et al., 2012). There is a general shortage of early intervention personnel, especially for the increasing number of families with children who have hearing loss (McCarthy et al., 2010). Additionally, many families live in remote areas; using videoconferencing equipment allows interventions to connect to families in their homes to provide the necessary services (Houston et al., 2013).

Tele-intervention provides intervention at home, which is a great convenience to the family. For example, consider the disruptions, starting with packing up the patient and siblings for a long drive. Other advantages include the fewer cancellations in the event of a minor family illness and the capacity to record sessions for both the family and interventionist to review. During videoconferencing, the caregivers are the ones interacting primarily with the child, not the clinician. The professional is appropriately functioning as a “guide on the side,” supporting the caregivers as the primary facilitator of the child’s communication, language, and behavior (Houston et al., 2013).

There has been an emerging increase in tele-intervention programs for infants with hearing loss in several countries (Davis et al., 2012; Houston et al., 2013; Richardson, 2012). Initial results have demonstrated positive acceptance by families and interventionists with recognition of the significant benefits offered by tele-intervention (Constantinescu, 2012).

Continued Professional Education

ICT is a powerful tool to enable professionals to obtain remote education. This may be achieved through several different avenues. Online lectures or courses on a variety of audiologic topics are already available from different providers as either live video streaming or offline downloading of prerecorded presentations, designed to facilitate long-distance continued development. Other educational tools include online forums where professionals can interact and share information about cases in an interactive manner. Experienced audiologists may also mentor less experienced colleagues through ICT by providing second opinions or even by using videoconferencing to observe specific procedures. An example may be an experienced audiologist having access to the desktop of the inexperienced colleague while they conduct an ABR assessment. As the experienced colleague observes the recordings, they could comment via an audio link and discuss certain aspects of the auditory-evoked potential software package. This concept has been coined as telementoring by other medical disciplines. Apart from professional education, audiologists may also use ICT to facilitate ongoing training and monitoring of telehealth facilitators, assistive personnel, or other healthcare providers.

CLINICIAN AND PATIENT PERCEPTIONS OF TELE-AUDIOLOGY

An important and relatively unexplored aspect of tele-audiology is the perceptions of both patients and clinicians regarding the provision of services through telehealth (Swanepoel and Hall, 2010). If patients and clinicians are not willing to participate in telehealth services, the technologies and the services will not be effective no matter how advanced the technology.

A common fear among clinicians and patients is the perceived challenge to establish a meaningful clinical relationship through telehealth means (e.g., videoconferencing) as opposed to a face-to-face consultation (Eikelboom and Atlas, 2005). However, many telehealth services include initial contact with patients through face-to-face consultations and following up via telehealth means, which will allay much of that fear. Early reports indicate that perceptions of patients and clinicians who have experienced services via telehealth are all positive. In a study on remote cochlear implant mapping, positive patient experiences on par with face-to-face assessments were reported (Ramos et al., 2009). Perceptions of patients who underwent an asynchronous online tinnitus treatment program also demonstrated similar perceived benefits to those who had face-to-face treatment (Kaldo et al., 2008; Kaldo-Sandström et al., 2004). A study of clinician and caregiver perceptions of tele-intervention for children with hearing loss indicated that that all parents were comfortable and

all interventionists were satisfied with the tele-intervention program (Constantinescu, 2012).

Future studies should be careful to investigate patient and clinician perceptions of individuals who have experienced tele-audiology across a range of services. As more tele-audiology programs emerge both patient and clinician perceptions should be documented to improve these services (Swanepoel and Hall, 2010).

FUTURE OF TELE-AUDIOLOGY

In keeping with the rapid pace of technologic developments, telehealth is a dynamic and rapidly changing healthcare delivery medium. The future of tele-audiology is likely to follow the trends in general technologic developments. This is reflected by the continuous emergence of new terminology to describe different forms of healthcare provision using ICTs (Fatehi and Wootton, 2012). One such area of current interest and rapid growth and development is mobile health (mHealth), often seen as a subset of eHealth but relating to the use of mobile phone technologies to promote, provide, and monitor healthcare services (Kelly and Minges, 2012). This field is particularly appealing with the widespread penetration of mobile phones and cellular network reception globally but particularly in underserved developing countries (Kelly and Minges, 2012). A 2013 review paper indicated that there are more than 15,000 healthcare applications for smartphones (Fiordelli et al., 2013). At present, the evidence in support of these applications is still largely absent but governments are increasingly employing mHealth for public healthcare initiatives (Kelly and Minges, 2012). In hearing health care, there are already numerous smartphone applications available to conduct hearing assessments (e.g., puretone audiometry, speech audiometry) and measure ambient noise levels. Smart phone apps now interact directly with hearing aids and can even function as a hearing aid. Although there are significant challenges when calibration is not controlled, these technologies have the potential to serve as access points for additional services (Foulad et al., 2013; Handzel et al., 2013; Szudek et al., 2012).

As tele-audiology services are validated and cost-effectiveness benefits are demonstrated, it is expected that these services will become integrated components of current ear and hearing healthcare service-delivery models. Major obstacles to increasing these services remain the challenges related to reimbursement and cross-state or even cross-country licensure. On the legislative and regulatory level, much work remains to be done to find compatible ways in which these aspects can be accommodated while ensuring best practice service delivery.

An area of current development in the broader field of audiologic service delivery that is sometimes wrongly associated with telehealth is patient acquisition of hearing aids over the Internet. Internet hearing aid sales are not a telehealth service, since there is no health professional taking

responsibility for the patient as is required through telehealth service delivery. With the proliferation of Internet and mobile phone-based services, audiologists must consistently promote best practice services and the validation of new technologies. Telehealth services may utilize the Internet, but the audiologist is accountable for the service provided. The profession of audiology should not shun new developments incorporating ICT, but should instead lead the way in evaluating these developments.

Audiology has always been a profession that has relied heavily on technology to diagnose and treat patients with hearing loss. As technologies change and advance more rapidly than ever before, audiologic practices must be grounded firmly on research evidence ensuring best practices for the patients we serve.

FOOD FOR THOUGHT

1. The fact that clinical audiology is heavily reliant on technology makes it uniquely suited to telehealth. This reliance on technology may also impact the patient-professional relationship. Consider this possible impact. Is it possible to develop positive patient relationships via tele-audiology? How?
2. Consider whether the automation of audiologic test procedures (typical in asynchronous telehealth services) such as puretone audiometry is a threat or asset to the profession.
3. Consider what population groups may be particularly difficult to serve through tele-audiology and what adaptations may be considered in these cases.

SECTION IV

Management of Hearing Disorders

Room Acoustics and Auditory Rehabilitation Technology

Joseph Smaldino, Brian Kreisman, Andrew John, and Lindsay Bondurant

INTRODUCTION

There is ample evidence that sensory/neural hearing loss (SNHL) causes communicative difficulty, particularly in listening environments that are noisy and/or reverberant (Needleman and Crandell, 1996). Because of the deleterious effects of SNHL on communication, individuals with hearing loss may exhibit reduced psychosocial function, including increased feelings of frustration, anger, fear, isolation, loneliness, and depression (Vesterager and Salomon, 1991). In addition, perhaps as the result of reduced psychosocial functioning, persons with SNHL tend to exhibit a higher incidence of health-related difficulties, including hypertension, ischemic heart disease, arrhythmias, osteoarthritis, and reductions in activity level, quality of life, and physical mobility (Mulrow et al., 1990).

There exists a broad range of potential disruptions of communicative and psychosocial function as well as health-related quality-of-life (HRQOL) issues that can be caused by hearing loss. It is therefore important that the audiologist consider intervention options in addition to hearing aids. In many cases, hearing aids alone may not be sufficient to restore effective communication, particularly if the patient is communicating in an environment with excessive background noise. In these cases, other assistive listening technologies, communication strategies, and auditory rehabilitation training must also be considered and used in conjunction with the hearing aids. It is reasonable to speculate that, if communication function is improved, then the negative psychosocial and/or HRQOL effects of reduced communication can be minimized. With these considerations in mind, the purpose of this chapter is to discuss rehabilitative technologies and communication strategies that have been shown to improve communicative efficiency in listeners with SNHL (and individuals with normal hearing who have difficulty processing auditory information) within the following environments: (1) Room settings that are commonly used for communication, such as churches, restaurants, classrooms, meeting/conference rooms, and theaters; (2) face-to-face situations; (3) telecommunications; and (4) broadcast media (radio, television [TV], etc.). In addition, this chapter will address signal/alerting technologies that can assist individuals with hearing loss in the awareness

of sounds within their listening environment. The term *hearing assistance technology (HAT)* will be used in this chapter, rather than the older term *assistive listening device (ALD)*, to discuss technologies that improve communicative status through the transmission of an amplified auditory, tactile, or visual signal to the listener since many of these technologies are not limited to improvement of listening.

IMPROVING COMMUNICATION IN ROOM SETTINGS

Perhaps the most persistent complaint heard from listeners with SNHL is difficulty communicating in places used for verbal communication. Such environments include churches, restaurants, classrooms, therapy rooms, shopping establishments, meeting/conference rooms, and theaters. To understand why these difficulties occur, it is important that the audiologist has a basic understanding of acoustic variables that can interfere with the perception of speech. These acoustic variables include (1) background noise; (2) speech signal level compared to background noise level; (3) reverberation time (RT); (4) distance between the talker and the listener; and (5) interactions among these variables.

Background Room Noise

Background noise refers to any auditory disturbance within the room that interferes with what a listener wants to hear (Smaldino and Flexer, 2012). A common way of measuring noise in a room is with a sound level meter (SLM). An SLM can range from a compact, inexpensive, battery-operated unit designed to measure sound amplitude to a computer-based device that can measure and record numerous acoustic properties of a signal. SLMs are classified according to standards set forth in American National Standards Institute (ANSI) S1.14-1998 (R2013). Type I meters meet the most precise standards, type II are general purpose, and type III are for hobby use. Detailed measurement of room noise requires, at minimum, a type II (and preferably a type I) SLM. Many SLMs incorporate weighting filter networks. The A-weighting network is designed to simulate the sensitivity of the average human ear under conditions of low

sound loudness (40 phons), the B-weighting simulates loud sounds (70 phons), and the C-weighting approximates how the ear would respond to very loud sounds. The convention for room measurements is the use of the A-weighting network. Unfortunately, the same single number obtained from a sound pressure measurement performed with the A-weighting scale can be obtained from a variety of very different sound spectra. Thus, a more accurate and complete way to measure room noise is to do a spectral analysis of the noise instead of attempting to use a single descriptor.

Noise criteria curves (NCCs) are one way to measure the frequency content of background noise in a room (as described in ANSI 12.2-2008). NCCs are a family of frequency and intensity curves based on the use of one-third octave-band sound pressure levels (SPLs). The NCC rating of a space is determined by plotting the SPLs within each frequency band relative to established NCC. Whenever possible, it is recommended that ambient noise levels in classrooms be measured using NCC measures since this procedure gives the examiner a more comprehensive assessment of the spectral characteristics of the noise.

Noise within an enclosure can come from several possible sources, including *external* sources (noise generated from outside the building), *internal* sources (noise originating from within the building, but outside the room), and *room* sources (noise that is generated within the room). High background noise levels have been measured in many enclosures including classrooms, professional office spaces, and residences (Bess et al., 1986; Smaldino et al., 2007). Crandell and Smaldino (1995) reported that background noise levels in 32 unoccupied classroom settings were 51 dBA and 67 dBC. More recently, studies have reported noise levels as high as 64 to 72 dBA in classrooms of schools as geographically disparate as the United States, Australia, and Hong Kong (see John and Kreisman, 2012, for a review). As will be discussed in a later section, such high levels of background noise can impair speech perception of not only listeners with SNHL, but also many with normal hearing sensitivity.

Background noise in a room can compromise speech perception by masking the acoustic and linguistic cues available in the message. Generally speaking, background noises in a room mask the weaker transient consonant phonemes more than the longer and more intense vowels (typically 10 to 15 dB more intense than consonants). A reduction of consonant information can have a significant impact on speech perception because approximately 80% to 90% of the acoustic information important for speech perception comes from the consonants (French and Steinberg, 1947). The extent to which speech is masked by background noise is influenced by a number of factors, including (1) the long-term acoustic spectrum of the noise; (2) the average intensity of the noise compared to the intensity of speech; and (3) fluctuations in the intensity of the noise over time. Often the most important factor for accurate speech perception is not the overall level of the background noise, but rather the

relationship between the level of the signal as a function of frequency and the level of the background noise as a function of frequency. This relationship is often simplified and referenced as the signal-to-noise ratio (SNR). Because the decibel is logarithmic, SNR can be stated simply as a difference between the overall level of the signal and the level of the noise. For example, if a speech signal is presented at 70 dB SPL and a noise is 60 dB SPL, the SNR is +10 dB. Because of high background noise levels, diminished SNRs have been reported in many communication settings. Pearsons et al. (1977) reported that average SNRs were +9 to +14 dB in urban and suburban residential settings, respectively. In outdoor settings, SNRs decreased to approximately +5 to +8 dB. In department store settings, the average SNR was +7 dB, whereas transportation settings yielded an average SNR of -2 dB. Plomp (1978) reported that the average SNR found at cocktail parties ranged from +1 to -2 dB. In classroom environments, the range of SNRs has been reported to be from +5 to -7 dB (Smaldino and Flexer, 2012).

Speech perception is generally greatest at favorable SNRs and decreases as the SNR of the listening environment is reduced (Finitzo-Hieber and Tillman, 1978; Smaldino and Flexer, 2012). In general, speech perception ability in adults with normal hearing is not severely reduced until the SNR reaches 0 dB. However, this is not the case for listeners with SNHL. To obtain perception scores comparable to those of normal hearers, listeners with SNHL require the SNR to be improved by 4 to 12 dB; an additional 3 to 6 dB is required in rooms with moderate levels of reverberation (Johnson, 2000; Moore, 1997).

Although a number of acoustic, linguistic, and articulatory factors influence the determination of appropriate SNRs in a room, the literature suggests that, for young listeners with SNHL, the SNRs in communication environments should exceed +15 dB (Bradley and Sato, 2008; Finitzo-Hieber and Tillman, 1978). To accomplish this SNR, unoccupied room noise should not exceed 30 to 35 dBA (ANSI S12.6-2002 [R2010]). The recommendation of a +15 dB SNR is based on the finding that the speech perception of listeners with hearing loss tends to remain relatively constant at SNRs in excess of +15 dB but deteriorates at poorer SNRs. Moreover, when the SNR decreases to below +15 dB, those with hearing loss tend to expend so much attentional effort in listening to the message that they often prefer to communicate through other modalities. In addition to listeners with SNHL, some children with “normal” hearing sensitivity have greater than normal perceptual difficulties in noise and/or reverberation (Bess, 1985; Nabelek and Nabelek, 1994). A list of populations that may or may not exhibit hearing loss but often find it difficult to listen and learn is presented in Table 37.1. A prominent feature of these populations is that they all have a developmentally delayed, incomplete, or distorted knowledge of language. Because of their language deficit, these individuals cannot always use the structure of language to fill in or predict

TABLE 37.1

Populations that Find it Difficult to “Listen and Learn”

- Young children (<15 y old)
- History of recurrent otitis media
- Language disorder
- Articulation disorder
- Dyslexia or other reading disorders
- Learning disabilities
- Nonnative English
- Central auditory processing deficit
- Developmental delays
- Attentional deficits

speech information when the information is distorted or inaudible. Because of the important relationship between the quality of the acoustic signal and language development, a favorable SNR is widely recommended for children in the developmental stages of language acquisition as well as children with language knowledge deficits. The importance of a favorable SNR in the classroom was highlighted in the ANSI standard S12.6-2002 (R2010) entitled “Acoustical Performance Criteria, Design Requirements and Guidelines for Classrooms,” which stipulates an unoccupied classroom background noise level for permanent classroom structures of no more than 35 dBA. Applying the ANSI classroom acoustics standard, Knecht et al. (2002) found that most of the 32 elementary grade classrooms they studied exceeded the recommended background noise level of 35 dBA.

Reverberation

Another factor impacting on speech perception in enclosed settings is reverberation. Reverberation refers to the prolongation or persistence of sound within an enclosure when sound waves reflect off hard surfaces (e.g., bare walls, ceilings, windows, floors). RT is often stated as the amount of time it takes for a sound, at a specific frequency, to decay 60 dB after termination of the signal. For example, if a 110-dB SPL signal at 1,000 Hz takes 1 second to decrease to 50 dB SPL, the RT of that enclosure at 1,000 Hz is 1 second. Generally, RT increases as room volume increases and decreases as the amount of absorptive material in the room increases. Specifically, reverberation is decreased when surfaces in the room have a large sound absorption coefficient, or alpha (α), which is calculated as the amount of sound energy absorbed by surfaces in the room divided by the total sound energy from the signal source. The α of a room varies with the thickness, porosity, and mounting configuration of materials in a

room and the frequency of the signal (Siebein et al., 1997). Materials with an α less than 0.2 are considered to be sound reflective, whereas materials with an α greater than 0.2 are considered to be sound absorbent. For instance, a brick wall has an α ranging from 0.03 at 125 Hz to 0.07 at 4,000 Hz, whereas a carpeted concrete floor ranges from 0.02 at 125 Hz to 0.65 at 4,000 Hz. Use of absorbent materials can decrease noise by 3 to 8 dB (Siebein et al., 1997). Note that rooms with irregular shapes (e.g., oblong) often exhibit longer RTs than rooms with more traditional quadrilateral dimensions.

All rooms exhibit some degree of reverberation. Audiometric test booths usually exhibit RTs of approximately 0.2 second (Smaldino et al., 2007). Living rooms and offices often have RTs between 0.4 and 0.8 second (Nabelek and Nabelek, 1994). RTs for classrooms are usually reported to range from 0.4 to 1.2 seconds (Bradley, 1986; Smaldino and Flexer, 2012), whereas auditoriums, churches, and assembly halls may exhibit RTs in excess of 3.0 or 4.0 seconds (Nabelek and Nabelek, 1994; Siebein et al., 1997).

The presence of people in a room further affects RT. A room full of people will have an RT that is 0.05 to 0.1 second less than when it is empty (Boothroyd, 2005). RT can be (1) measured using commercially available, handheld, special-purpose reverberation meters that directly measure the decrease in intensity of a test signal as a function of time or (2) derived from the impulse response of the room. The impulse response methods require the introduction of controlled noise bursts to energize the acoustics of the room. The responses obtained from the bursts can be used to calculate nearly all standard acoustic performance measures, including reverberation.

Ideally, RT should be calculated at each octave interval from 63 to 8,000 Hz. More commonly, however, one low-, one middle-, and one high-frequency octave RT are calculated. For example, reports of RT are often obtained using the average of 500, 1,000, and 2,000 Hz (Siebein et al., 1997). Generally speaking, RT is longest at low frequencies (i.e., below 500 Hz), about equivalent in the range between 500 and 2,000 Hz, and shortest for higher frequencies (Nabelek, 1982). This is because of the fact that sound-absorptive materials have a greater α for higher frequency energy than for lower frequency energy.

Reverberation degrades speech perception through masking of the directly transmitted sounds (Nabelek, 1982). That is, reverberant speech energy reaches the listener some time after the corresponding direct sounds, overlapping subsequently presented speech sounds. This results in a “smearing” or masking of the directly transmitted speech signal. In other words, reverberation causes a prolongation of the spectral energy of the vowel sounds, which tends to mask succeeding consonant phonemes, particularly consonants in word final positions. The masking effectiveness of reverberation involving vowels is greater than for consonants since vowels exhibit greater overall power and are of longer duration than consonants.

Speech perception tends to decrease as the RT of the environment increases (Finitzo-Hieber and Tillman, 1978; Gelfand and Silman, 1979). Speech perception in adults with normal hearing is not compromised until the RT exceeds approximately 1.0 second (Gelfand and Silman, 1979). Listeners with SNHL, however, need considerably shorter RTs (0.4 to 0.5 second) for maximum speech perception (Finitzo-Hieber and Tillman, 1978). In addition, studies have indicated that the populations of “normal-hearing” children discussed previously have greater speech perception difficulties in reverberation than were traditionally suspected (see John and Kreisman, 2012, for a review of these studies).

Appropriate RTs (0.4 to 0.5 second) for persons with hearing loss are rarely achieved (Crandell and Smaldino, 1995). Crandell and Smaldino (1995) reported that only 9 of 32 classrooms (27%) examined in their study had RTs of 0.4 second or less. ANSI (2002; revised 2010) recommended an RT of 0.6 second for moderately sized permanent learning environments. Knecht et al. (2002), applying the ANSI criteria for reverberation, found that most of the 32 elementary grade classrooms they studied did not meet the 0.6-second maximum RT recommended in the standard.

Effects of Noise and Reverberation

Noise and reverberation do not occur separately in a room. In most enclosures, both noise and reverberation combine in a synergistic manner (Finitzo-Hieber and Tillman, 1978; Smaldino and Flexer, 2012). That is, the sum of the deleterious effects of noise and reverberation is greater than one would expect by simply adding these two variables together. It appears that this synergy occurs because reverberation fills in the temporal gaps in the noise. These gaps and modulations contribute significantly to speech perception for listeners with normal hearing (Hygge et al., 1992). However, reverberation eliminates these gaps, making the noise more steady state in nature and, thus, a more effective masker.

Similar to the findings obtained for noise and reverberation in isolation, research indicates that listeners with hearing loss and children with normal hearing (and even more so for children with processing-related deficits) experience greater speech perception difficulties in noise plus reverberation than do adults with normal hearing. Studies by Klatte et al. (2010) and Neuman et al. (2010) reported that elementary school-aged children show speech perception declines in the presence of typical classroom levels of noise and reverberation, and that those declines are significantly greater than those seen in adults. Notably, the participants in Klatte’s study self-reported that the noise and reverberation in the classroom did not prevent them from hearing and understanding speech. This finding suggests that the interference to understanding caused by a poor acoustic environment may be underrated by children in an informal evaluation of the classroom.

TABLE 37.2

Mean Speech Recognition Scores (% Correct) by Children with Normal Hearing ($N = 12$) and Children with Sensory/Neural Hearing Loss ($N = 12$) for Monosyllabic Words Across Various Signal-to-Noise Ratios (SNRs) and Reverberation Times (RTs)

Testing Condition	Groups	
	Normal Hearing (%)	Sensory/Neural Hearing Loss (%)
RT = 0.0 s		
QUIET	94.5	83.0
+12 dB	89.2	70.0
+6 dB	79.7	59.5
0 dB	60.2	39.0
RT = 0.4 s		
QUIET	92.5	74.0
+12 dB	82.8	60.2
+6 dB	71.3	52.2
0 dB	47.7	27.8
RT = 1.2 s		
QUIET	76.5	45.0
+12 dB	68.8	41.2
+6 dB	54.2	27.0
0 dB	29.7	11.2

Source: Adapted from Finitzo-Hieber T, Tillman T. (1978) Room acoustics effects on monosyllabic word discrimination ability for normal and hearing-impaired children. *J Speech Hear Res.* 21, 440–458.

An example of the synergistic effects of noise and reverberation on the monosyllabic word perception of children with normal hearing and SNHL is shown in Table 37.2. Note that, even at the best SNR and RT conditions (SNR = +12 dB, RT = 0.4 second), 83% of children with normal hearing did not recognize speech perfectly, and children with hearing loss performed even more poorly (60%). As the SNR became poorer or as the RT lengthened, speech perception continued to decrease. In the listening condition of SNR = 0 dB and RT = 1.2 seconds, children with normal hearing achieved a score of 30% correct, whereas children with hearing loss achieved a score of only 11%. Each of the listening situations mentioned here have been reported in numerous classroom environments.

Distance

A final factor affecting speech perception in a room is the distance between the talker and the listener. Sound is distributed essentially in three different ways in a room (Figure 37.1). The “direct” sound is the sound that travels from the speaker to a listener without striking other surfaces in the room. This

FIGURE 37.1 Components of sound [direct sound, early reflections, and late reflections or reverberation] within a room. [Siebein G, Crandell C, Gold M. [1997] Principles of classroom acoustics: reverberation. *Educ Audiol Monogr.* 5, 32–43, with permission.]

is usually the first sound to arrive at the listener since it travels the shortest path between the speaker and the listener. The power of the direct sound decreases with distance since acoustic energy spreads over a larger area as it travels from the source. Specifically, the direct sound decreases in accordance with the inverse square law, or approximately 6 dB SPL with every doubling of distance from the sound source. For example, if a speaker’s voice is 80 dB SPL at 1 m, then it will be 74 dB at 2 m, 68 dB at 4 m, and so on. Because the direct sound energy decreases so quickly, only those listeners who are seated close to the speaker will actually hear the direct sound energy.

The auditory system allows the listener to orient to the sound source using information from the first direct sound energy received. This ability is variously known as the “Haas effect” (after Helmut Haas, the first researcher to describe it in 1951), the “precedence effect,” or the “law of the first wavefront” (Haas, 1972). Using the precedence effect, the auditory system uses the physical characteristics of the head (two ears at different points in space with a barrier, the head, in between them) to determine the direction from which an incoming sound originates by analyzing the first sound energy to arrive at each ear. The precedence effect requires that the sound be discontinuous and be followed by reverberated sound energy no sooner than 1 ms and no later than about 40 ms after the first sound received (Moore, 1997). These conditions are usually met in reverberant rooms that are not very large, as sound reflecting off solid surfaces in a room typically reaches the ear first at around 30 to 50 ms after the direct sound.

Slightly greater distances from the speaker result in early sound reflections reaching the listener. Early sound reflections are those sound waves that arrive at a listener within very short time periods (approximately 50 ms) after

the arrival of the direct sound. In a typical room, most of the early reflections strike minimal room surfaces on their path from speaker to listener. Early sound reflections are usually combined with the direct sound and may actually increase the perceived loudness and intelligibility of the sound (Bradley, 1986; Nabelek and Nabelek, 1994). This increase in loudness may actually improve speech perception in listeners with normal hearing.

Early reflections are dependent on the intensity level of the original sound, the directionality of its source (tendency of the source to radiate energy in a forward direction rather than equally in all directions), and the volume and RT of the room (Boothroyd, 2005). Early reflections are increased when the room is small and highly reverberant because these conditions allow the sound to reflect off many surfaces before decaying. A source with low directionality also produces more reflected energy; that is, when sound is radiated omnidirectionally, less energy will be directed at the listener, and more energy will need to strike room surfaces to reach that listener.

As a listener moves farther away from the speaker, reverberation begins to dominate the listening environment. As discussed earlier, reverberation consists of sound waves that strike multiple room surfaces as they move from the speaker to the listener. As they strike multiple room surfaces, the sounds generally decrease in loudness because of the increased path length traveled and the partial absorption that occurs with each reflection from the room surfaces. Late reflected energy is degraded more than early reflections because this energy has traveled a greater total distance and undergone more partial absorption (especially high frequencies) subsequent to striking many surfaces (Nabelek, 1982). In addition to the change in spectrum, late reflections interfere with speech perception by masking meaningful parts of the signal.

Distance from the speaker can affect speech perception directly (Leavitt and Flexer, 1991). Specifically, speech perception tends to decrease until the critical distance (i.e., the point at which the direct and reverberant sound energies are equal) of the room is reached. The critical distance in most rooms is approximately 2 to 6 m from the speaker. Beyond the critical distance, perception ability tends to remain essentially constant unless the room is very large (e.g., an auditorium), where speech perception may continue to decrease as a function of increased distance. In general, direct sound is the major component of sound level within the critical distance, whereas reverberation is the dominant component beyond the critical distance (Boothroyd, 2005; Bradley, 1986).

These findings suggest that speech perception can be improved by decreasing the distance between a speaker and listener only if it is within the “critical distance” of the room. This explains why the simple recommendation of preferential seating in the classroom is often inadequate to ensure an appropriate listening environment. That is, teachers often

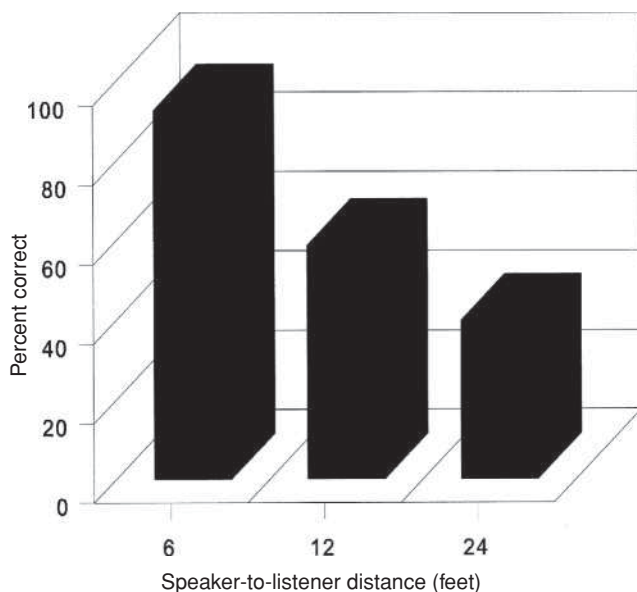

FIGURE 37.2 Mean speech recognition scores [% correct] of children with normal hearing in a typical classroom environment [signal-to-noise ratio = +6 dB; reverberation time = 0.6 second] as a function of speaker-to-listener distance. [Adapted from Crandell C, Smaldino J, Flexer C. [1995] *Sound Field FM Amplification: Theory and Practical Applications*. San Diego, CA: Singular Publishing Group, with permission.]

move around the room or turn their back to write on the blackboard, thus moving them out of the critical distance of the listener.

Crandell and Bess (1986) examined the effects of distance, noise, and reverberation on the speech perception of 20 children (5 to 7 years old) with normal hearing in a classroom environment. The classroom had an SNR of +6 dB and an RT of 0.45 second. Multitalker babble served as the noise competition. Sentences were presented to the children at distances of 6, 12, and 24 feet. Results from this investigation are shown in Figure 37.2. As can be seen, a significant decrease in speech perception occurred as the speaker-listener distance increased (i.e., 89%, 55%, and 36% were obtained at 6, 12, and 24 feet, respectively).

ACOUSTIC MODIFICATIONS OF THE ROOM

The first strategy for improving speech perception within an enclosure is acoustic modification of that environment. The most effective procedure for achieving this goal is through appropriate planning with contractors, school officials, architects, architectural engineers, audiologists, and/or teachers of individuals with hearing loss *before* the design and construction of the building. Recall that acoustic guidelines for populations with hearing loss indicate that (1) SNRs should be above +15 dB; (2) unoccupied noise levels should

not exceed 30 to 35 dBA; and (3) RTs should not surpass 0.4 second. Unfortunately, as mentioned previously, such guidelines are rarely achieved in most listening environments. One reason for the discrepancy between acoustic guidelines and actual room settings is that rooms often exhibit minimal degrees of acoustic modification. Bess et al. (1986) reported that, although 100% of the classrooms examined had acoustic ceiling tiles, only 68% had carpeting and only 13% had draperies. None of the classrooms contained any form of acoustic furniture treatment such as glides on the chair legs, projector tables of a height to keep the noise above ear level, or smaller desks to reduce the amount of sound-reflective surface in the room. Findings of Crandell and Smaldino (1995) were even less favorable.

STATUS OF CLASSROOM ACOUSTIC STANDARD

ANSI standards are reviewed on a regular cycle. A working group considered revisions and debated public comments concerning the original 2002 classroom standard. As a result of these debates and discussions, it was decided that a separate part should be devoted to issues unique to portable classrooms.

The first part of the revised standard, American National Standard Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools, Part 1: Permanent Schools (ANSI/ASA S12.60-2010), is a refined version of the 2002 standard. The major performance requirement for furnished but unoccupied classrooms is basically unchanged from the 2002 standard. The 1-hour average A-weighted background noise level cannot exceed 35 dB (55 dB if C-weighting is used) and for average-sized classrooms (with a volume less than or equal to 10,000 cubic feet) the reverberation time (RT60) cannot exceed 0.6 second (35/55 dBA/dBC) and 0.7 second if the volume is greater than 10,000 but less than or equal to 20,000 cubic feet). Among other changes are improvement of the requirements for exterior walls and roofs in noisy areas, consideration of activities close to classrooms, clarification of the definition of a “core learning space,” addition of the limit of 45 dBA for sound in hallways, clarification and simplification of measurement procedures, and addition of the requirement that if an audio distribution system is deemed appropriate it should provide even coverage and be adjustable so as not to disturb adjacent classes.

The second part of the revised standard, American National Standard Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools, Part 2: Relocatable Classroom Factors (ANSI/ASA S12.60-2010), phases in performance requirements for portable classrooms. The current standard sets a 41-dBA limit for background noise in unoccupied classrooms, which would be lowered to 38 dBA in 2013 and 35 dBA in 2017. Reverberation time (RT60) in unoccupied relocatable classrooms must not

exceed 0.5 second in classrooms with volumes of 10,000 cubic feet or less and 0.6 second in classrooms with volumes of 10,000 to 20,000 cubic feet. Both parts of the standard are available without charge from the Acoustical Society of America store (<http://asastore.aip.org>).

A third part is currently under development and will focus on control of noise from informational technology in the classroom.

As of this writing, compliance with the revised standards remains voluntary. Special effort was made during the crafting of the revision to include language so that the standard could be considered for incorporation into the International Building Code, which would make compliance mandatory for new school construction. Efforts to incorporate the standards into the 2012 building code failed; another opportunity will occur as the International Code Council will begin the 2015 building code development in 2013.

PERSONAL AND GROUP AMPLIFICATION SYSTEMS

Because of a lack of appreciation of the impact of acoustics on communication and additional construction costs, compliance with favorable classroom acoustic guidelines is often not a priority during construction. Because of this, even with subsequent room modifications, noise and reverberation levels often remain excessively high. As noted earlier, appropriate planning prior to the design and construction of a building is the most effective procedure for meeting acoustic guidelines. Because of inappropriate room acoustics, other methodologies, such as the use of assistive technologies, should be implemented. One well-recognized strategy for improving speech perception in rooms is through the use of personal or group amplification systems. Investigations of room amplification systems have shown that they can improve significantly speech perception, listening, attention, academic performance, and on-task behaviors (John and Kreisman, 2012). The goals of room amplification systems are to (1) maintain a high SNR with minimal reverberation at the listener's ears; (2) allow the signal to be modified to meet the acoustic needs of the individual(s); (3) provide wide frequency amplification with a minimal degree of distortion; (4) allow mobility for both the speaker and the listener; (5) allow listeners to hear not only the primary speaker, but also other speakers in the room as well as their own voices; and (6) accept inputs such as computers, portable digital devices, and TVs. Possible room amplification systems include personal hearing aids as well as personal frequency modulation (FM), sound field, induction loop, infrared, and hardwired systems.

Personal Hearing Aids

Numerous investigations have demonstrated that traditional hearing aids offer little speech perception benefit

in noisy or reverberant environments (e.g., Duquesnoy and Plomp, 1983; Plomp, 1978, 1986). This result should not be surprising because, although it is improving, traditional amplification technology does little to increase the SNR of the listening environment. Duquesnoy and Plomp (1983) indicated that minimal benefit occurred from personal amplification when background noise levels reached 60 dBA. Plomp (1986) reported that hearing aids offered limited speech perception benefit when background noise levels exceeded 50 dBA. A review of everyday background noise levels suggests that most environments exhibit background noise levels in excess of 50 to 60 dBA. These data strongly suggest that children wearing traditional amplification will require other technologies that enhance SNR and can augment the capabilities of the hearing aid. This situation has changed more recently, however, since several potential SNR-enhancing options for hearing aids have been introduced that may help the listener in noisy or reverberant environments. Some of these new technologies are described below (see also Chapter 38).

DIRECTIONAL MICROPHONE TECHNOLOGY

Directional microphones were first used in hearing aids in 1972. The main design characteristic of a directional microphone is a single microphone, or two or more microphones that are differentially sensitive to acoustic spectra coming from different azimuths around the head: Specifically, more sensitive to spectra from in front of the head and less sensitive to spectra coming from other azimuths (the side or back). The differential sensitivity of a directional microphone can provide an improvement in SNR if the desired signal is coming from a sensitive azimuth and the background noise is originating from a less sensitive azimuth. The advantages of a directional microphone, however, may be compromised in a reverberant room (Dillon, 2012). Both the desired sound and reflections from the background noise can arrive simultaneously at the microphone's most sensitive azimuth, thereby possibly negating the beneficial effects of the directional microphone. Many microphone technologies have been recently developed to improve on typical directional microphone performance. See Chapter 38 for a discussion of these technologies.

ADAPTIVE SIGNAL PROCESSING STRATEGIES

Most hearing aids today use some form of adaptive signal processing in an attempt to enhance the listener's SNR. Recently, some hearing aids have been designed to reduce the effects of reverberation on the hearing-impaired listener. Adaptive signal processing strategies are often based on digital signal processing algorithms and can be simple or very complex. As these strategies are refined, more consistent and larger speech perceptual improvements are likely.

HEARING AIDS MAY NOT BE ENOUGH

Although there have been striking developments in hearing aid technology, this technology alone will not maximize speech perception for the most listening challenged in noise and reverberant environments. Fortunately, there are other technologies that can be used in these situations. Some of these are described in the following section.

Personal Frequency Modulation Amplification

FM systems have a long history of use and benefit with the hearing impaired and other special populations. FM systems have also been beneficial in improving communication in large room areas (conference rooms, theaters, churches) as well as in face-to-face settings.

An example of a personal FM system is shown in Figure 37.3. With a personal FM system, the voice is picked up by an FM wireless microphone located near the speaker's mouth where the detrimental effects of reverberation and noise are minimal (i.e., the microphone placement is well within the direct field). The acoustic signal is then converted to an electrical waveform and transmitted via FM signal to a receiver tuned to the same frequency. The electrical signal is separated from the FM signal and amplified, then converted back to an acoustic waveform and conveyed to the listener. The Federal Communications Commission (FCC) initially allocated the frequency region of 72.025 to 75.975 MHz for ALDs used by individuals with hearing loss. This frequency region was subdivided into 40 narrowband or 10 wideband channels. The FCC also allocated the frequency range of 216 to 217 MHz for assistive device use, which has improved quality and reduced interference.

FIGURE 37.3 An example of a personal frequency modulation [FM] system. (Photo courtesy of Listen Technologies Corporation, Bluffdale, UT.)

Figure 37.4 shows various FM coupling strategies for use with children who have hearing loss, whereas Figure 37.5 shows various FM microphone and transmitter options. As can be seen in Figure 37.4, the signal can be presented through headphones (or ear buds) or directly to the hearing aids via induction loop or direct auditory input (DAI) technology. The FM unit can also be coupled directly to the ear via a button or a behind-the-ear transducer. Furthermore, for children with conductive or mixed hearing losses, the FM system can be coupled to a bone-conduction transducer. However, it is recommended that, for children with hearing loss, the child's personal hearing aid or aids be incorporated with the FM system whenever possible. This allows the child's personal hearing aid, which is often more electroacoustically flexible than the FM system, to more accurately meet the child's puretone sensitivity requirements. By coupling the FM system to the child's hearing aid, a high SNR is provided for the child's listening environment. That is, it is best to allow the hearing aid to do what it does best (improve hearing sensitivity) and let the FM system accomplish what it does best (improve the SNR of the listening environment). Of course, one concern with this recommendation is that it assumes that the child has a completely functional hearing aid with the option of switching between the following transmission modes: (1) FM only, for the purpose of focusing primarily on the talker; (2) environmental microphone (EM) only, for the purpose of listening to all individuals in the immediate listening environment as well as monitoring his/her own voice; and (3) FM + EM for listening to the teacher as well as other individuals in that listening environment.

The American Academy of Audiology's Clinical Practice Guidelines for Remote Microphone Hearing Assistance Technologies for Children and Youth Birth-21 Years (2008) provides a rationale and comprehensive protocol for devices that use remote microphones such as personal-worn FMs, classroom audio distribution systems (CADS), and Loop systems. These guidelines apply not only to children with all degrees of hearing loss, but also to children with normal hearing who have special listening requirements; that would include children with CAPD.

The protocol contains a core statement that addresses the complex process of HAT selection, fitting, and management plus supplements that outline procedures for fitting and verification of ear-level FM (Supplement A) and CADS (Supplement B). A third supplement for personal neck loops is under development.

The guidelines discuss regulatory considerations and qualifications of personnel as well as candidacy, fitting, and verification protocols. Monitoring and managing equipment is discussed in detail including procedures for checking systems to be sure they are working. Strategies for implementing guidelines in the schools are offered. For access to the full document, please refer to the American Academy of Audiology Clinical Practice Guidelines (2008, 2011).

FIGURE 37.4 Various coupling options for use with frequency modulation (FM) systems for children with hearing loss. [Reprinted from Lewis D. (1998) Classroom amplification. In: Bess F, ed. *Children with Hearing Loss: Contemporary Trends*. Nashville, TN: Bill Wilkerson Center Press; pp 277-298, with permission.]

For children with “normal” hearing, the signal can be presented through earphones (see Figure 37.4). It is imperative to realize that there are personal FM systems manufactured for children with hearing loss as well as FM systems developed for children with normal hearing or slight

degrees of hearing loss. Systems manufactured for children with hearing loss often offer the user a high degree of electroacoustic flexibility, including the potential for extended frequency response, high gain, and elevated OSPL90s. In addition, these latter systems usually have external controls

FIGURE 37.5 Various frequency modulation (FM) microphone and transmitter options. [Reprinted from Lewis D. (1998) Classroom amplification. In: Bess F, ed. *Children with Hearing Loss: Contemporary Trends*. Nashville, TN: Bill Wilkerson Center Press; pp 277-298, with permission.]

that allow the child to switch between the various transmission modes (i.e., FM only, EM only, or FM + EM). In contrast, systems developed for children with “normal” hearing offer limited electroacoustic variability with limited gain and reduced OSPL90s. These systems are designed simply to provide the child an improved SNR with little to no amplification. Unfortunately, we, the authors, have often seen children with “normal” hearing wearing FM devices designed for those with hearing loss. This form of FM use is alarming in that hearing loss could ensue if a child was wearing a device set for moderate gain and a high OSPL90. Thus, it is imperative that all children with “normal” hearing be fit with the appropriate FM system. In fact, since even these devices provide some gain, it is recommended that these children use an attenuated headphone when using FM technology in the classroom. An attenuated headphone will reduce the gain/output of the unit by approximately 10 to 20 dB, thus reducing the potential for over amplification. Certainly no FM system (or any other HAT) should be fit prior to the verification of that fitting via real-ear measures. The reader is directed to the American Academy of Audiology Clinical Practice Guidelines (2008, 2011) for further information regarding selection and verification of FM systems.

Personal FM systems are also available in ear-level models. The FM-only models are designed for children with auditory learning difficulties, auditory processing disorders (APDs), attention deficits, or mild conductive hearing loss. For children with hearing loss, integrated hearing aid/FM systems have been developed that provide the user with a combination of both a hearing aid and an FM system in the same ear-level device. For children with hearing within normal limits (WNL), the FM system is simply located in a behind-the-ear configuration, often in conjunction with an open earmold. An example of a system specifically designed for normal-hearing individual with difficulty communicating in noise (APDs, attention deficit disorders, or other learning disabilities) is the Phonak iSense which is offered as an ear-level device similar to a cell phone Bluetooth receiver or as an MP3 player-sized device (Figure 37.6). Unobtrusive devices like these may be more acceptable for classroom use, especially by image-conscious students.

With the continuing evolution of “boot technology,” FM receivers can be added to virtually any BTE hearing aid or ear-level cochlear implant. The FM “boot” is a miniature FM receiver that permits a transmitting microphone to be located close to a desired sound source. The FM “boot” usually attaches through a direct audio input connection to the hearing aid (Figure 37.7). High-quality sound from an associated FM transmitter is received at the ear level by the FM boot, providing clear sound from a distance and in noisy environments. Similarly, an “audio shoe” can be attached to the hearing aid, allowing an FM receiver to communicate with the hearing aid via direct audio input, similar to the FM “boot.” Audio shoes provide flexibility to attach FM receivers to hearing aids from multiple manufacturers.

FIGURE 37.6 Example of an iSense micro personal frequency modulation [FM] system. (Photo courtesy of Phonak, Warrenville, IL.)

Recently design-integrated FM receivers have become available, which replace the battery door and are internally integrated with the amplification circuitry.

Infrared Light Wave Systems

Infrared systems consist of a wireless microphone, infrared converter, and an infrared receiver. The microphone converts the acoustical signal to an electrical signal that is then transmitted to the converter. The converter transduces the electrical signal to an invisible infrared signal and transmits it to a receiver worn by the listener. The receiver (which also serves as an amplifier) contains photo detector diodes that pick up the infrared signal and transduce the infrared signal back into electrical energy. The electrical signal, in turn, is

FIGURE 37.7 Frequency modulation [FM] system coupled to a hearing aid via a wireless “audio boot.” (Photo courtesy of Phonak, Warrenville, IL.)

then changed into acoustic energy and routed to the listener via an induction loop/hearing aid telecoil setup or through headphones/insert earphones. Direct audio input can also be used by those listeners whose hearing aids have the required audio boot. Currently, the majority of infrared systems designed for individuals with SNHL use a narrowband carrier frequency of 95 kHz or a wideband carrier frequency of 250 kHz. Recently, other infrared carrier frequencies have been introduced, making system compatibility an issue. Infrared systems are often used in larger room settings, such as auditoriums, conference halls, theaters, and churches. For large rooms, such as theaters and auditoriums, arrays of transmitters must be used to ensure that all listeners are appropriately placed relative to the transmitted infrared light beams. In the home setting, infrared systems are often used for TV viewing. This application will be discussed in a later section.

For optimal sound quality with infrared systems, the listener must be in a direct line with the transmitter. Infrared light waves cannot pass through or bend around obstacles such as walls. Of course, this can be an advantage or a disadvantage. For example, in the classroom setting, it may not be practical to keep the child in direct line with the transmitter throughout the school day. That is, if other children move in front of the child using the infrared system, the signal may be blocked and not reach that child. Infrared systems also cannot be used outdoors or in highly sunlit rooms since they are susceptible to interference from sunlight. Because infrared light cannot penetrate solid barriers, this form of technology is excellent in large room settings (in which there is limited individual movement when the infrared is used) or adjacent room settings (e.g., multiplex cinemas) to avoid interference from the other rooms.

Classroom Audio Distribution Systems

Another form of SNR-enhancing technology is the CADS, formerly referred to as “sound-field amplification.” A CADS is similar to a personal FM system; however, with this form of technology, the speaker’s voice is conveyed to listeners in the room via one or more strategically placed loudspeakers (Figure 37.8).

The speaker’s voice can be transmitted using a transmitting microphone operating in the infrared, FM, or radio frequency (RF) band. The radio or light signal is sent to a receiver connected to an amplifier, and the amplified signal is distributed to loudspeakers in the room. Infrared has become the preferred technology in sound-field amplification systems because of a major limitation of FM technology. There are a finite number of FM frequencies that can be used in proximity with one another without interference. If an entire school is outfitted with CADS technology, then there may not be enough available frequencies for all of the

FIGURE 37.8 Components of a classroom audio distribution system [CADS]. (Photo courtesy of Phonak, Warrenville, IL.)

classrooms. Since infrared signals are confined by the walls of the classroom, interference with another classroom system is unlikely, and so the number of infrared systems that can operate in nearby rooms is virtually infinite. Additionally, if a second transmitting microphone (the pass-around microphone) is desired, another FM frequency is required, which further exacerbates the FM limitation. Infrared systems are typically stereo, and so there is another infrared channel available for the pass-around microphone. CADS are generally used to assist children with “normal” hearing in the classroom who require a better SNR. The objectives when placing a CADS in a classroom are twofold: (1) To amplify the speaker’s voice by approximately 8 to 10 dB, thus improving the SNR of the listening environment; and (2) to provide amplification uniformly throughout the classroom. Systems vary from compact, portable, battery-powered, single-speaker units to more permanently placed, alternating current (AC)-powered speaker systems that use multiple (usually four) loudspeakers. Typically, loudspeakers are placed on stands and are strategically placed within the classroom. However, several companies now sell loudspeakers that can be placed in ceiling mounts (Figure 37.9). In addition, portable sound-field systems that can be placed on a student’s desk and carried easily from classroom to classroom are also available (Figure 37.10). For a more detailed discussion of CADS technology options, the reader is referred to

FIGURE 37.9 Classroom audio distribution system placed in the ceiling. [Photo courtesy of Lightspeed Technologies, Tualatin, OR.]

Smaldino and Flexer (2012) and the American Academy of Audiology Clinical Practice Guidelines (2011).

Numerous investigations have shown that when CADS systems are positioned within the classroom, educational and psychosocial improvements occur for children with normal hearing sensitivity (e.g., Langlan et al., 2009; Massie et al., 2004). The original investigation concerning the effectiveness of CADS was a 3-year longitudinal project called the Mainstream Amplification Resource Room Study (MARRS) (Sarff, 1981). The project demonstrated that students with minimal hearing loss and children with learning disabilities (without any hearing loss) who received instruction using CADS made significantly greater academic gains, at a faster rate, to a higher level, and at one-tenth the cost compared with students in unamplified classrooms receiving instruction with pullout resource room intervention. Younger children tended to demonstrate greater academic improvements than older children. A number of subsequent studies have reported similar findings (see John and Kreisman, 2012, for a review of these studies).

FIGURE 37.10 Portable classroom audio distribution system (FM) on desk. [Photo courtesy of Lightspeed Technologies, Tualatin, OR.]

FIGURE 37.11 Mean speech recognition scores [% correct] of children with normal hearing in a “typical” classroom environment [signal-to-noise ratio = +6 dB; reverberation time = 0.6 second] without [dark bars] and with [light bars] classroom audio distribution (FM) amplification. [Adapted from Crandell C, Smaldino J, Flexer C. [1995] *Sound Field FM Amplification: Theory and Practical Applications*. San Diego, CA: Singular Publishing Group, with permission.]

It is reasonable to assume that these academic improvements were the result of the improved listening environment offered by CADS. For example, Crandell and Bess (1987) examined the effects of an FM CADS on the speech perception of children without any history of learning difficulty or hearing loss in a classroom environment (SNR = +6 dB, RT = 0.45 second). Bamford–Kowal–Bench (BKB) sentences were recorded in both amplified and unamplified listening conditions at speaker–listener distances of 6, 12, and 24 feet. Multitalker babble was used as the noise competition. Subjects consisted of 20 children, aged 5 to 7 years, who listened to the experimental tapes and repeated back the stimuli that they heard. Results from this investigation (Figure 37.11) showed that use of the FM CADS improved speech perception at every speaker–listener distance, particularly at 12 and 24 feet.

Obviously, the same CADS unit and loudspeaker arrangement cannot be suitable for all classrooms. Consequently, Smaldino and Flexer (2012) recommended a pragmatic approach to installing CADS equipment. The pragmatic approach takes into consideration the individual classroom, the individual teacher/teaching style(s), and the pupils in that particular classroom. For instance, if group learning is the primary mode of teaching, the goal is to have each student in the classroom perceive the teacher’s voice maximally at all times during the school day. Typically, the

larger the classroom, the more loudspeakers are needed. If angled properly, three or four loudspeakers positioned about 5 feet up on the walls, or in a ceiling array, should provide “surround” sound for all students. If the classroom has specific learning centers/areas, a loudspeaker can be positioned close to each learning center for maximum effective amplification at each of the critical locations. If only one learning center is used at a time, then the other loudspeakers can be turned off. If a small resource classroom is used, two loudspeakers can provide an even and consistent SNR throughout the area. In fact, if the room is quite small, with only a few students seated close to the teacher, even a single loudspeaker might be effective. If the classroom and class size are small, with only one teacher-instructed learning center in use at any given time, then a single battery-powered loudspeaker can be carried by the teacher to each teaching location to amplify that specific environment. In each of these cases, it is imperative that SPLs of the teacher’s voice be measured via an SLM to ensure that a uniform, 8- to 10-dB improvement in SNR has been obtained in each of the specific learning areas.

There is the potential for CADS to provide several benefits. First, CADS can provide benefit to virtually *all* children in the classroom. As previously noted, with a CADS, the teacher’s voice is transmitted to *each* of the children in the classroom via one or more strategically placed loudspeakers. Consequently, whereas CADS is usually recommended for “normal-hearing, at-risk” children, *all* of the children in that classroom receive, and subsequently can benefit from, an improved SNR. Second, CADS can provide benefit to children with mild degrees of SNHL while malfunctioning hearing aids or auditory trainers are being repaired. Logically, an increase in classroom SNR should augment, at least minimally, the perceptual cues available to these children until their own amplification systems are returned.

Third, CADS are often the most inexpensive procedure for improving speech perception in the classroom. Recall that guidelines for acoustic conditions in classrooms indicate that, for adequate communicative efficiency to occur in the classroom, RTs should not surpass 0.4 second, classroom SNRs should not be less than +15 dB, and background noise levels should not exceed 30 to 35 dBA. Extensive acoustic modification of the classroom (acoustic ceiling tiles, acoustic wall panels, or acoustically modified furniture) can be cost prohibitive for schools. Use of CADS has been shown to be extremely cost effective in overcoming poor room acoustics. An illustration of the cost effectiveness of CADS is shown in Table 37.3. If we estimate the average cost of a CADS at approximately \$1,500 and this cost is divided by all of the children in the classroom (since it will benefit the vast majority of children in the room), this equates to approximately \$60.00 per child (considering a class size of 25 students). If this cost per student is prorated over a 10-year period (the estimated average life span of a CADS), the annual unit cost per child is only \$6.00. There are additional

TABLE 37.3

Example of the Cost Effectiveness of a Sound-Field Frequency Modulation Amplification System

Approximate initial cost of sound-field unit	\$1,500.00
Cost per child in classroom (25 children)	\$60.00
Cost per child over 10-year time span	\$6.00

Source: Adapted from Crandell C, Smaldino J, Flexer C. [1995] *Sound Field FM Amplification: Theory and Practical Applications*. San Diego, CA: Singular Publishing Group.

savings of CADS that should be noted. Specifically, CADS has been shown to reduce the number of children requiring resource room assistance, which is often the most expensive assistance offered by schools (Smaldino and Flexer, 2012).

Fourth, use of a CADS does not stigmatize children, which can be the situation with auditory trainers or hearing aids (i.e., because the latter require the children to wear hardware). Children with “normal” hearing who demonstrate perceptual difficulties, particularly those in junior or senior high school, often experience negative reactions from their classmates when using personal listening systems that necessitate the use of headphones or ear buds. Because of this negative stigma, these students frequently choose to use HAT sparingly. Thus, whereas personal listening systems offer an improved SNR compared to CADS, this technology is only useful if the student is motivated to wear it. Rosenberg and Blake-Rahter (1995) reported that 93% of students who used sound-field technology in the classroom responded positively to the use of such systems. Moreover, by passing around the microphone (for oral reports, oral reading, and asking/answering questions) students reported improved classroom interaction and participation.

Fifth, teachers report positive health effects of CADS use during teaching activities. Several studies have found CADS use to significantly reduce vocal load in teachers (reducing the possibility of strain leading to vocal attrition and abuse) as well as lower stress and clearer speech (e.g., Morrow and Connor, 2011).

Sixth, CADS can be used to enhance other instructional equipment. Obviously, in the educational setting, all information presented to children should be audible. Sound-field systems can be connected to equipment such as TVs, media players, computers, and digital devices to make the output more audible in the classroom (Smaldino and Flexer, 2012).

Finally, parents willingly accept CADS. Crandell et al. (1997) reported that more than 97% of parents willingly accept the concept of sound-field technology, even if they have not seen the instrumentation used within the classroom. Presumably, parents overwhelmingly accept this technology not only because of the positive comments they hear

from children and teachers, but also because of the significant improvements in academic performance noted by their children when a CADS is implemented in the classroom.

It must be noted, however, that there are several potential disadvantages of CADS. First, CADS may not provide adequate benefits in excessively noisy or reverberant learning environments. Whereas the exact levels of noise or reverberation that may negate the benefit of CADS is a topic of ongoing research, it is reasonable to assume that, if classroom noise levels are loud enough to mask the speech signal, a 10-dB improvement in the teacher's voice may not be enough to make all elements of speech audible. Moreover CADS are not appropriate in a highly reverberant classroom because these systems do not significantly reduce reverberation and, in fact, may increase the overall RT in some rooms. Therefore, it is imperative to know the acoustic characteristics of a room (noise levels and RT) and minimize these effects with acoustic modifications *before* the installation of sound-field equipment is attempted.

Second, if the loudspeaker arrangement or number of loudspeaker(s) is not appropriate for the classroom, the level from the speakers may not be uniform throughout the classroom. In other words, the teacher's voice may be too loud for some children, whereas not loud enough for other children.

Third, CADS may not be feasible in smaller classrooms. In smaller classrooms or learning environments, it may not be possible to amplify the teacher's voice by 10 dB because of feedback problems associated with the interactive effects of reflective surfaces and speaker closeness. Although it is clear that a system that has frequent feedback will not be of benefit in a classroom setting, it is not clear whether an improvement in SNR of less than 10 dB would still warrant the installation of a system.

Fourth, the teacher and students need appropriate in-service information and follow-up support if a CADS is to provide maximum benefit in the classroom. As with any HAT, it is imperative that the teacher thoroughly understand why a CADS is being recommended and placed in the classroom prior to installation. Specifically, it is critical to make the teacher comfortable with the instrumentation by explaining its theoretical and practical applications in nontechnologic, easy-to-understand terminology. In instances when a CADS is not used effectively in the classroom, inadequate training of the teacher on its use is frequently at fault.

Fifth, CADS may not benefit children with severe recruitment or hypersensitive hearing. By increasing the level of the sound in the classroom by even 10 dB, it is conceivable that a problem could be created for these children.

Finally, classroom-based CADS generally are not portable, which could prove to be a problem if the child uses several different classrooms during the day. However, as noted earlier, individual students may now use personal portable CADS that can be carried from class to class or benefit from the newer personal systems. Also with the growing accep-

tance of this technology, school districts often equip nearly every classroom in a school with this technology, so moving from classroom to classroom is less of a problem.

RECOMMENDING PERSONAL OR SOUND-FIELD FREQUENCY MODULATION SYSTEMS

There is limited information comparing the effectiveness of CADS to personal FM systems (e.g., Anderson and Goldstein, 2004; Flexer, 1992). Clearly, the personal FM system should offer a more favorable SNR than the CADS. Anderson and Goldstein (2004), for example, found that desktop and personal FM systems (combined with personal hearing aids) provided significant benefit for speech perception in noise and reverberation whereas an infrared CADS did not.

Because CADS can be expected to provide only about 8 to 10 dB of amplification, such systems may not provide a sufficient communicative environment for students with moderate to severe degrees of SNHL. Thus, for children with greater than mild degrees of SNHL and/or severe perceptual difficulties in noise, a personal FM system may be the more appropriate amplification. In addition, these children are more likely to require an improved classroom SNR throughout their academic career (Flexer, 1992). It must be remembered, however, that many children, particularly those in junior or senior high school, may not use personal FM systems because of the potential stigma associated with such devices, necessitating the use of a CADS. If a child with more than a mild degree of hearing loss uses a CADS, it is important that some measure of efficacy be obtained to evaluate the effectiveness of the system (see "Outcomes Measures" section in this chapter).

Electromagnetic Induction Loop Systems

An example of an induction loop amplification system (one of the oldest forms of room amplification) is shown in Figure 37.12. As can be noted from this figure, an induction loop system consists of a microphone connected via hard wire (or an FM transmitter) to an amplifier. A length of wire extends from the amplifier. This wire is placed either around the head of an individual (neck loop) or around a designated area, such as in a classroom or theater. When an electrical current flows through the wire loop, it creates an electromagnetic field that can be picked up by any device using telecoil technology. A telecoil is a special device often found in hearing aids that picks up and amplifies electromagnetic signals, and, in turn, converts these signals into acoustic energy that can be heard by the hearing aid user.

Some telecoil-equipped hearing aids and listening systems incorporate digital processing in the conversion from electromagnetic energy to an analog acoustic signal. Interestingly, for years, induction loop systems have commonly

FIGURE 37.12 Components of a large-room electromagnetic induction loop system. Note that, in this figure, the electromagnetic signal is being received by listeners via telecoils located within an in-the-ear [ITE] hearing aid, behind-the-ear [BTE] hearing aid, and a portable induction receiver [for use without a hearing aid]. [Photo courtesy of Oval Window, Nederland, CO.]

been used in international conferences to provide simultaneous translation service to conference attendees. In this case, the attendee uses an induction loop ear bud or a handheld wand that contains a receiver/amplifier and speaker. The device can be turned on or simply held to the ear when language translation is required.

There are several advantages of induction loop systems over other forms of room amplification. Primarily, induction loop systems tend to be the least costly of the room amplification systems. One reason for this cost reduction is that induction loop systems do not require additional receivers as do FM or infrared systems. Induction loop systems have relatively few components and are fairly easy to install. Troubleshooting and maintenance of such systems also tend to be relatively easy.

Unfortunately, there are several limitations of such systems in classroom settings. First, recall that induction loop systems require the student's hearing aid to have a functional telecoil that is sensitive enough to pick up the electromagnetic field throughout the classroom. It is incumbent on the dispensing audiologist to be sure to include a strong telecoil in the student's hearing aid(s) if use of an induction system

is expected. Failure to do so would make this technology unavailable or less effective to the student and perhaps force the use of more expensive technology to improve the SNR. Furthermore, even when the hearing aid has telecoil technology, past investigations have indicated that many children's hearing aids often malfunction (see Flexer, 1992, for a review). Unfortunately, younger children may not be able to explain the resultant decreased acoustic signal when their telecoil is malfunctioning.

Moreover, many telecoils do not provide enough gain to significantly improve perception with an induction loop system. Variables affecting telecoil gain include the absence/presence of a telecoil preamplifier and the position and/or orientation of the telecoil within the hearing aid. In 2006, a revised inductance loop standard was published by the International Electrotechnical Commission (IEC 60118-4:2006) that specifies reference magnetic field strength levels and coverage as well as acceptable background noise levels. Induction loop systems that are installed in compliance with the standard should demonstrate more consistent volume and frequency response of the system across listeners. However, inductance systems installed without regard to the standard may provide unpredictable and possibly substandard performance.

A second disadvantage of an induction loop system is that some hearing aids do not contain the microphone (M) + telecoil (T) option. Thus, the user without such switching capability would not be able to hear individuals other than the ones closest to the microphone. For example, a student may not hear other students' questions (or even be able to monitor his/her own voice) when receiving the signal from the induction loop system.

Third, the quality of the signal and, therefore, speech perception may decrease as the listener moves away from the induction loop. That is, depending on the orientation of the telecoil within their hearing aid and/or the placement of the induction loop itself, a child seated in the middle of a room may not be obtaining as high a signal quality as the child seated next to the induction loop. Moreover, in larger rooms, the induction loop may not be powerful enough to assist all of the listeners within that enclosure.

Fourth, although the induction loop system is relatively portable, it is often impractical to move such systems to accommodate outdoor activities.

Fifth, since a hearing aid with an appropriate telecoil is required, the system cannot often be used for children with normal hearing. However, it should be noted that there are several devices on the market that use telecoil technology for individuals with normal hearing, such as handheld induction loop receivers with ear buds or a headset.

Sixth, the number of rooms in a building that can be equipped with induction loop technology is often limited because "spillover" (up to 50 to 100 feet) can occur across such systems. Spillover occurs when the electromagnetic signal generated in one room is picked up by a telecoil in an

adjacent room. Notably, modern telecoil installations have successfully decreased this problem, though it remains for older loop installations.

Finally, the quality of the signal produced by induction loop systems and picked up via telecoils may be reduced by other electrical devices in the room that produce magnetic fields (and as a result generate a 60-Hz hum or, in many other parts of the world, a 50-Hz hum). Examples of such devices include fluorescent lighting and electric power lines.

Hardwired Systems

Hardwired systems are those assistive technologies that provide a direct physical connection between the sound source and the individual. Specifically, hardwired systems are so named because a wire connects the microphone to the amplifier, and the amplifier is connected directly to the receiver (headphones, ear buds). An example of such a system is shown in Figure 37.13.

One advantage of such systems is that they provide an inexpensive approach for the amplification of sound. In addition, it is often easy for the consumer to purchase such equipment in electronics stores, through the mail, or over the Internet. Such systems have been shown to be useful for some patients with hearing loss who may not be able to use conventional amplification (e.g., those with cognitive declines, physical disabilities, and/or severe manual dexterity difficulties).

Although inexpensive, there are a number of concerns with hardwired systems. First, such systems are not specified as medical devices by the Food and Drug Administration (FDA). Therefore, there are no standards for the electroacoustic characteristics (gain, frequency response, OSPL90, harmonic distortion) of such devices. The audiologist should perform comprehensive electroacoustic and real-ear measures before placing a hardwired system on an individual with hearing loss. A second concern with hard-

FIGURE 37.13 Example of a portable assistive listening device. [Photo courtesy of Williams Sound, Eden Prairie, MN.]

wired systems is the limitation of movement for the user. That is, since each part of the device is connected via a wire, the user can only be as far from the sound source as the wire length will allow. Hardwired systems are generally not used for larger rooms such as classrooms because they require the child to sit in predetermined locations and the microphone wire can restrict teacher movement.

Advances in Digital Transmission Technology

The design options available to designers of CADS and other listening systems are improving rapidly as digital technology becomes faster, smaller, and more versatile. New systems have incorporated proprietary communication protocols and processing algorithms to replace the standard FM and infrared channels used in personal listening systems and CADS. Digitization of the signal allows for advanced signal processing, such as error correction in the transmission and dynamic maintenance of desirable SNRs.

Bluetooth is a proprietary open wireless technology standard for exchanging data over short distances using short wavelength radio transmissions in the ISM (Industry, Scientific, Medical) band from 2,400 to 2,480 MHz. Electronic devices, including mobile phones, tablets, and laptop computers, may employ Bluetooth to create personal area networks (PANs) with high levels of security. Bluetooth streaming has enjoyed some application in connecting cell phones and hearing aids. This technology has obvious potential in the CADS arena. Indeed, some CADSs that transmit using other methods do employ Bluetooth communications to interface with other devices such as media players.

Digital inductance transmission is different from the analog inductance systems discussed previously. In a digital induction loop system, the analog audio signal from the microphone is transformed into a digital stream by an analog-to-digital converter. This digital data is then coded and modulated onto an inductive carrier frequency. This coded and modulated signal is fed into a loop of wire which generates a magnetic field. The field is received by a special type of telecoil and is demodulated and decoded to retrieve the transmitted digitized signal. The digital signal is then converted back into an analog signal by a digital-to-analog converter in the receiver or hearing aid and processed as an analog signal. Digital inductance loop technology promises less interference, a wider frequency band, and more consistent signal. The downside is that the signal cannot be received by the typical analog telecoil found in modern hearing aids, and so does not enjoy universal compatibility. Whereas some manufacturers may include coils for both analog and digital inductance in their hearing aids, the simplicity, low cost, and universality of analog inductance systems argue against widespread use of digital inductance technology, at least in the near future.

COMMUNICATION STRATEGIES

Although technology can significantly improve the acoustic environment in the classroom, it should not be entirely depended on to enhance listening and learning. Active participation of the teacher and students is necessary to optimize the effectiveness of the technology. Effort should be made to compliment the technology with physical positioning of teacher–student, the use of clear speech principles, optimization of visual speech cues, and learning to listen.

Reducing Speaker–Listener Distance

In the absence of any HAT, for optimal speech perception to occur, the listener needs to be in a face-to-face situation and in the direct sound field of the talker. Recall that speech perception can only be improved within the critical distance of the room. Beyond the critical distance, speech perception ability tends to remain constant. Therefore, in any listening environment, the speaker–listener distance should not exceed the critical distance of the room. Unfortunately, the critical distance in many rooms occurs only at close speaker–listener distances. To remain within the critical distance of a room, restructuring of the room dynamics may need to be considered. For example, small group instruction (where the speaker addresses one small group at a time) should be recommended over more “traditional” room settings (where the speaker is situated in front of numerous rows of students). Crandell et al. (1997) reported that speech perception scores of children were very good or excellent when such small group instruction was used in a classroom.

Clear Speech

Clear speech procedures may also facilitate speech perception in many enclosures. Clear speech refers to a process in which the speaker focuses attention on clearer pronunciation, while using a slightly slower rate of speech and a slightly higher intensity—a speech style used by most newscasters. Several investigations have demonstrated that clear speech can significantly improve speech perception in noisy and reverberant environments (e.g., Schum, 1996). For example, Payton et al. (1994) demonstrated that, in poor listening environments, the average improvement in speech perception when clear speech was used was 20% for listeners with normal hearing and 26% for listeners with SNHL. It is reasonable to expect speakers, such as teachers, to learn clear speech procedures easily because talkers can be trained to produce clear speech continuously after a minimum amount of instruction and practice (Schum, 1996).

Optimizing Visual Communication

Face-to-face communication at relatively short speaker–listener distances also aids the listener with hearing loss by

maximizing speechreading opportunities. Optimal speaker–listener distance is approximately 5 to 10 feet. Speechreading ability tends to decrease significantly at 20 feet. Several investigators have also reported that speechreading benefit increases as a function of decreasing SNR (Erber, 1979; Middleweerd and Plomp, 1987). That is, listeners rely more heavily on visually transmitted information as the acoustic environment becomes more adverse.

Improving Listening Strategies

Listening (as opposed to hearing) refers to the ability to detect, discriminate, identify, and comprehend various auditory signals. Listening is a major component of the communication process. Listening comprises 45% of daily communication for adults, whereas school children spend as much as 60% of the school day in the process of listening (Rosenberg and Blake-Rahter, 1995). Research has demonstrated that listeners who experience difficulty at any level of the listening process will find it more difficult to use auditory information in an efficient manner. Despite the importance of listening in communication, the process of listening is rarely taught to individuals with hearing loss (Rosenberg and Blake-Rahter, 1995). Erber (1979) emphasized the importance of a thorough audiologic and developmental speech assessment to determine the placement of a student on an auditory skill development continuum. This continuum, which includes sound awareness, sound discrimination, identification, and comprehension, forms the basis for the listening training activities that must be taught specifically to children with hearing loss but that develop normally without training in normal-hearing children. It is important to recognize, however, that listening training may also be necessary when new amplification devices are fit (because of the new signal characteristics) and if room acoustics reduce the intensity or distort the quality of the acoustic signal. It is also noteworthy that some normal-hearing children, such as those with APDs or nonnative speakers, may also benefit from listening training.

TECHNOLOGIES WITH APPLICATION TO INDIVIDUALS WITH HEARING LOSS/AUDITORY PROCESSING DEFICITS

Many new technologies have recently become available that can assist individuals with hearing loss; many of these same technologies are also useful for people with normal hearing who have processing-related difficulties and/or find themselves in adverse listening environments. It is beyond the scope of this chapter to overview all of these technologies. A web search will provide the interested reader with access to this ever-expanding list of assistive technologies. We have selected for review a cross section of prominent and

promising technologies. We realize that as technology has advanced, the line between broadcast media devices, telephony devices, and computers has blurred; however, we still think it helpful to distinguish between the technologies as much as possible for the purpose of discussing the available HATs.

Reception of Broadcast Media

Individuals with SNHL often have a difficult time hearing and/or understanding the auditory broadcast over the TV or radio. As was outlined in the first section of this chapter, a number of factors, such as distance from the sound source, background noise, and poor room acoustics, can interfere with the signal to those with hearing losses. Hearing aids alone often do little to reduce background noise or overcome poor room acoustics and thus may not be a viable solution. Modern TVs often have multiple audio-visual inputs and outputs, which make utilizing assistive technologies much easier than in the past. Assistive technologies, such as those discussed for large rooms (e.g., infrared systems), can also be used to link broadcast media to the individual with hearing loss and therefore effectively improve the quality of the audio signal. The use of assistive technologies to improve reception of the TV or radio can be accomplished with or without the use of a hearing aid. For example, one of the more popular TV listening devices (Figure 37.14) sends the audio signal to a receiver worn by

FIGURE 37.14 Personal infrared assistive device used to improve television listening. [Photo courtesy of Sennheiser, Old Lyme, CT.]

the user via infrared technology. The audio signal of the TV or radio may also be enhanced by coupling the individual's hearing aids to the receiving device through DAI or by an induction neck loop. Personal sound-field FM systems can also be useful. In this case, the transmitting microphone is placed close to the TV or radio speaker and the receiving speaker amplifier is placed close to the listener. The increased volume and reduction of room acoustics improve sound reception. Additionally, TVs with audio output jacks can be connected to a stereo receiver. The listener can then plug earphones into the phone jack of the receiver and use the volume control and frequency adjustments to provide an amplified TV signal. If the listener's hearing loss is too great for the use of stereo headphones without feedback, then an inductance neck loop can be connected to the stereo receiver and the signal picked up by the telecoil in the listener's personal hearing aid. Most hearing aid companies now offer proprietary TV devices that plug into an audio out jack of the TV and wirelessly transmit the signal to the hearing aids, usually via a small streaming device that is worn by the listener.

Captioned Media

For the individual with hearing loss (or an individual for whom English is a second language), TV viewing can be enhanced with various forms of captioned media (closed, real time, and open). With closed captioning, the text of the broadcast is encoded in the TV signal and must be recoded to appear on the TV screen. Closed-captioned words appear in white uppercase format and are encased in a black box that usually appears in the lower portion of the TV screen, although recent innovations allow the captions to vary in location so as not to block any other text or the talker's face. A TV with a decoder chip or a separate decoder box is necessary to view the closed captioning. As a result of the Television Decoder Circuitry Act of 1990 (PL 101-431), all TV sets more than 13 inches must come equipped with a decoder chip so that individuals can have access to closed captioning when available.

Real-time captioning is available for live broadcasts such as the news and sporting events. In real-time captioning, a trained stenographer-captioner follows the audio signal and, with a delay of 2 to 3 seconds, converts it to text that appears on the TV screen. Recently, voice-to-text technology has become refined enough to use as a real-time captioning device. Using sophisticated voice recognition technology, these devices hold promise of directly converting the speech signal into text that can be read by the individual with hearing loss.

Another form of captioned media is open captioning. With open captioning, the captions are permanently placed on to the video and always available to the viewer with no decoder needed. Open-captioned letters are usually white with a black shadow or border. Some movie theaters now offer open caption viewings of certain movies at given times.

A new captioning technology promises to significantly improve access for people who are deaf or hard of hearing. Discrete personal captioning uses state-of-the-art electronic, optical, and voice recognition technologies to provide text in a “heads-up” display (similar to that found in fighter aircraft) built into a pair of glasses. A text readout seems to float in the air about 18 inches in front of the wearer.

Telephony

HEARING AID TELECOILS, REHABILITATIVE TECHNOLOGIES, AND TELEPHONE USE

A telephone induction pickup coil, or “telecoil,” picks up the electromagnetic leakage from the telephone receiver. The signal is then amplified, transduced into acoustic information, and delivered to the individual’s ear. Improved telephone communication is obtained because the hearing aid microphone is turned off, thus reducing the level of the background noise. Some hearing aids will also simultaneously turn down the gain of the hearing aid on the opposite ear, further reducing background noise. In addition, the frequency response of most telecoils tends to be smoother than when the hearing aid is coupled acoustically to the telephone. Unfortunately, because of the miniaturization of hearing aids, many amplification systems are not equipped with telecoils at all or strong telecoils because of size restrictions. It is our view that hearing aids, whenever possible, should be equipped with telecoil technology because their use far exceeds telephone communication. It must be noted that there is great variability in telecoil power and frequency responses across hearing aids and even within hearing aid companies. Thus, we recommend that real-ear measures be conducted with telecoils to ensure their proper function. Certainly, whenever telecoil technology is implemented into a hearing aid, it is imperative that the patient be instructed concerning its proper use.

In addition to telecoil technology, a number of rehabilitative technologies can be used in conjunction with telephone use to improve communication in individuals with hearing loss. For example, one device consists of a disc-shaped microphone that attaches to the telephone handset. The signal is then routed into the listener’s personal hearing aid via DAI (thus avoiding the use of the telecoil). Often, the use of individual personal rehabilitative technologies, particularly with DAI, can be beneficial in environments where electromagnetic interference (e.g., computers, fluorescent lights) is high.

TELEPHONE AMPLIFIERS AND ACCESSORIES

Telephone amplifiers and accessories designed specifically for individuals with hearing loss are readily available. Amplified phones offer an array of built-in features, such as hearing aid-compatible headsets, amplifiers with up to 50 dB of amplification, a volume control, and signal process-

ing to maximize comfort and clarity; high-output adjustable ringers; a tone control to adjust the frequency response of the headset to improve intelligibility of words; background noise suppression circuitry to remove unwanted background noise; and visual ring indicators such as a strobe light. Many also have speakerphone capability. Stand-alone in-line amplifiers provide some of the features of the dedicated amplified phone but can be used with many modular unamplified phones.

Cell phone amplifiers are available that can be used with external headsets or earphones. The amplifier plugs into the 3.5-mm audio adapter of the cell phone, and the external headset then plugs into the amplifier. There are also Bluetooth devices that can interface with the cellular phone and be connected via DAI to the hearing aid (see section on Bluetooth). Also, portable telephone amplifiers can be strapped onto a nonamplified telephone to provide up to 30 dB of amplification.

TELECOMMUNICATION DEVICES

Individuals with severe to profound hearing losses may not be able to use the telephone effectively, even with amplification devices. In addition, there are individuals with severe speech impairments or extremely poor speech perception who may not be able to use a conventional telephone. For these individuals, telecommunication devices for the deaf (TDDs), also called teletypewriters (TTYs) or text telephones (TTs), may be required (Figure 37.15). Note that the preferred term at this time by the deaf community is TTY. Using typewriter technology, the TTY transmits a typed, visual message (in Baudot code) over standard telephone lines. The typed communication either appears on an LED display or can be printed on paper. Braille TTYs are also available to those with visual as well as hearing difficulties.

FIGURE 37.15 A telecommunications device for the deaf [TDD] that consists of a keyboard and a telephone cradle on top. [Photo courtesy of Silent Call, Clarkston, MI.]

The maximum rate of transmission is approximately 60 words per minute, depending on the sender's typing skills. For a TTY conversation to take place, both the sender and the receiver must have TTY instrumentation that is compatible. Recent evidence indicates that users of TTYs that are connected directly to the telephone network experience more successful conversations with less message interference than with acoustic coupling (Spicer et al., 2005). The Americans with Disabilities Act (ADA; PL 101-336) mandates that all emergency access services have TTY accessibility. Unfortunately, it appears that many agencies and businesses do not use TTYs effectively. A TTY system can be modified to communicate with a computer (i.e., one individual uses a TTY, whereas the other individual receives/sends transmissions on his/her computer).

MOBILE PHONE

The mobile phone has become a pervasive multimedia platform for communication. Because these phones can connect to the Internet, much of the assistive communication technology such as text messaging, e-mail, video conferencing, and Bluetooth interconnectivity is available in a highly compact and portable form. Downloads of text and video information to mobile phones from the Internet are already possible, and the capabilities of these phones are sure to expand in the future.

Federal Communications Commission Rules Governing Telephony for the Deaf and Hard of Hearing

A common complaint of listeners with SNHL is difficulty understanding speech over the telephone. The Hearing Aid Compatibility Act of 1988 (HAC Act) requires that the FCC ensure that all "essential" telephones and all telephones manufactured or imported for use in the United States after August 1989 are hearing aid compatible. FCC rules require that phones subject to the HAC Act (1) produce a magnetic field of sufficient strength and quality to permit coupling with hearing aids that contain telecoils; and (2) provide amplification with a volume control so the phone can be effectively used by individuals with hearing loss (with or without hearing aids). In 2003, the FCC adopted rules to make digital wireless telephones compatible with hearing aids and cochlear implants. Beginning September 8, 2012, the FCC required nearly all wireless service providers and handset manufacturers that offer three digital wireless handsets in the United States to offer at least one model that is compatible with hearing aids.

Communication through Video Conferencing

Video conferencing technology has become common for business situations, distance teaching and learning, and

interpersonal communication. With such technology, a camera-based system is placed on the computer or TV. Both the caller and the person receiving the call must have the camera-based system and supporting software to use this technology and thus receive both the audio and video signals. Systems are also available that provide for full motion video support for sign language. Keyboard-produced text and TDD capabilities are also available options.

RECENT CROSSOVER TECHNOLOGIES WITH APPLICATION TO THE DEAF AND HARD OF HEARING

Multiuse Handheld Devices

Over the past several years, handheld multiuse devices (i.e., smart phones) have become commonplace. For example, a single device may serve as a cell phone with video screen, text messenger, and digital camera. In addition, the device can access the Internet, send and receive e-mail, receive Internet broadcasts or webcasts, and contain technology that enables it to communicate with several other electronic devices at any given time. Although these features may be integrated within a single device, they are described individually in greater detail in the following sections.

BLUETOOTH

Bluetooth is a short-range wireless technology that can connect a wide variety of electronic devices. Bluetooth operates in the 2.4- to 2.5-GHz frequency range and has a range of approximately 10 m. Because of the high frequency range and the method of transmission, Bluetooth requires only very small antennas and allows several devices to be connected simultaneously. Thousands of products use this technology. One HAT product that has been made commercially available recently is an ear-level device that couples to BTE hearing aids through the DAI port. The device can then communicate with other Bluetooth-enabled devices, such as cell phones, TVs, and computers. Most hearing aid companies now offer a gateway device that will receive a signal to any Bluetooth device to which it is paired, and then wirelessly transmit that signal to the hearing aids. For example, users can hear their cell phones ring through a hearing aid, push a button to activate the Bluetooth gateway device, and receive the phone signal through the hearing aid via the Bluetooth gateway device. Furthermore, the user's voice is picked up via a microphone built into the gateway device, which is relayed to the cell phone. The device automatically ends the connection when the call is finished. Essentially, the cell phone itself is used only for dialing phone numbers. Individuals whose hearing aids do not have DAI can still couple their hearing aids to cell phones by plugging a

compatible neck loop into the audio output jack of the cell phone.

TEXT MESSAGING/TEXT PAGER

These technologies enable individuals to send and receive text messages between handheld devices, such as cell phones, or from computers to cell phones. Text messaging is a popular form of communication among individuals with and without hearing impairment. As text-based communication continues to gain popularity, it may assist in breaking down barriers in communication between individuals with hearing loss and those with normal hearing.

RELAY SERVICES

Telephone relay services (TRSs) are available to the TTY user who needs to communicate with a non-TTY user. With the TRS, the individual using the TTY types a message to a state-designated central telephone number that is picked up by a normal-hearing operator and, in turn, transmitted verbally to the non-TTY user. The non-TTY user can then respond to the TTY user by speaking to the relay operator, who, in turn, relays the message via written text to the TTY user. Thus, with TRSs, individuals with normal hearing ability can telephone individuals who use TTYs.

Video relay allows a person who is deaf or hard of hearing to make a call to a traditional voice phone number but allows them to use sign language transmitted via a camera or video phone instead of text. When using a computer, the person goes to the appropriate website, enters the number to be called, and can then begin the conversation. An interpreter watches the person signing and verbally translates to the person being called. Responses from the person being called are then translated into sign language by the interpreter.

Relay calls can also be placed using certain instant messenger services or multiuse handheld devices. Federal Relay Conference Captioning (RCC) is also available. This government-mandated service allows individuals with hearing loss to participate in conference calls with users on voice lines by providing services including video relay and live captioning. The caption can then be read on any computer with an Internet connection. This service is free to all federal employees.

COMMUNICATION TECHNOLOGIES AND THE HOME COMPUTER

Home computers (including desktops, laptops, and tablets) have enabled people with hearing loss (and people with normal hearing) to have better access to communications. Technologies available via a home computer with network/Internet capabilities include electronic mail (e-mail), instant

messaging (IM), video conferencing, audio broadcasts (webcasts), and videos. E-mail allows a user to send and receive text messages that, in turn, can also have attachments of photos or electronic files. These messages can be sent and received almost instantly, and most can be of unlimited length. E-mail allows users to sort and store messages sent to them. Limitations of e-mail include spam (receiving unsolicited advertising via e-mail) and the spreading of computer viruses through e-mail.

Unlike e-mail, IM allows two computer users to communicate in real time via text messages sent through the IM software. Therefore, IM is more conversational in nature than e-mail. Many people with hearing loss are using IM more often because IM is faster than TTY. IM conversations can also be saved to an electronic file and can be printed via the computer printer.

Web telephone/videophone website use has increased in popularity recently. Generally, a broadband Internet connection and a computer microphone and speakers are required for the use of such websites. Potential advantages of this technology include high-fidelity reproduction of sound compared to standard phone lines and the ability of each user to raise or lower the volume of the received message using the computer's speakers or internal volume control. One advantage of using computer speakers is that the volume can be adjusted more readily, and unlike standard telephones, the signal should not interfere with the use of hearing aids. The disadvantage of external speakers is that the other person may hear an echo of his/her own voice if the speaker volume is too high. This problem can be alleviated for the most part by using headphones or induction neck loops connected to the headphone slot.

Webcasts, or Internet broadcasts, enable the relatively low-cost distribution of prerecorded audio or video files for download to the computer, portable digital audio devices, and many mobile telephones. Certain websites also offer the option of automated closed captioning for the videos, although the technology for doing so is still not perfected. In an educational setting, netcasts webcasts may be used to reinforce classroom teaching and may enable individuals with hearing loss to access the material at their own speed. Debevc and Peljhan (2004) reported that adults and students who had access to web-based lectures performed better than adults using traditional lectures.

ONLINE COMMUNITIES

Online community websites are now ubiquitous. These websites allow users to post messages, pictures, and videos, as well as IM and e-mail. Although the IM is synchronous, most of the other features allow for asynchronous communication, meaning that messages and responses are posted by people at different times. Online communities have largely replaced electronic chat rooms and discussion boards, although these forms of online communications

still exist and have also been incorporated into online educational platforms.

ELECTRONIC CHAT ROOMS AND DISCUSSION BOARDS

Internet chat rooms and discussion boards have become a very popular means of communication. Chat rooms can be formed based on a discussion topic and can be specially created for communication among individuals who are deaf or have hearing loss. The chat can be synchronous, meaning that everyone is online and communicating simultaneously. The discussion boards are asynchronous, meaning that messages and responses are posted by people online at different times. Both chat rooms and discussion boards can be used to reinforce classroom teaching or for distance education.

ALERTING SYSTEMS

For a person with hearing loss, common appliances that rely on sound to convey a signal to the user may not be useful. The term “alerting systems” is used to describe devices that can focus the user’s attention and/or indicate the presence of sounds in the environment through one of three modalities: Auditory (e.g., amplified or lowered pitch signal), visual (e.g., turning on/off lamp, strobe light, bright incandescent light), or vibrotactile (e.g., devices that vibrate, such as pocket pagers and bed shakers, or increases in airstream, such as a fan). These devices are widely available and are often thought to be appropriate for individuals with profound degrees of hearing loss; however, many such devices may also be beneficial for persons with milder degrees of hearing loss. For example, many persons with high-frequency hearing loss can exhibit difficulties hearing the microwave timer, doorbell, or telephone ringer, particularly if they are not in the same room as that device.

Direct Electrical Connect Systems

Direct electrical connect systems are interfaced permanently with, and activated directly by, the electrical system of the sound-activating device. For example, the alerting device may be connected directly to the telephone, alarm clock, microwave timer, or doorbell. When the device is activated, a visual, auditory, or tactile signal is transmitted to the individual. Generally speaking, such devices, although highly reliable for alerting purposes, are not portable.

Sound-Activated Systems

Sound-activated systems use a microphone to detect the presence of a particular environmental sound and relay the signal to an alerting system. For example, a microphone

placed near the microwave or oven timer can inform the individual via an alerting system, such as a body-worn vibrotactile device or on/off activation of a lamp, when that timer has been activated. Another common example of this technology is the placement of a sound-activated microphone near a baby crib so that parents can be informed when the child cries or makes noises. Sound-activated systems generally have sensitivity settings to reduce the possibility of other environmental sounds activating the system. Sound-activated systems are portable and therefore may be advantageous to an individual with hearing loss who is traveling. Recent technologies have been developed that allow the user with hearing loss to monitor important traffic noises (such as emergency vehicles and car horns) when driving.

Induction-Based Systems

Induction-based systems use the electromagnetic field emitted from an activated electrical device to trigger a separate alerting device. An electromagnetic detector is typically placed via suction cup onto an electrical device such as a telephone. When the phone rings, the electromagnetic field that is generated triggers an alerting device such as a flashing table light. Although such systems are easy to use and portable, incorrect placement of the detector can cause the system to malfunction.

Service Animals

In addition to traditional alerting systems, an individual with hearing loss may also choose to use a professionally trained service animal, such as a “hearing dog,” to indicate important environmental sounds. Service animals are trained to attract the attention of the person with hearing loss when particular sounds occur (such as a phone ringing) and to lead them to the source of the sound. Restrictions on the use of service animals vary by state, but many establishments welcome service animals such as hearing dogs and guide dogs for individuals with loss of vision.

ASSESSING COMMUNICATION DEFICITS AND NEEDS

The aural rehabilitation process is designed to minimize the communication deficits caused by a hearing loss. The first step in this process is a thorough evaluation of the audiologic dimensions of the hearing loss. In addition to the usual comprehensive audiologic tests, which include pure-tone and speech audiometry and immittance measures, the individual’s speech perception ability (using stimuli such as nonsense syllables, monosyllabic words, and sentences in quiet and noise) and central auditory processing capabilities should be evaluated. These procedures are discussed

elsewhere in this handbook. Furthermore, a communication disability and needs assessment is a crucial component of the rehabilitative process. On the basis of the audiologic and communication assessments, audiologists can provide counseling regarding technologies and/or therapies that will minimize the impact of the individual's hearing loss in everyday activities. However, some audiologists may find the prospect of evaluating communication disability daunting. Tye-Murray (2009) discussed four possible issues underlying the difficulty associated with the communication needs assessment. First, communication handicap varies as a function of the communication setting and communication partner. For example, an individual may have a significant handicap in some situations when talking with unfamiliar people, yet have little handicap in quiet situations with a well-known family member. Second, handicap can vary as a function of the topic of conversation. A person may have no handicap when discussing the weather but may experience great obstacles during a discussion involving an unfamiliar topic. Third, handicap does not always manifest itself during conversations between the clinician and the individual with hearing loss. The office assessment is merely a snapshot in time that may not be representative of real communication ability or disability. Fourth, communication handicap is a construct made up of many dimensions; no single assessment measure is likely to capture all of these dimensions. As a result, several assessment measures should be taken to obtain a more comprehensive overview of an individual's communication handicap in various everyday life situations.

A number of procedures have been developed to quantify the extent of communication handicap imposed on the individual as a result of hearing loss. The same procedures can be used to monitor and document the effectiveness of interventions in reducing the communication handicap. Tye-Murray (2009) presents five general procedures. The first of these is the interview process, wherein specific information about a person's hearing problems is elicited through the use of informal or formalized questions. One of the problems with the interview process is that it is hard to quantify the responses of the individual with hearing loss. However, an interview approach called the Client Oriented Scale of Improvement (see Dillon, 2012) requires the interviewees to rank order the five listening priorities they wish to address through the intervention process. The quantification of these problems can then be used as a measure for assessing whether the intervention has been effective. If the initial problem areas are no longer considered to be problematic or if the rank ordering changes to a lower ranking, the intervention might be considered to be successful.

A second procedure is the use of a questionnaire. Many hearing handicap questionnaires have been developed and can be quite useful if the questions match the everyday listening situations of individuals with hearing loss. A hearing

handicap scale that is well matched to the individual can provide important information concerning the effectiveness of intervention. If after the intervention the individual reports a reduced hearing handicap, then the intervention can be considered effective.

A third procedure to evaluate communicative handicap is a daily log or diary, wherein the individual provides quantitative information about his/her communication difficulties. These logs provide an ongoing self-report of changes that occur as a result of the intervention and can be used to assess the intervention's effectiveness. In addition, in reporting use of communication strategies, the client may actually become more skilled at using the recommended strategies. For this reason, daily logs can be used as part of a training procedure.

A fourth procedure, group discussion, can also serve as an effective measure of communication handicap. The interactions that occur during a group discussion between persons with hearing loss often force individuals to reflect on their communication problems and possible solutions. Over time, group interactions can provide information and psychosocial support and thereby empower individuals to accept their hearing loss and encourage them to explore technologies that may maximize their potential.

The fifth procedure is called structured communication interactions, in which conversations between the individual with hearing loss and the evaluator are simulated to reflect communication situations typical for that person. The effectiveness of intervention can be assessed directly by simulating difficult communication situations with and without HAT.

Extended audiologic and communication handicap evaluations allow the audiologist to have a comprehensive picture of the auditory capabilities and communication needs of the client. This information is integrated into the counseling phase, and a rehabilitative plan is determined. Typically, such a plan would involve consideration of hearing aids, assistive devices, and a communication strategies training program (Tye-Murray, 2009). All three facets should be considered and integrated for communication handicap intervention to be most effective. Unfortunately, too often only one of the three options, the hearing aid evaluation, is suggested and implemented.

The technology requirements for effective communication for a particular individual will vary depending on the setting and the type of communication (e.g., face to face, over the telephone). The outcomes can be assessed through the assessment procedure as discussed earlier.

Communication Strategies Training

As a result of the audiologic and communication assessments, recommendations can be made regarding appropriate hearing aids and assistive devices. However, to have maximum impact on the communication handicap, the person must

also be provided with the means to take ownership of his/her own communication environment and to have the psychosocial and behavioral tools to minimize miscommunication in everyday listening situations. The process by which the client is provided these tools is known as communication strategies training and is an important component of an overall audiologic rehabilitation plan. Tye-Murray (2009) conceptualizes communication strategies training as being composed of three stages. In the formal instruction stage, the client is provided with information about various types of communication strategies and appropriate listening and speaking behaviors. Included are presentations describing facilitative strategies (tactics a person can use to improve the reception of a message by varying the message, the speaker, the environment, and/or the listener), receptive and expressive repair strategies (tactics a person can use when a message is not understood), and instruction in using clear speech (a speaking technique for making speech highly intelligible).

The second stage is called guided learning. In this stage, the professional creates simulated real-life communication situations in which the strategies acquired in the formal instruction stage can be practiced. The audiologist provides feedback and tips to clients as they progress through the simulations.

The last stage requires the client to engage in prescribed real-world listening situations and to answer prepared questions regarding the effectiveness of the information learned in stage one and practiced in stage two. The reader is referred to Tye-Murray (2009) for a complete description of the communication strategies training component of the rehabilitative process.

OUTCOMES MEASURES

Whenever HAT is recommended, it is important for the audiologist to identify and quantify the effects of the recommendation. Not only is this documentation often required by third-party payers, but also, as a profession, feedback for our recommendations is a means to establish best practices. In the realm of hearing aids, there are a number of approaches to measuring rehabilitative outcomes (see Weinstein, 2000, for a review). Tools for measuring the efficacy of technology in the classroom are also available (Smaldino and Flexer, 2012). These and other measures can be used to document the changes that occur as the result of recommending or fitting an assistive device. For example, the Client Oriented Scale of Improvement could be used with assistive technologies as easily as hearing aids for which the assessment measure was designed. In either case, the client is required to list situations in which hearing help is needed and rate the difficulty experienced in each situation. After intervention (the fitting of a hearing aid or other HAT), the list is reviewed and re-rated to document changes as a result of the intervention.

REHABILITATION TECHNOLOGY IN THE AUDIOLOGY SETTING

Although this chapter has addressed the many advantages that assistive technologies can provide to listeners with hearing loss, unfortunately few audiologists are actively dispensing such technologies. Consumers also demonstrate a much lower knowledge level for HAT than for hearing aids or cochlear implants. To some extent this may be due to the fact that HAT is a less profitable venture for audiologists in private practice than are conventional hearing aids. It seems apparent that audiologists underrate the importance and benefits of assistive technologies. This is unfortunate because there is ample evidence that integrating assistive technologies into rehabilitative plans can be very effective when hearing aids are not enough (e.g., Wayner, 2004).

Consumer Acceptance of Assistive Technologies

Audiologists themselves must first be convinced of the value of assistive technologies in the overall rehabilitative plan for a client. Until now, great emphasis has been placed on the proper fitting of hearing aids, whereas little attention has been given to the benefits of HAT for addressing the rehabilitative needs of the individual with hearing loss. Therefore, the first step in creating consumer acceptance of these technologies is the development of a philosophy of rehabilitation that includes a multidimensional assessment of the individual's auditory and communication capabilities and needs. An outline of how this can be accomplished has been presented in this chapter. Within the context of the comprehensive rehabilitative plan, the value of assistive technologies is self-evident because these technologies are an integral part of the services provided in the rehabilitative plan for an individual, along with hearing aids and communication strategies training.

Outside of a carefully constructed rehabilitation program, there is a need to engage in activities for enhancing consumer acceptance of assistive technology. The same negative stigmas that are attached to hearing loss and hearing aids are likely to be attached to assistive devices and likely will occur to an even greater extent because assistive technologies are typically more noticeable and intimidating than a hearing aid. Sutherland (1995) details the following strategies for increasing consumer acceptance of assistive technologies: (1) Educating consumers about technical devices, including their strengths and limitations; (2) training consumers to use technical devices; (3) helping consumers to make informed choices; (4) providing consumers with support; (5) encouraging experienced consumers to help others who are just learning about technical devices; (6) empowering consumers by working closely with them as part of a team or partnership; and (7) aligning with consumers to advocate for better laws and services and for universal accessibility for

people with hearing loss. Wayner (2004) describes how assistive devices can be integrated into a hearing aid practice to increase awareness and acceptance. Wayner (2004) describes how an assistive device demonstration center was established in the classrooms where hearing aid orientations were performed. In this way, devices could be demonstrated in conjunction with hearing aids in difficult listening situations when hearing aids alone might not provide enough assistance. In a study of the effectiveness of the integrated center, Wayner (2004) reported that 86% of those surveyed found the center helpful and reported satisfaction with learning about assistive technologies and having the opportunity to try the technologies. In the same study, 75% of those purchasing HAT used the technology regularly and reported benefit in conjunction with their hearing aids or cochlear implants in daily activities. It is clear that integration of assistive technologies into our rehabilitative services is a best practice goal for our rehabilitative efforts. To accomplish this best practice goal, higher priority must be given to the evaluation, selection, and dispensing of assistive technologies.

LEGISLATION FOR HEARING ASSISTANCE TECHNOLOGY

During the 1980s and 1990s, the civil and education rights of individuals with disabilities were strengthened, and the important role that assistive technologies have in improving the quality of life of disabled individuals was recognized. Since 1988, federal laws specifically addressing the HAT needs of persons with disabilities have been passed.

Beginning in 1975 with the Education of All Handicapped Children Act and with the implementation of the Americans with Disabilities Act (1990) and, most recently, the 2004 reauthorization of the Individuals with Disabilities Education Act of 1997, there has been a sustained interest in removing barriers for persons with hearing loss and other disabilities. One of the ways that acoustic barriers to communication can be diminished is through the use of assistive listening technology. These technologies have been included as a reasonable accommodation under many federal laws (Education of Handicapped Children, P.L., 94-142, 1977; Education of Handicapped Children, P.L., 99-457, 1986; Education of Handicapped Children, P.L., 101-476, 1990; Individuals with Disabilities Education Act, 1997, 2004). For example, in rooms that require permanently installed assistive technologies, the availability of such technologies must be posted using the international symbol of access for persons with hearing loss (Figure 37.16).

HEARING ASSISTANCE TECHNOLOGY RESEARCH NEEDS

There is an ever-expanding need for research concerning assistive devices. This need is driven by the federally enforce-

FIGURE 37.16 International symbol of access for individuals with hearing loss.

able standards for accessibility and accommodations for hearing loss in the Americans with Disabilities Act, as well as an awareness on the part of many audiologists that, by including assistive technology in their rehabilitative plans, they can significantly improve the quality of care provided. Assistive technologies are constantly changing. As a result, one of the biggest research needs in the field of audiology is the development of protocols that can better evaluate the needs of individuals with hearing loss and a method for efficiently matching needs to technologies.

In addition to developing tools for the selection process, we must also have tools that allow us to measure the efficacy of the technology more accurately. Since any one technology might be used in a variety of situations, it is important to measure whether that technology is equally effective in all circumstances or if there are situations/populations for which that technology has a distinct advantage. Research is needed to explore ways that legislatures and rural school districts can make Internet resources and HAT more widely available in rural educational settings (e.g., the use of electronic technology could be expanded to provide instructional services to individuals in rural areas who are deaf or have hearing loss).

A final area of future research involves exploring ways to make assistive technologies more accessible and acceptable for those in need. A promising possibility is telehealth, defined as the use of telecommunications and information technologies to share information and to provide clinical care, education, public health, and administrative services at a distance. The term “teleaudiology,” in turn, refers to the use of technology to provide audiology services when the

client and practitioner are in different locations. Diagnostic applications of teleaudiology have been well documented and validated (see systematic review by Swanepoel and Hall, 2010) and are in use in many areas of Africa, Australia, Europe, and North America. However, there has been less research into the use of teleaudiology applications for intervention, and even fewer studies of teleaudiology as it relates to assistive technology. Given that one of the deterrents to wider use of assistive technology might be the need for extensive or intensive instruction in device setup and use (Boothroyd, 2004), teleaudiology could provide an avenue for reducing some of this burden by allowing audiologists to use videoconferencing to schedule virtual troubleshooting appointments and refresher sessions with a minimum of travel for either party. For devices such as FM systems that require programming, remote programming (in which the audiologist's computer is connected via Internet to a local technician's computer at the patient's location) might further reduce the number and/or distance of office visits for device users. However, for all of the promise offered by these emerging technologies, research is needed to address various challenges. Unfamiliarity with teleaudiology is common and can lead to resistance when a teleaudiology option is offered (Eikelboom and Atlas, 2005). With regard to the use of videoconferencing and other telehealth interactions, some have expressed concern about confidentiality and security (Demeris et al., 2009; Stanberry, 2000). Despite the challenges associated with the growing field of teleaudiology, it offers an exciting new avenue for interacting with and assisting patients in many different domains.

SUMMARY AND FUTURE RESEARCH ISSUES

There is a growing awareness of the negative influence of room acoustics on the adequate perception of speech and on communication. The influences of distance, background noise, and reverberation are well documented. Various assistive technologies (such as induction loop, FM, and infrared assistive listening systems) and communication strategies can be used alone or together to reduce the influence of poor room acoustics on communication. This chapter also covered other assistive devices that have been designed to improve receptive communication in situations such as those involving face-to-face communication, broadcast media, telecommunications, and alerting situations as well as methods to augment the capabilities of assistive devices. For HAT to be accepted and used by an individual with hearing loss, however, the communication needs and proper selection of assistive devices must be conducted within the context of an overall rehabilitative plan. Outside of the comprehensive rehabilitative plan, there is still a need to engage in activities to improve consumer acceptance of assistive devices and to help people understand the federal mandates that are already

in place to remove acoustic barriers to communication. Research is needed to improve the type and quality of assistive devices available to individuals with hearing loss and to develop better methods of identifying the individuals who will benefit most from a particular technology. HAT offers the hearing healthcare professional a significant challenge but, at the same time, a wonderful opportunity to maximize the client's communication *and* human potential.

ACKNOWLEDGMENT

The late Carl Crandell provided much of the foundation on which this chapter is built. His enthusiasm for helping people who cannot hear will not pass this way again, but his spirit lives on in us, the authors of this revision. We hope our rendering honors Carl and provides the kind of information and inspiration he would wish for the reader.

FOOD FOR THOUGHT

1. Given the evidence for the value of assistive technologies, why has such little attention been given the role and benefits of HAT within audiologist's overall rehabilitation plans?
2. A child in your classroom could benefit from additional amplification beyond hearing aids. What would be the advantages and disadvantages of advocating for a personal FM system versus a classroom audio distribution system?
3. The influence of distance, background noise and reverberation worsen the situation for those populations "at risk" for listening and learning difficulties. How might we evaluate patients who might need HAT during a rehabilitative evaluation?

Hearing Aid Technology

Jennifer Groth and Laurel A. Christensen

INTRODUCTION

This chapter serves as an introduction to hearing aid technology with a discussion of the current state of hearing aids, including how hearing aids work to process sound and deliver this sound to the hearing aid user's ear. The chapter will also include an overview of the styles of hearing aids, hearing aid measurement, and wireless connectivity in hearing aids.

HEARING AID STYLES COMMONLY USED TODAY

Hearing aids used today can be broadly classified into two styles: Those that fit behind-the-ear (BTE) or more specifically are worn over the pinna (commonly called BTE hearing aids) and those that fit in-the-ear (ITE) or in the concha and ear canal (commonly called ITE hearing aids). A BTE hearing aid is coupled to the ear with tubing and either an earmold made custom for the hearing aid user's ear or with an ear dome, also commonly called an ear tip. Figure 38.1 shows an example of an ITE and a BTE hearing aid as worn by a hearing aid user.

Within these two broad categories are many different specific styles and sizes of hearing aids. When considering what style of hearing aid is appropriate for a patient, many factors are taken into account including the ability of the patient to manipulate the controls on the hearing aids and change the battery and the features contained within the hearing

aid. Generally, the smaller the hearing aid, the harder it is to manipulate the controls and change the battery. Choosing a style of hearing aid is also related to an individual's cosmetic preference. For the most part, the signal processing can be implemented in any style of hearing aid with the exception of a few features such as telecoils (a feature for phone communication and looping and directionality). If a telecoil is a desired feature, a hearing aid style with a telecoil built inside must be selected. Directionality, a feature that helps hearing aid users to hear better in noise, cannot be implemented in the smallest ITE devices. The largest percentage (about 71%) of hearing aids sold in the United States is BTE hearing aids (Hearing Industries Association (HIA), 2012).

Behind-the-Ear

BTE hearing aids can be further broken down into those with the receiver located within the case of the hearing aid (traditional BTEs) and those with the receiver removed from the case and instead located at the end of the tubing and placed inside the ear canal (receiver-in-the-ear (RIE)). RIE aids have also been termed receiver-in-the-canal (RIC) but for the purposes of this chapter the term RIE will be used. Figure 38.2 shows a traditional BTE hearing aid and an RIE hearing aid. The traditional BTE aid is shown with tubing and an earmold attached to the aid. The RIE is also shown with tubing which includes the receiver and an ear dome for placement into the ear. A better view of the actual receiver at the end of the tube is shown in the circled image

FIGURE 38.1 An example of an in-the-ear [ITE] and a behind-the-ear [BTE] hearing aid as worn by a hearing aid user. [Courtesy of ReSound [left] and Starkey Laboratories [right].]

FIGURE 38.2 An example of a traditional BTE hearing aid and a receiver-in-ear (RIE) hearing aid. The traditional BTE aid is shown attached to tubing and a custom earmold. The RIE hearing aid is shown with the thin receiver tube attached to the aid and a standard ear dome. The receiver which is at the end of the receiver tube is shown close up in the *circle*. The dome is placed on the receiver and this part is placed in the ear canal of the hearing aid user. [Courtesy of Phonak (**left**) and Beltone (**right**).]

of Figure 38.2. Both traditional BTEs and RIE hearing aids can be worn in an “open” configuration where the coupling includes a tube to the ear and the ear domes do not completely occlude or plug up the ear. These “open” fittings have made BTE hearing aids the most popular styles available today. Open hearing aid styles are particularly good for hearing aid users with normal hearing in the low frequencies because the low-frequency sound can exit the ear canal as it does for listeners with normal hearing. Open styles using thin tubes are generally more cosmetic, comfortable, and better sounding because of this reduction of occlusion.

TRADITIONAL BTEs

Traditional BTE hearing aids come in different sizes and are primarily defined by the hearing aid battery that they use and how they are coupled to the ear. Figure 38.3 shows several BTE hearing aids. The one on the left would be fit to the patient with a length of plastic tube attached to a custom-made earmold, whereas the other two are configured to use thin tubing and would be fit to the ear with either a noncustom plastic tip or custom-made earmold. These BTE aids use battery sizes 312, 13, and 675, respectively. As a general rule, the larger the battery used, the more gain the hearing aid is capable of producing. However, the battery size mainly determines how long the patient can use the hearing aid before having to change the battery, with the larger batteries lasting longer. Today, the only hearing aids that use

FIGURE 38.3 Examples of different sizes of traditional BTE hearing aids. [Courtesy of Beltone.]

the largest batteries (size 675) are for fitting patients with severe-to-profound hearing losses. As stated earlier, BTE hearing aids are coupled to the ear with a tube running from the aid to the ear with either a custom earmold or an ear dome for placement in the ear.

RECEIVER-IN-THE-EAR

RIE hearing aid style makes up over 45% of the hearing aids sold in the United States (HIA, 2012). This may be different in other countries. RIE hearing aids use a thin tube and couple to the ear with an ear tip or an earmold called a micro mold. An RIE is like a BTE device in that part of the instrument fits behind the ear, but the receiver is located at the end of the tube within the ear canal. A small wire cable running through a thin tube connects the device behind the ear to the receiver (see Figure 38.3). RIE devices have become popular in the last few years because of their cosmetics and thin-tube options; however, there are thin-tube options in traditional BTE devices as well. To determine if there are benefits to the RIE style over the traditional BTE, Hallenbeck and Groth (2008) studied the gain (amount of amplification provided to the hearing aid user) before feedback (squealing in hearing aids) in the two styles as this was thought to be one of the reasons that RIE aids had become so popular. Their study concluded that similar gain could be achieved in the two styles and should not be used as a reason to select an RIE product over a traditional BTE. The study did point out that RIE hearing aids potentially offer a smoother, wider frequency response and that there are no moisture problems associated with the tube because of the design. The drawback of RIE hearing aids is that the receiver being located in the ear might cause it to malfunction more often and the receiver is significantly more expensive to replace than a thin tube.

In-the-Ear

ITE hearing aids come in many specific styles and make up approximately 29% of the hearing aids sold in the United States (HIA, 2012). Like BTE hearing aids, this may be

FIGURE 38.4 Examples of ITE hearing aids. [Courtesy of ReSound.]

slightly different in other countries. ITE hearing aids are for the most part custom devices made specifically to fit an individual's ear. There are, however, a few styles that fit into the ear that come in standard, noncustom sizes.

Figure 38.4 shows a variety of ITE hearing aids in different sizes. The largest ITE hearing aid fits completely into the concha and is termed a full-shell ITE. Smaller ITE styles include half-shell styles that partially fill the concha and in-the-canal (ITC) styles where most of the hearing aid is within the ear canal. The completely-in-the-canal (CIC) style fits within the ear canal and terminates at the opening of the ear canal. Finally, a recent style termed an invisible-in-the-canal (IIC) device has been introduced. Figure 38.5 shows this style of hearing aid in an ear. An IIC fits completely in the canal and terminates just before the ear canal opening. In general, more power and output are obtained in the full-shell style. However, because the receiver can be placed closer to the tympanic membrane in a smaller volume in the ear for the IIC and CIC styles, these aids can produce enough gain to fit hearing losses up to the severe range. ITC hearing aids are the smallest ITE styles where directionality using two microphones to improve hearing in noise can be achieved.

FIGURE 38.5 An invisible-in-the-canal [IIC] hearing aid. [Courtesy of ReSound.]

FIGURE 38.6 An example of an MIC hearing aid. [Courtesy of ReSound.]

One additional style of hearing aid is the microphone-in-concha (MIC) design. In this style the microphone has been removed from the hearing aid case and is attached to a wire and tubing and placed in the helix. This type of design allows for several advantages over other ITE styles because the removal of the microphone from the case frees up space for several options including a larger receiver in a smaller style to achieve greater amplification in a more cosmetic package; a very large vent that will make the device less occlusive in the ear; or to build a smaller hearing aid that fits deeper in the ear canal. Figure 38.6 shows an example of MIC hearing aid.

NONCUSTOM ITE STYLES

There are some ITE styles that are not custom-made products but do fit in the ear. Figure 38.7 shows examples of three of these types of products. These products are placed in the ear but are not made individually for a patient. Generally these hearing aids do not cost as much as custom-made or BTE devices and they do not have as many features as the other styles overall. Some of these devices are being sold over the counter. If the manufacturer of such devices has not attained Food and Drug Administration (FDA) approval for them as medical devices, they are termed personal sound amplification products (PSAPs) rather than “hearing aids.” PSAP is a category of devices defined by the FDA that is “not intended to compensate for impaired hearing, but rather is intended for non-hearing-impaired consumers to amplify sounds in the environment for a number of reasons, such as recreational activities” (FDA, 2009). They are often compared to reading glasses for the ear and typically marketed for part-time use.

HOW A HEARING AID WORKS

This involves a complex interaction between the device and the individual who uses it. Hearing aids of excellent quality meeting all technical specifications may not always be judged to “work” by the user. The many factors which contribute to the ultimate effect of wearing amplification are discussed elsewhere in Section IV of this book. In this chapter, we limit ourselves to the purely technical aspects of the hearing aid itself.

Components

Hearing aids are wearable electronic amplifiers of sound in the environment that are used to assist with communication for a hard-of-hearing person. At a minimum, hearing aids require a microphone to pick up the sound and convert it to an electrical signal, electronic circuitry to amplify and treat the signal, a speaker—called a “receiver”—to convert the signal back to sound waves, and a battery to power the device. An example of how these components may be assembled in a BTE device is shown in Figure 38.8.

MICROPHONE

The microphone is one of the hearing aid’s *transducers*. A transducer converts one form of energy to another. The microphone contains a diaphragm that is set into vibration by the pressure variation of sound waves that enter the opening of the microphone, often called a *port*. The motion of the diaphragm transduces the acoustical energy (sound) to electrical energy. Although various microphone technologies have historically been used in hearing aids, virtually all devices now have either *electret* or, increasingly, *microelectrical-mechanical system (MEMS)* microphones. These microphone technologies offer high-quality technical performance, can be very small, and are well suited to mass

production. Hearing aid microphones can faithfully transduce sounds over a broad range of frequencies as well as a large span dynamic range and contribute very little noise to the processed sound that exits the hearing aid. Compared to other hearing aid components, microphones impose the fewest limitations on overall hearing aid electroacoustic design and performance.

DIGITAL SIGNAL PROCESSOR

The circuitry which manipulates the signal in a hearing aid has traditionally been referred to as the *amplifier*. The amplifier has traditionally been thought of in terms of how it increased the level of the signal at different frequencies. Although the goal of hearing aids is still to amplify sound for compensation of hearing loss, the circuitry in modern hearing aids treats the signal in many other ways to accomplish

FIGURE 38.8 Schematic of a behind-the-ear (BTE) style hearing aid showing the major components of a modern hearing aid. [Courtesy of Derek Stiles © 2006.]

additional goals, such as noise reduction, prevention of hearing aid squealing, and analysis of the acoustic environment.

Prior to 1996, hearing aids primarily used analog processing. However, it is safe to say that all modern hearing aids are based on digital sound processing. Digital hearing aids became widely commercially available in 1996, with sales completely overtaking that of analog hearing aids within the first few years of the 21st century. Because of the development and production costs relative to sales, it is no longer feasible for hearing aid manufacturers to manufacture analog hearing aids.

How do analog and digital hearing aids differ? Sound is an analog signal, meaning that it is continuous. In analog hearing aids, the time-varying pressure variations of sound are represented by uninterrupted, time-varying changes in electrical voltage. The continuous electrical voltage changes are *analogous* to the continuous changes in the original acoustic signal. The manipulation of the signal that is carried out by the analog circuitry is virtually instantaneous.

In contrast, digital hearing aids represent sound by analyzing it at discrete intervals and converting it to a series of numbers. Processing of the resultant signal occurs by applying *algorithms*, which are sets of arithmetic operations. For example, to amplify a digital signal requires only multiplying the numbers by an amount that would yield the desired output.

The digital circuit in a modern hearing aid consists of a minimum of subcomponents, including the *A/D (analog-to-digital) converter*, *digital sound processor (DSP)*, *memory*, *clock*, and *D/A (digital-to-analog) converter*. Of these, the DSP corresponds to what is traditionally called the amplifier, carrying out all the signal processing algorithms. The capabilities of the DSP in modern hearing aids far exceed

what was possible in analog hearing aids. However, depending on the technical characteristics of the digital system, there can be limitations that were not found with analog hearing aids. One example of this is that the dynamic range of input levels is smaller for digital hearing aids than for analog hearing aids.

The precision with which the sound can be represented digitally, the signal processing capabilities of the hearing aid, and the time it takes for the signal to be processed depend on a number of digital circuit characteristics. An overview of some of these characteristics is presented in Table 38.1.

RECEIVER

Like the microphone, the receiver is also a transducer. It converts the processed electrical signal back to acoustic sound waves. The principle is similar to that of the microphone insofar as a diaphragm is set into vibration. The movement of the diaphragm in this case creates the sound waves that are produced by the hearing aid, and the sound waves travel through tubing that connects the receiver to the outside of the hearing aid. Physical properties of the receiver components and the tubing, as well as magnetic forces that drive the vibration of the diaphragm are deciding factors for the output and frequency response of the receiver. The hearing aid receiver most often also incorporates the function of digital-to-analog conversion.

BATTERY

The battery provides the electrical energy to hearing aids. The most common type of hearing aid battery is the zinc-air. It has small holes that allow oxygen to enter the cell when

TABLE 38.1

Digital Circuit Characteristics Overview

	Unit	What It Means	What Effect It Has
Sampling rate	Typically kHz	How often the incoming signal is sampled per unit of time	Determines the frequency range of sound that can be represented
Bit depth	bits (binary digits)	Refers to the length of the digital “words” that describe the signal; also called the resolution	Increasing bit depth reduces noise in the signal
Clock frequency	Typically MHz	Processor speed	Coordinates arithmetic operations and data transfer; a higher clock speed can “schedule” activities faster and more efficiently
Millions of instructions per second	MIPS	Computational power	Increasing MIPS capacity allows the hearing aid to run more algorithms simultaneously, or more complex algorithms

the user peels off a sticker, causing a chemical reaction that activates the battery. The amount of energy that is stored in the battery is called the *capacity* and is given in milli-Ampere hours (mAh). Larger batteries can store more energy and thus provide more hours of use than smaller batteries. The combination of how much electrical current in milli-Amperes (mA) is drawn by the hearing aid and the capacity of the battery allows an estimation of battery lifetime. For example, a hearing aid battery may have a capacity of 90 mAh. If the hearing aid draws 1 mA of current, then the estimated hours of use per battery is $90 \text{ mAh}/1 \text{ mA} = 90$ hours. In real-life use, current consumption by the hearing aid is variable, which means that actual battery lifetime is virtually always shorter than estimated in this way. Operating conditions such as humidity and temperature also affect battery performance, and thus, hours of hearing aid use per battery.

Until recently, zinc–air batteries have contained small amounts of mercury amalgamated with zinc. The purpose of the mercury content was to prevent gas from forming inside the battery. This could cause the cell to swell and its components to separate and leak. Although mercury has been banned from other types of batteries since the mid-1990s, zinc–air batteries for hearing aids were exempted because of lack of an alternative technology. Numerous states in the United States, as well as other countries, began to enact bans of the sale of zinc–air batteries containing mercury in 2011. After many years of research, mercury-free zinc–air batteries are now available that provide a reliable energy source for hearing aids and which are largely on par with mercury-containing zinc–air technology.

Rechargeable battery technology is available in virtually every consumer small electronic product, so one might expect hearing aids also to make use of rechargeability. However, rechargeable hearing aids are still a rarity. Hearing aids need a power supply that is small enough to fit inside the device and that has great enough energy density (energy per volume) to power the device for a defined unit of time (1 day of use would be a minimum). Currently, zinc–air batteries are the only technology that can meet these requirements, as rechargeable battery technologies have comparatively low energy capacity and low energy density. This means that a rechargeable cell with the same capacity as a given size of zinc–air battery would need to be much larger. For now, rechargeable solutions are available only for hearing aids with low requirements for power consumption.

OTHER

There are other components that are common with certain styles of hearing aids or used for specific patient needs.

User Controls

User controls include on/off switches, volume controls, and program buttons. A hearing aid may have any combination of these or none of these. Some hearing aids also have user

controls that have more than one function. For example, the on/off switch may be part of the volume control, or the volume control and control to change programs may be combined in one toggle switch. User controls can also be located on a remote control device.

Multiple Memories

Most of today's hearing aids have the capability of multiple memories. Within a memory, certain hearing aid adjustments are stored, and various hearing aid features can be turned on or off. The patient can access a given memory through the use of a button on the hearing aid or using a remote control device. The presumed benefit of multiple memories is that very specific hearing aid settings may be desirable for one listening situation but not another. For example, many audiologists believe that the hearing aid settings for listening to music should be different from those for listening to speech in background noise. The patient, therefore, could simply switch the hearing aid to the "music program" whenever needed. As will be discussed later, hearing aids also have signal classification systems, that is, the hearing aid can detect the content of the input signal (e.g., music vs. speech vs. noise). Automatic adjustments to the signal processing can be made based on the content. As these algorithms have become more advanced, there has been less need for multiple memories. However, new functionality in hearing aids, such as digital wireless connectivity, continues to make multiple memory capability relevant.

Programming Interface

A programming interface refers to a socket or connector, usually on the body of the hearing aid or inside the battery compartment that allows connection to a cable or boot. This can be used for programming the hearing aid and/or for attaching an external audio input device. Hearing aids are becoming available that can only be programmed wirelessly and do not have a mechanical programming interface.

Telecoil

Historically, hearing aids and telephones have not worked well together without some sort of interface. This was because of the feedback that results from placing the telephone receiver in close proximity to the hearing aid microphone (and receiver). Feedback management features have helped in making phone communication easier, but there are still individuals who struggle to use the telephone. There are several ways to effectively couple hearing aids and telephones. One of these is through a telecoil. A telecoil is a tiny coil of wire around a core that induces an electrical current when it is in the presence of a changing magnetic field. Originally, it was intended to "pick up" the magnetic signal generated by the older telephones, whose speakers were driven by powerful magnets. Newer phones often do not carry the strong magnetic signal but contain extra

electronics to generate such a signal and are referred to as “hearing aid compatible” (HAC), allowing the hearing aids to pick up the magnetic signal from the phone. The induction coil is formed by wrapping copper wire many times around a metal rod; the strength of the inductive pick up is determined by the number of turns of the copper wire around the metal axis rod. Larger rods permit more turns and more powerful telephone coils. By using an integrated amplifier to amplify the strength of the signal, the size can be reduced for hearing aid use. The strength of the electric current induced in the telecoil is directly proportional both to the energy in the magnetic field and to the relative positions of the induction coil in the hearing aid to the magnetic field generated from the telephone. This means that, in some positions, little or no electric current will be created in the induction coil. This is why hearing aid users must often experiment with the positioning of unfamiliar telephones to find the “hot spot” where the strongest signal is heard.

When a hearing aid is in the telecoil mode, nearby electromagnetic signals are detected and amplified, including those that are not the desired signal. Some common sources of electromagnetic interference include powerful fluorescent lights, microwaves, televisions, computer monitors, power lines, and electrical transformers. Any of these electrical devices can produce strong electromagnetic “static” or noise. This electromagnetic static can interfere with the telecoil and with telephone reception in general. Because the strength of the electromagnetic field often varies considerably with small changes of position, it is sometimes possible to minimize the amount of the noise just by moving the telephone or hearing aid position slightly.

The telecoil can also be used to pick up electromagnetic fields generated by electric currents traveling through wires, such as induction loop systems (e.g., used in public facilities such as places of worship) or neck loops (e.g., connected to FM receivers). See Chapter 37 for more in-depth discussion of this topic. A coil similar to a telecoil may also be used in some hearing aids to receive and emit digital data and audio signals.

Radio

Some hearing aids contain a radio and an antenna for sending and receiving digital data and audio signals. Such hearing aids use wireless technology based on radio frequency (RF). These will be discussed in the section on digital wireless technology.

Direct Audio Input

Direct audio input (DAI) is a connection found on BTE and some RIE-style hearing aids that allows an analog electrical audio signal to be delivered directly to the hearing aid. It is sometimes the same physical connection as used for the programming interface. An adaptor called an audio boot is attached to this connection, and the user can plug in audio devices via a cable. FM receivers can also be plugged into the

audio boot. Some audio boots have integrated FM receivers. The use of FM is discussed in detail in Chapter 37.

Acoustic Coupling to the Ear

EARMOLDS AND CUSTOM SHELLS

Earmolds and custom shells are fabricated from an impression of the ear. The purpose of the custom shell is to house the electronics of an ITE hearing aid so that it fits within the individual ear, directing the amplified sound into the user’s ear canal. For BTE and RIE hearing aids, an earmold may be used to direct the acoustic signal into the ear canal and to assist with retention of the device on the ear.

As with custom ITE hearing aids, custom earmolds come in various styles, ranging from large models that fill the entire concha of the outer ear to skeleton molds in which only a small piece of tubing extends into the ear canal. Custom earmolds can also be made with an opening to insert the receiver of RIE styles or with the receiver encased. Custom earmolds are usually made of a hard acrylic or a soft silicone material. In general, the greater the hearing loss is, the larger the earmold needed. Figure 38.9 shows the samples of many of the earmold styles that are available.

Once the earmold is coupled to the hearing aid, the properties of the sound reaching the user’s ear are changed. The acoustic properties of the earmold itself and the length and diameter of the connecting tube play an important part in the final acoustic characteristics of the hearing aid system. To some extent, the signal can be modified by making changes to the earmold. The most common modification is called a vent, or a small hole drilled into the canal portion of the earmold. Earmolds (and custom hearing aids) are vented for four primary reasons: (1) To allow unwanted

FIGURE 38.9 Earmold styles for BTE hearing aids. [Courtesy of Westone Laboratories (A) and Oticon A/S (B).]

FIGURE 38.10 Example of venting effects. [Adapted from Lybarger S. (1985) Earmolds. In Katz J, ed. *Handbook of Clinical Audiology*. 3rd ed. Baltimore, MD: Williams and Wilkins; pp 885-910].

amplified low frequencies to escape from the ear canal; (2) to release pressure to avoid a “plugged ear” sensation; (3) to reduce the occlusion effect (one’s own voice sounds “hollow”); and (4) to allow the normal input of unamplified sound (Mueller et al., 2006). Variable vents are also available that use small plastic plugs or different sizes of tubing that can totally occlude an existing vent or provide smaller openings of various diameters.

Because a vent allows primarily low-frequency energy to enter and leave the ear canal, the effect of venting can be observed as a reduction in low frequency gain. As the size of the vent increases, the degree of reduction increases. The effects of different vent sizes can be seen in Figure 38.10. In general, it is believed that for frequencies where there is normal hearing, it is better to have the hearing aid user hear “natural” sound than amplified sound. Hence, the vent size is selected to correspond with the range of normal hearing in the low frequencies.

Whereas venting can be applied to both ITE hearing aids and earmolds, other physical changes can be made to earmolds that affect the acoustic response (Figure 38.11).

FIGURE 38.11 Venting, dampers and filters, and the sound bore affect different portions of the frequency response. [Redrawn from Libby ER. (1980) Smooth wide-band hearing aid responses – the new frontier. *Hear Inst.* 31 (10), 12-18.]

One of these is the sound bore, which is the tube through which sound passes through the earmold to the ear canal of the user. Whereas venting affects the low frequency response of the sound in the ear canal, the sound bore mainly affects the high frequencies. For example, a sound bore with a flared shape (called a *horn* or *Libby horn*) can enhance the high frequencies. In contrast, narrowing the diameter of the sound bore damps the high frequencies. With modern hearing aids, where the digital filtering allows for quite flexible frequency shaping, it has become less common to change earmold acoustics to manipulate the hearing aid response in the ear.

Finally, as part of the overall plumbing of the BTE hearing aid, it is common for manufacturers to place a damper in the tone hook (that fits over the ear) to smooth the response in the 1,200- to 1,600-Hz range. Some manufacturers provide different hooks with different size dampers.

NONCUSTOM COUPLING

In recent years, there has been an increase in “open” fittings. An open fitting is one where the coupling to the ear canal allows low-frequency energy to enter and escape the ear canal unhindered. Although this can be attained with a custom earmold and an effective vent, it is most common to use a soft silicone dome-shaped tip. An example of this can be seen in Figure 38.9. It is convenient to fit hearing aids with such tips, as it is not necessary to take an impression of the ear canal and wait for a custom earmold to be manufactured. Because of this convenience, noncustom tips that occlude the ear canal have also come into regular use for fitting of more severe hearing losses, particularly with RIE styles.

FIGURE 38.12 Examples of hearing aid couplers used to test different hearing aid styles. [Courtesy of Frye Electronics.]

ELECTROACOUSTIC PERFORMANCE

Measurement and Standards

Hearing aid performance must be assessed to make sure that a hearing aid is working as defined by the manufacturer

FIGURE 38.13 Two examples of hearing aid test boxes. [Courtesy of Audioscan (**top**) and Frye Electronics (**bottom**).]

according to a test standard. There are two different types of hearing aid measurements: Coupler tests and real-ear measures (REMs). REM uses a small probe microphone in the ear canal to verify a hearing aid's performance in the user's ear. These measures are the subject of another chapter in this book. Coupler measures are performed inside an acoustically controlled hearing aid test box using a coupler. A coupler is an open metal cavity that substitutes for the ear canal simulating its residual volume. Figure 38.12 shows coupler examples used for different styles of hearing aids. Coupler tests should be performed on all hearing aids to ensure they are meeting specifications according to a standard termed ANSI S3.22 1996 or 2003 or the applicable international standard such as IEC 118 (see also Chapter 39). The measures outlined in these standards provide a level of quality control for hearing aids. Manufacturers are required to include the results of these standards with the hearing aid so that the performance can be tested in individual clinics before fitting the hearing aid to a patient's ear. A series of tests according to the standard are run on the hearing aid to verify its performance.

Figure 38.13 shows two common test box systems used to measure hearing aids. To perform coupler measurements, a hearing aid is attached to the appropriate coupler. The coupler and the hearing aid are then placed into an acoustically controlled environment (test box) which contains a speaker or speakers used to generate sounds. At one end of the coupler a microphone (termed a coupler microphone) is inserted. Figure 38.14 shows the configuration for testing in a hearing aid test box for an RIE hearing aid. The coupler microphone measures the output of the hearing aid to calibrated signals presented through the speakers in the test box.

Some of the tests performed include tests of the amount of amplification provided by the aid throughout the hearing

FIGURE 38.14 Configuration of the hearing aid, coupler, and microphone for hearing aid testing. [Courtesy of Audioscan.]

aid's frequency response to various input signal levels, the bandwidth of the hearing aid, the OSPL90 or maximum output of the hearing aid, the amount of distortion and internal noise, and measures regarding the function of the amplification system.

SIGNAL PROCESSING

When sound enters the hearing aid it is processed by the digital signal processor mathematically. These signal processing algorithms will be discussed in this section.

Audibility

The most important signal processing that takes place in the DSP of a hearing aid is the amplification of the sound so that it becomes audible to the listener. Simply put, sound entering the hearing aid is provided gain or amplified so that it can be heard by the hearing aid user. Three terms must be defined to understand how sound is amplified in a hearing aid:

- **Input:** The signal entering the microphone of the hearing aid. It is characterized in terms of frequency (Hz) and intensity (dB SPL).
- **Output:** The signal that enters the hearing aid user's ears, which is also described in terms of frequency (Hz) and intensity (dB SPL). The output is higher than the input because the sound is amplified.
- **Gain:** The difference in decibels between the input level and the output level. This is how much the input was amplified. The function showing how the gain varies according to the frequency of the sound is called the "frequency-gain response," or often just "frequency response."

LINEAR AMPLIFICATION

There are two common ways to provide amplification in a hearing aid, linear amplification and amplitude compression. Hearing aids using linear amplification often utilize a form of compression to limit the output when the OSPL90 (maximum output) of the device is reached. Linear amplification applies the same gain to the input until the hearing aid reaches the OSPL90. For example, a hearing aid with 20 dB of linear gain would amplify a 45-dB SPL input signal to 65 dB SPL and a 55-dB SPL input signal to 75 dB SPL. The amount of gain, in this case 20 dB, applied to the input signal is independent of the level of the sound entering the hearing aids (input level). When the OSPL90 is reached, the output is limited either by peak clipping or by amplitude compression limiting (discussed below). Peak clipping cuts off the peaks of the input signal that exceed the OSPL90. Peak clipping is not the preferred method of limiting output because this technique adds distortion to the hearing aids and compromises the sound quality. Compression limiting reduces the gain when the

input reaches a certain level, called the kneepoint, and thus limits the output. This technique provides a better sound quality than peak clipping and will be discussed in more detail below.

AMPLITUDE COMPRESSION

Most hearing aids today use amplitude compression to apply a different amount of gain depending on the level of the input of the incoming signal rather than using linear amplification. Amplitude compression is used in two ways in modern hearing aids; the first discussed earlier is to limit the output of a linear hearing aid. Limiting the output is necessary to protect patients from exposure to amplified sound that exceeds their levels of loudness comfort. This approach is commonly called compression limiting. The second is called wide dynamic range compression (WDRC). The term "wide" refers to the fact that this type of amplitude compression is applied over a wide range of input levels and distinguishes it from other compression schemes that work over a smaller range of input levels, and which are less commonly used today. WDRC applies greater gain to soft sounds and less gain to loud sounds. In this way, it can be applied to restore normal loudness to a hearing aid user within his/her reduced dynamic range. Remember that individuals with sensory/neural hearing loss (SNHL) have a reduced dynamic range. The normal-hearing person has a dynamic range of approximately 100 dB. For this person, 0-dB HL sounds are "very soft" and 100-dB HL sounds are "too loud." A listener with SNHL has a reduced dynamic range which is defined by his/her threshold at a particular frequency and his/her loudness discomfort level (LDL) at that same frequency. Thus, a patient with a 50-dB HL threshold at a frequency and a 95-dB HL LDL has a dynamic range of 45 dB at that frequency. In this case, 50 dB HL is "very soft" and 95 dB HL is "too loud." The loudness growth from "very soft" to "too loud" is steep. The amplitude compression strategy attempts to place the amplified signals within the hearing aid user's dynamic range restoring loudness growth so that soft sounds are still perceived as soft and loud sounds are perceived as loud. This philosophy is in line with making sure all the signals are audible to the listener (within his/her dynamic range) but still comfortable. Loud inputs in the WDRC strategy are often given no gain and are thus transparently processed through the hearing aid.

AGCi and AGCo

Amplitude compression can be referenced to either the input to the hearing aid or the output of the hearing aid. Although the technicalities of the level detection may differ among hearing aids, the conceptual distinction is whether the level detection that controls the compression is done before or after gain is applied. This gain includes the setting of the user-operated volume control if present on the

device. Input-referenced compression detects the level of the sound prior to amplification and applies a certain amount of gain depending on that level. Input-referenced compression is called “AGCi,” which stands for “automatic gain control.” The “i” refers to “input.” The WDRC scheme described above is an example of AGCi amplitude compression. If a hearing aid with AGCi processing has a volume control, turning the volume up or down will have no effect on the gain applied by the compressor, because the gain depends only on the intensity of the sound before it is amplified.

Output-referenced compression detects the level of the sound *after* it has been amplified. This type of compression is called AGCo, where the “o” refers to “output.” Output-referenced compression can be used in combination with both linear amplification as well as AGCi and is nearly always used to limit the output of the hearing aid. If a hearing aid with AGCo has a volume control, turning the volume up or down will affect whether the compression is activated and how much gain is subsequently applied to the signal.

Compression Characteristics

The characteristics of a compressor are defined by the compressor’s threshold of compression (kneepoint), compression ratio, and time constants (attack and release times).

Kneepoint and Compression Ratios

The kneepoint of a compressor is the level of an incoming sound that is loud enough to trigger the compressor. A common way to display the function of a compressor is using an input/output function. Figure 38.15 shows different input/output functions for output (AGCo) and input (AGCi) controlled compressors. These functions show the input on the x -axis and the output on the y -axis. These functions can be used to determine the characteristics of a specific compressor. For example, for output-controlled compression at volume 2, for a 50-dB input, the output is approximately 75 dB; for a 60-dB input, the output is approximately 85 dB; and so on. Notice that, when an output of 110 dB SPL is reached, there is no further increase in output when input increases. This point is the kneepoint of the output-controlled compression and is also the maximum output of the hearing aid (OSPL90). The kneepoint of a compression function is the point where the output curve deviates from linear. The ratio of the function is the degree of deviation. For example, if the output of the hearing aid increases by only 5 dB for every 10-dB increase in input, this would be described by a compression ratio of 2:1 (stated as 2 to 1). If the output changed by only 3.3 dB for every 10-dB increase in input, this would be a compression ratio of 3:1. In Figure 38.15 the AGCo has a kneepoint of 110 dB SPL and a ratio of 10:1. Recall that AGCo is most often used for output limiting. Thus, it typically has a very high kneepoint and a compression ratio of at least 10:1 and often higher. The AGCi, on the other hand, has a compression kneepoint of 55 dB SPL. For sound inputs up to 55 dB, the hearing aid provides linear gain. Observe that

FIGURE 38.15 Input/output functions for input-referenced compression [AGCi] and output-referenced compression [AGCo].

when the input reaches 55 dB, the output of the hearing aid no longer increases by the same amount as the input, but rather by a smaller amount. Since AGCi is used for WDRC, it has a low kneepoint corresponding to soft levels of speech and low compression ratios, almost always less than 4:1 and quite often less than 2:1.

Compression Time Constants

Compression time constants have historically been part of the ANSI/IEC test battery but will not be mandatory tests in future revisions. The reason for the change is that checking time constants was a way to access the capacitor in a hearing aid and modern digital hearing aids do not have a capacitor so the test does not make sense any longer. Even though the test is not part of the quality standard, understanding time constants is important because they can make a difference in the performance of the hearing aids. Compression systems

in hearing aids have time constants that can be defined as follows.

Attack time. Using a puretone signal that changes abruptly from 55 to 90 dB SPL, attack time is the time required for the output to reach 3 dB of the steady-state value for the 90-dB input (American National Standards Institute (ANSI) S3.22-2003). Attack time is sometimes considered the time for the instrument to go “in” or “out of compression; however, for AGCi with low kneepoints, the hearing aid may not go “out” of compression for most listening situations.

Release (recovery) time. The interval between the abrupt drop from 90 to 55 dB SPL and the point where the signal has stabilized to within 4 dB of the steady-state value for the 55-dB input (ANSI S3.22-2003). In other words, release time is the time required for a circuit to respond to a decrease in the input and adjust to a lower compression characteristic (which, for some types of compression in some hearing aids, could be linear amplification).

The measures of attack time and release time are gradually being phased out. In the new IEC 118 standard (which will be consistent with future ANSI standards), these two measures will be relegated to the annex and be regarded as optional measures. Historically, attack time and release time was a quality control measure of the capacitor in the analog hearing aid. With the advent of digital technology the capacitor is no longer required. More on this issue can be found in Chapter 39.

Figure 38.16 illustrates the attack and release of a compression circuit. For most compression circuits the attack times are very fast (e.g., <10 ms). This is because the hearing aid needs to react quickly so that the input is placed appropriately within the patient’s dynamic range. The release times can vary more. There are products with short release

FIGURE 38.16 Schematic of the effect of attack and release of a compression circuit. [Courtesy of Harvey Dillon, personal correspondence.]

times (<10 ms) and those with long release times (>5 seconds). The release times are usually defined by the manufacturers according to their specific audiologic rationale for applying compression. The hearing aid may also use an algorithm that changes the time constants depending on the acoustic environment. This is because different compression parameters may be preferred for sound quality in some listening situations.

Multiple Channels

Most hearing aids today have multiple channels. This allows the input signal to be divided and processed into separate frequency bands and then recombined. In terms of multi-channel compression, the compression characteristic can be changed independently for different frequency regions. These regions are separated by a crossover frequency, although there may be quite a degree of overlap between the regions. The kneepoint, compression ratio, and compression time constants can be adjusted independently with the channels. This type of compression allows the hearing aid to tailor the compressor to a hearing aid user’s dynamic range that may be different in different frequency ranges. It should be noted that the terms hearing aid band and hearing aid channel are often used interchangeably. Some manufactures use the term channel to describe frequencies that are controlled by an individual compressor and the term band to describe frequencies whose amplitudes can be controlled by a single gain control.

Fitting Rationales

There are several fitting rationales for selecting the appropriate amount of gain for a hearing aid user’s hearing loss. These are referred to as prescriptive gain formulas. The two most popular peer-reviewed rationales are NAL-NL2 and DSL i/o. These rationales prescribe the amount of gain required at each frequency for various input levels for a particular threshold of hearing. These prescriptions are used to set the compressor characteristics when programming the hearing aids. Manufacturers also develop rationales of their own for selecting the gain characteristics of the hearing aids, which typically do not have peer-reviewed support. It is important that once a rationale is selected, the gain is actually verified in the hearing aid user’s ear at the hearing aid fitting using REM.

EXPANSION

Expansion is intended to improve the sound quality of hearing aids in quiet situations. It is not unusual for audiologists to be confused about the concepts of amplitude compression and expansion. Part of the reason for this is that from an audiologic viewpoint, they each seem to do something opposite of what the name implies. WDRC makes a broader range of sound intensities audible for the user. Although it is compressing the wide range of sound intensities into the limited

FIGURE 38.17 Input/output function for a compressor with expansion.

dynamic range of the hearing aid user, it can also be thought of as expanding the range of sounds that are made audible. Despite the confusing terminology, expansion reduces audibility for very soft sounds. Also commonly known as “squelch” or “microphone noise reduction,” expansion keeps the hearing aid from overamplifying very soft sounds which are not of interest to the wearer, such as internally generated noise or very low level environmental sounds.

Expansion is part of the amplification system. As such, its characteristics are described in the same terms as compression, including kneepoints, expansion ratio, and time constants. Expansion reduces gain for sound levels below its kneepoint, whereas compression reduces gain for sound levels above its kneepoint. Expansion kneepoints are lower than the system’s compression kneepoints, although this does not guarantee that soft speech will always remain audible. Figure 38.17 shows an input/output function for a hearing aid with expansion. Notice how these low inputs are in the range of linear amplification and thus receive maximum gain. Below the expansion kneepoint, gain is reduced for those inputs.

FREQUENCY LOWERING

Frequency lowering refers to signal processing algorithms that take high-frequency input signals and present these sounds to lower frequency regions. This technique has generally been recommended for hearing aid users who have “dead” regions in their cochleae. “Dead” regions refer to areas in the cochlea with loss of inner hair cell function, which, in turn, means that the corresponding auditory nerve fibers will not be stimulated (Moore, 2004). This tends to occur in frequency regions where the energy for many voiceless consonants critical for speech understanding lies (e.g.,

/s/, /f/, /t/). Without inner hair cells in these regions of the cochlea, any effort to provide gain cannot be successful. The best candidates for frequency lowering are those that have severe-to-profound hearing loss in which a hearing aid cannot adequately amplify the high-frequency signals or those with diagnosed “dead” regions. Dead regions can be assessed by diagnostic tests such as the TEN test (Moore et al., 2004). As of this writing today, there is controversy around using this type of signal processing for hearing aid users who do not have severe-to-profound hearing loss or “dead” regions. Some studies have indicated that it can be beneficial for speech understanding but large individual differences have been seen (Simpson et al., 2006). There are two large-scale studies using frequency compression for hearing-impaired children being undertaken today in Australia and in the United States. The results of these studies should shed more light on who is the right candidate for frequency lowering.

Two methods for accomplishing frequency lowering are available in commercial hearing aids today. They are frequency transposition (Kuk et al., 2009) and frequency compression (Glista et al., 2009). Frequency transposition uses a mixer to lower the signal by a fixed frequency value. Frequency transposition does not reduce the overall bandwidth of the hearing aid, rather it simply shifts frequencies to another region. The transposed high frequencies are laid over and coexist in the frequency region one octave below the selected start frequency. Frequency compression reduces both the frequency and the bandwidth by a preset ratio (factor) beginning at a selected cutoff frequency. So, for example, if the cutoff frequency was 2,900 Hz and the compression ratio was 4:1, the energy above this frequency would be divided by four and shifted to the area slightly higher than 2,900 Hz. The selected cutoff frequency and compression ratio both depend on the user’s hearing loss and may be modified to reflect a person’s listening experiences. Frequencies lower than 2,900 Hz (in this example) would be amplified as they would be normally.

Improving Signal-to-Noise Ratio

Individuals with hearing impairment not only have hearing loss, or loss of audibility, which is compensated for through amplification in hearing aids as discussed earlier in this chapter, but also have increased difficulty hearing in noise. This difficulty of hearing in noise can be quantified by measuring a listener’s signal-to-noise ratio (SNR) loss (Killion, 1997). SNR loss is the increase in SNR (in dB) required by someone with a hearing loss to understand speech in noise, relative to the average SNR required for listeners with normal hearing. Two tests are commercially available to measure SNR loss, the Speech-in-Noise (SIN) test (Fikret-Pasa, 1993; Killion, 1997) and the Hearing-in-Noise Test (HINT) (Nilsson et al., 1994). There are large individual differences among hearing-impaired listeners on measures of SNR loss. A general trend is that SNR loss increases with hearing loss,

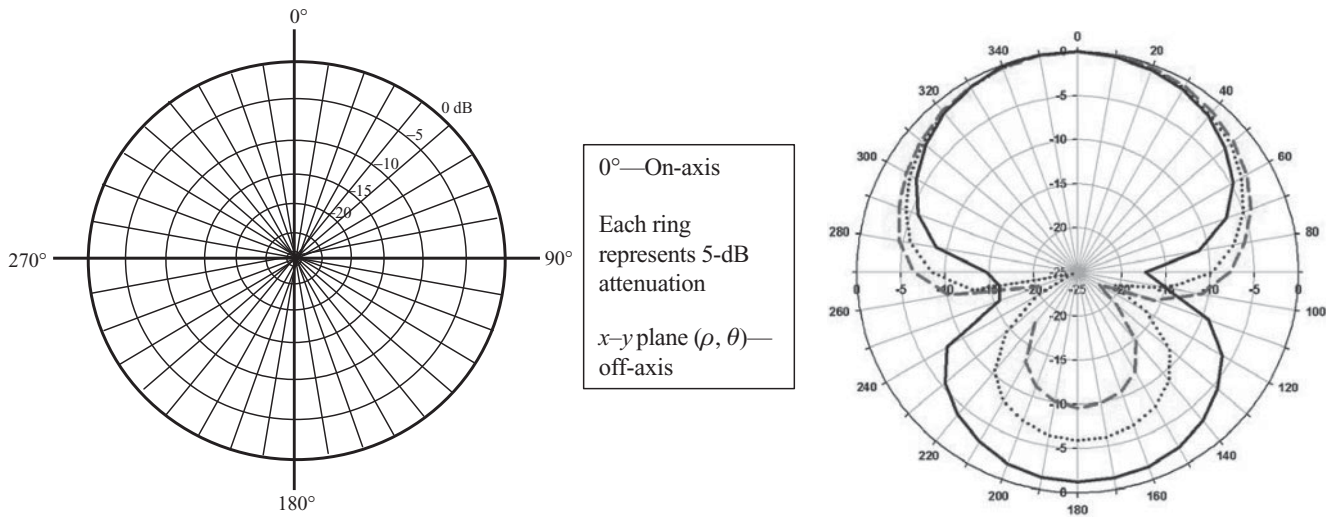

FIGURE 38.18 How to read a polar pattern. [Courtesy of Andrew Dittberner, personal correspondence.]

but the variance is quite large and can range from no loss (normal-hearing performance in noise) to greater than 20 dB of SNR loss. To provide better hearing in noise, hearing aids incorporating directionality improve the SNR for users of hearing aids (Pumford et al., 2000). A rough estimate is that well-fit hearing aids incorporating directionality will improve the SNR for a listener by approximately 3 dB. This is enough for many hearing aid users to be able to follow a conversation in moderate levels of noise.

DIRECTIONALITY

A two-microphone method of obtaining a directional pattern is the most common technology available with modern hearing aids. Sound enters the microphones where the acoustic energy is converted to electrical energy. Following electrical conversion, the two signals are sent through an electrical network where a time delay is applied to the rear microphone signal. Finally, the two signals are subtracted to produce directivity. When both microphones are active a directional pattern is achieved. When an omnidirectional condition is desired the rear microphone is shut off usually automatically when a quiet environment is detected by the hearing aid’s sound classifier.

Spatial Directionality Patterns

Fixed

Polar plots are a graphic representation of the sensitivity of the microphone for sound originating from various azimuths or angles. A polar plot is presented on a circle with the outermost circle typically representing 0-dB attenuation. Each line inside the outer circle typically represents 5 dB of attenuation. An azimuth of 0° represents sound arriving to the front of the listener whereas 180° azimuth represents sound arriving to the back of the listener. Figure 38.18 shows an empty pattern that the polar plot is graphed on and an actual polar

plot. The point where there is maximum attenuation of sound is called the null. Figure 38.19 shows four polar plots. The first pattern is omnidirectional where the microphone is equally sensitive to sound from all angles. The other three designs are the cardioid, supercardioid, and hypercardioid directional patterns. The difference in the designs is mainly the location and depth of the null points. When the nulls are always at the same angle of the pattern and do not change depending on the location of noise or frequency they are called fixed directional patterns. From the polar plot a measure called the directivity index (DI) can be obtained for

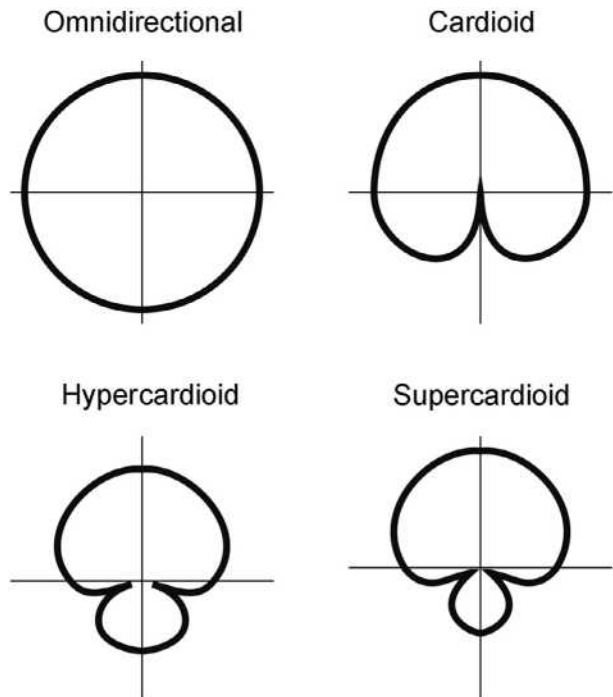

FIGURE 38.19 Four common polar patterns.

individual frequencies. The DI is a number that represents how sensitive a microphone is to sounds arriving from the front relative to sounds arriving from other directions. An omnidirectional microphone has a DI of 0 dB when measured in a test chamber. Directional microphones in hearing aids have DIs that commonly range from 2 to 5 dB measured in the test chamber. Measured in real-life situations, directional microphones in hearing aids improve the SNR of sounds arriving from the front by approximately 3 dB.

Adaptive

Adaptive directionality is a type in which the null can be moved to the angle where the most noise is detected in the environment, thus adapting the attenuation to the specific environment. This can even be done at different frequencies such that a hearing aid might have different directionality patterns depending on the frequency and location of the noise in the environment. Many hearing aids today come with adaptive directionality.

Microphone Mode Steering

Directional microphones in many hearing aids can be switched from omnidirectional to directional settings manually by the hearing aid user. Cord et al. (2004) indicated that 30% users did not switch between the settings and often did not know when to switch and/or did not want to do this manual switching in everyday life. To overcome this manual switching problem, automatic switching hearing aids were introduced where the hearing aid automatically changes from an omnidirectional setting to a directional setting depending on the environment. These types of switching algorithms depend on environmental classification systems which analyze the acoustic scene and make a decision about which microphone mode would be most beneficial. Thus, these systems are limited by the accuracy of the classification system and have no ability to determine the hearing aid user's intent in complex listening situations.

ASYMMETRICAL DIRECTIONALITY. The standard way to use directional processing in a bilateral hearing aid fitting is to program both hearing aids with a directional setting for use in a noisy environment. Another way to use directional processing is to keep one hearing aid set to omnidirectional and the other hearing aid set to directional. This seemingly unconventional way to apply directional processing can provide a better listening experience for users of hearing aids and overcomes the limitations of directional systems discussed above. Specifically, an asymmetric fitting can overcome the lack of use of manual systems and the reliance on environmental classification systems. An additional benefit is that it does not cut off a listener from his/her environment as wearing two hearing aids in directional settings can do. The user can choose to attend to whatever signal he/she may be interested in hearing. The key to asymmetrical directionality is to understand that one hearing aid in the directional set-

ting and one in the omnidirectional setting provide the same SNR benefit for speech presented from in front of the user as using two hearing aids set in the directional settings (Bentler et al., 2004; Cord et al., 2007). Using hearing aids with the microphone modes set asymmetrically comes with the added benefit of better ease of listening (Cord et al., 2007) and better acceptance of background noise (Kim and Bryan, 2011).

Improving Comfort

A facet of successful hearing instrument use is the user's acceptance that not all amplified sounds are desirable, interesting, or pleasant. Hearing instrument users must resign themselves to hearing sounds that are not of interest to hear speech which is of interest. It is probably safe to say that no one seeks hearing help because they cannot hear their refrigerator humming or paper crinkling, yet they must accept hearing sounds like these to become successful users of amplification. A number of hearing aid technologies are aimed at reducing the drawbacks of amplification, such as the annoyance and effort associated with listening at elevated levels of background noise.

NOISE REDUCTION

Noise reduction refers to signal processing that reduces gain in frequency areas where the SNR is estimated to be poor. It is often referred to as "digital noise reduction" which distinguishes it from spatial noise reduction schemes, such as directionality, as well as early noise reduction schemes that simply reduced gain for low-frequency sounds. These early attempts at noise reduction were based on the rationale that background noise typically has the most energy in the low frequencies.

Theoretically, noise reduction has two goals. One is to improve the SNR in noisy situations. Although it is possible to set up laboratory test conditions where a small improvement in SNR can be demonstrated, this advantage is not repeatable in more realistic test conditions and is not accepted as a benefit of noise reduction. It is not difficult to understand why noise reduction fails on this objective. To be successful, the algorithm must separate speech from noise when both signals usually have energy at the same frequencies at the same time.

Complicating matters further is that many noises have speech-like characteristics and many parts of speech have noise-like characteristics. The other aim of noise reduction is to make the experience of wearing hearing aids more acceptable and pleasant, which currently appears to be an attainable goal. Although the overall objectives of noise reduction are similar, the actual signal processing algorithms and their effects on different types of sounds can be very different both in the physical (Bentler and Chiou, 2006) and perceptual domains (Brons et al., 2013). Several examples of differences in the way sounds are affected

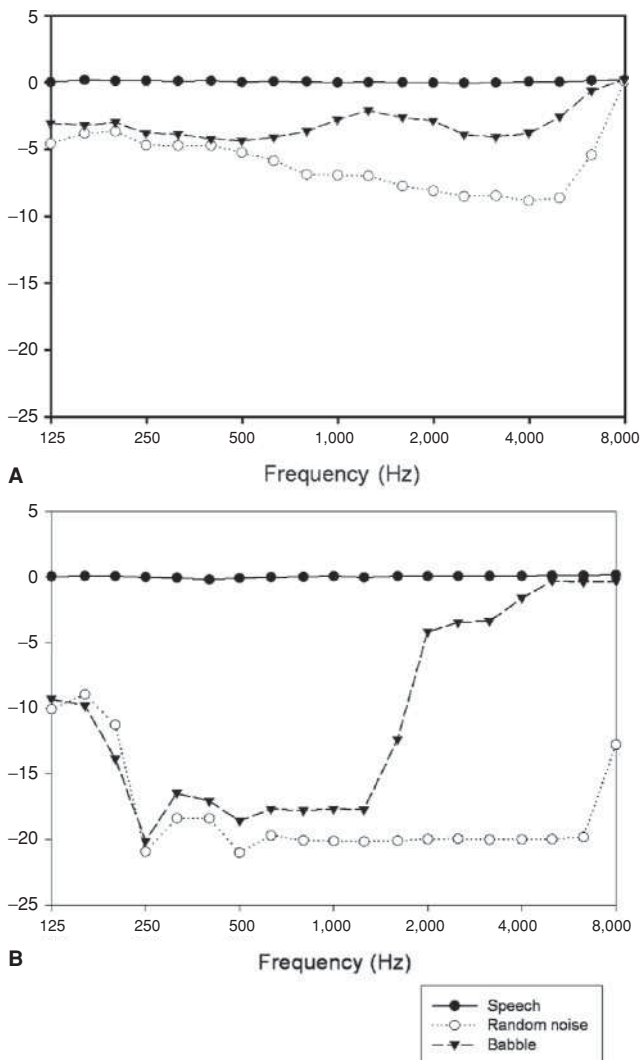

FIGURE 38.20 Example of different outcomes for two different digital noise reduction schemes.

by different noise reduction algorithms are shown in Figures 38.20A and 38.20B. From a technical perspective, noise reduction algorithms differ in terms of how many frequency channels they operate in, how quickly they engage and disengage, how they identify speech and noise in the incoming sound, and what rules they follow to reduce gain.

Identifying speech and noise, which are mixed together in the input sound, is key to how noise reduction processing works. The first digital noise reduction algorithms used *modulation* as an approximation of the SNR. With a modulation-based approach, the signal observed at the microphone is analyzed to determine whether modulations in the amplitude fluctuation (or waveform) are similar to those observed in speech. The modulated waveform, or temporal envelope of speech, contains information that is essential for the identification of the different parts of speech, such as phonemes, syllables, and words.

For modulation-based noise reduction, high modulation depth in a frequency channel is considered to be indicative of high SNR, and there will be minimal or no gain reduction applied. As the modulation depth decreases, this is considered to indicate the presence of noise and/or absence of speech, and the gain will be reduced according to rules that are specific to the particular manufacturer's algorithm. Modulation-based noise reduction works well when the wanted signal is a single talker in the presence of steady noises, like a fan or motor. However, this type of system does not work as well when the competing noise consists of other people talking, which is a common scenario. As a result, the use of modulation-based algorithms to detect and eliminate noise has obvious limitations. Even if the noise *could be* identified and removed from the environment for specific spectral regions, the speech information in that same region would be removed as well.

Increasingly, manufacturers are using a multifaceted way of identifying speech and noise portions of the sound and applying a "spectral subtraction" approach to noise reduction. This approach attempts to estimate the spectrum of the noise background and subtract it from the total signal. The noise estimate is updated in pauses between speech segments, which means that more advanced methods for identifying speech are needed than reliance on modulation of the signal. A spectral subtraction approach to digital noise reduction will typically work faster than a modulation-based approach (Kates, 2008) and may improve the ability of the algorithm to work in different types of noise backgrounds, including environments with multiple talkers.

There is no consensus on which noise reduction methods and parameter settings are the most advantageous or whether different methods may differ in terms of how suitable they are for individuals. Nevertheless, noise reduction algorithms have become widely accepted because of achieving the goals of improved listening comfort and ease of listening, and evidence is gathering in support of these benefits (Palmer et al., 2006; Bentler et al., 2008; Sarampolis et al., 2009; Wu and Stangl, 2013).

WIND NOISE REDUCTION

Wind noise is a phenomenon that most people recognize from outdoor cell phone conversations or news correspondents trying to report from stormy areas. The wind blowing on the microphone in each of these cases causes a very loud rushing sound that can drown out the speaker's voice. It might come as a surprise to know that wind noise is also a significant problem for hearing aids. Turbulence is created when wind flows across or around any object. A microphone placed in the midst of turbulent air flow will pick up the random pressure variations and convert them to voltage changes in the same way the microphone picks up and converts the pressure variations of airborne sound waves. The wind noise picked up by the microphones is amplified and heard by

the user as a very loud and annoying noise. Depending on where the hearing aid microphones are located and how the user's head is oriented relative to the wind, this issue can be a source of great dissatisfaction. The pinna itself serves as an obstruction when wind comes from the front, creating turbulence behind the ear. Thus BTE and RIE styles, where microphone placement is behind the ear, are particularly susceptible to wind noise. Directional microphone systems are also more sensitive to wind noise than omnidirectional microphones (Chung et al., 2010).

Wind noise can be so intense that it overloads the microphone preamplifier, resulting in a signal that is distorted before it even reaches the DSP stages of the hearing aid. The ideal solution for wind noise is to keep it from entering the hearing aid microphone(s) in the first place. Some hearing aid designs incorporate wind screens for this purpose. Generally speaking, ITE-style hearing aids may also provide better protection of the microphone from wind noise. This is particularly true if the microphone is recessed, such as with a deep fitting CIC, an IIC, or the MIC styles.

Some hearing aids also have signal processing algorithms that attempt to reduce wind noise. Because wind noise contains mostly low-frequency energy, wind noise reduction algorithms target the low frequencies for gain reduction. However, as is the case with digital noise reduction, wind noise reduction algorithms differ in terms of their approach to identification of wind noise, time constants, and rules for reducing the wind noise component. These differences translate to different effects on the acoustic signal, which make each wind noise reduction system sound different.

REDUCING FEEDBACK

The amount of gain that is actually available to a hearing aid user is often limited by acoustic feedback, which is the squealing that comes about when sound from the hearing aid receiver returns to the microphone and is reamplified. There are a number of pathways by which this can occur, the most obvious of which are vents and acoustic leakage around the earmold or shell. Some additional routes by which sound can travel from the receiver back to the microphone include earmold tubing and coupling between tubing and earmold, earmold and earhook, or earhook and receiver; emission from the hearing aid shell; and structural and acoustic

transmission within the hearing aid (Hellgren et al., 1999a). Although bone-anchored hearing aids (BAHAs) are not part of this chapter, it has also been demonstrated that feedback can occur as a result of skull vibration, especially if the coupling is poor. The sum total of the various transmission lines constitutes the feedback path (Figure 38.21). When the gain in the hearing aid exceeds the damping provided in the feedback path, acoustic feedback results.

The management of that annoying outcome has been to (1) remake the earmold/shell to be fuller or deeper so that there is less leakage between the mold and the wall of the ear canal, (2) reduce the size of the venting, (3) roll off the high frequencies, and more recently, (4) reduce the gain in narrow frequency bands or through notch filtering centered in those bands. Each of these solutions may be counterproductive to the intent of the fitting. Solution 1 may result in an uncomfortable fit; solution 2 may impact on the acoustic characteristics desired; and solution 3 may decrease speech intelligibility. One possible negative outcome of solution 4 is the introduction of distortion for the listener. Even when the hearing aid gain is set to a level below the oscillation point, the signal feeding back may still cause alterations, or fluctuations, in the signal that are perceptible to listeners, especially when these alterations occur at formant transitions (Cox, 1982). It has been suggested that this gain be reduced 4 to 8 dB below the feedback onset to avoid these deleterious effects (Skinner, 1988). To do so, however, undermines the goal of providing optimal gain for audibility.

Digital hearing aids have enabled more advanced approaches to feedback management. The method most similar to the previously described approaches is adaptive notch filters that can change the frequency area at which they are applied depending on where feedback occurs. Other processing schemes attempt to increase the amount of gain available for the user without changing the frequency response of the hearing aid. For example, shifting the frequency of the hearing aid output by a small amount is one method that can add a small margin of usable gain, as it reduces the correlation between the external sound and the amplified sound which re-enters the microphone. Too much of a shift in frequency, however, causes an altered sound quality that is likely to be unacceptable to hearing aid users.

Another technique for feedback reduction which aims to increase the available gain for the individual fitting is phase cancellation. This type of algorithm has become

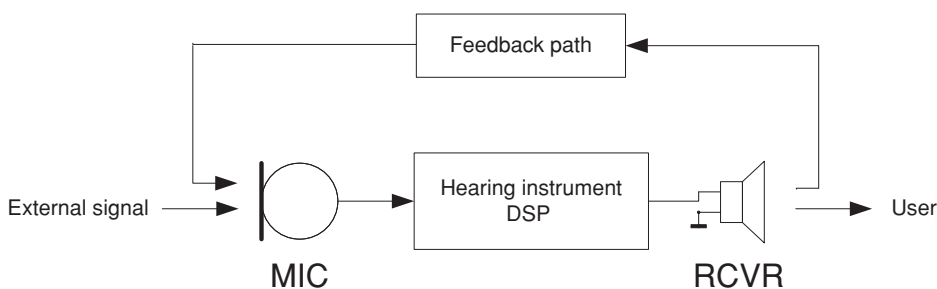

FIGURE 38.21 The feedback path describes in terms of frequency, amplitude, and phase how the amplified sound is changed as it returns to the hearing aid microphone[s].

FIGURE 38.22 Feedback cancellation systems attempt to model the feedback path, create a signal that is equal but opposite in phase, and add it to the input to the hearing aid.

ubiquitous in modern digital hearing aids and is conjectured to be a contributor to improved satisfaction with hearing aids in terms of “whistling and feedback” (Kochkin, 2010). The principle behind feedback phase cancellation is for the system to analyze the feedback path, create a signal with the same frequency and amplitude characteristics but opposite in phase, and add it to the input of the hearing aid. If the added signal matches the feedback path perfectly, the feedback is completely cancelled from the input to the hearing aid (Figure 38.22). Although this sounds simple, there are significant limitations to feedback cancellation algorithms. For one thing, they must always provide an accurate model of the feedback path. The feedback path can change by 20 dB or more quite rapidly (Hellgren et al., 1999b), and the system must track these changes. The feedback path may also be complex, with multiple peaks at different frequencies.

Reverberation effects in the acoustic environment also affect the feedback path (Kates, 2008). All of these require complex computations, which take additional time and power, neither of which are in abundance in current hearing aids. As a result, the feedback cancellation algorithms are limited in how well they can react to many fast changes in the feedback path, and the potential for additional gain relative to no feedback cancellation is 10 to 15 dB (Kates, 2008). In practice, there can be large differences in the feedback cancellation algorithms from different manufacturers. Studies have demonstrated additional stable gain as a result of feedback cancellation ranging from near zero to more than 18 dB (Freed and Soli, 2006; Merks et al., 2006).

A negative consequence of these algorithms is the occurrence of *entrainment* (Merks et al., 2006). Entrainment refers to the unintentional result of the filter attempting to cancel what appears to be feedback but, in reality, is some other tonal input to the microphone (e.g., from a musical production). The listener often reports hearing either an additional tone or a modulation-type distortion during entrainment. This is an obvious detriment to sound qual-

ity. Manufacturers employ various methods for avoiding entrainment, examples of which are slower time constants for applying feedback cancellation or adding an “acoustic signature” to the output of the hearing aid to help the algorithm distinguish between feedback and nonfeedback signals in the input. The adaptive behavior of the cancellation algorithm may also be limited in terms of frequency area and extent of adaptation. No perfect solution has yet been introduced, which means that feedback cancellation algorithms are necessarily a trade-off between additional stable gain and preserved sound quality.

Personalization

Hearing aid fittings begin with some sort of prescription of settings based on user data, usually an audiogram. The main goal of fitting prescriptions is to provide amplification for optimum speech understanding while ensuring comfort for loud sounds. The presumption of this approach is that one set of hearing aid parameters will meet the listening needs of an individual in all conditions. In reality, a hearing aid user may want to enhance or diminish different aspects of the amplified sound in different situations. There is plenty of evidence that this is the case: Hearing aid users have different preferences for gain–frequency responses depending on their listening environment (Keidser et al., 1995), different volume preferences (Surr et al., 2001), as well as different preferences for directional or omnidirectional microphones in different situations (Walden et al., 2004). Studies have also shown preferences for different compression characteristics depending on acoustic environment or nonaudiologic factors such as cognitive function (see Kates, 2010 for a review).

Personalization features aim to account for individual needs and preferences in the way hearing aids work. Although many of the hearing aid features discussed in this chapter are candidates for personalization, the ones covered in this section are specifically for that purpose and may in fact interact with or control other features.

ENVIRONMENTAL CLASSIFICATION

A cornerstone of personalization is to capture and use information that accounts for the unique situation of each individual hearing aid user. One hearing aid feature that contributes to personalization is environmental classification. This type of algorithm attempts to categorize and track the type of listening environments that the hearing aid user is in while wearing the devices. It provides input to data logging in the hearing aid and may also be used by decision-making algorithms to turn certain features on and off, change programs in the hearing aid, or change feature settings in other algorithms. For example, when a noisy environment is detected by the environmental classifier, the degree of noise reduction applied might be increased relative to the setting used for a quiet environment. The purpose is to adjust the hearing aid to better suit the preferences of the individual for how it should sound in a particular environment.

An obvious issue with environmental classification is that the number and characteristics of acoustic environments in the real world are infinite. Hearing aid manufacturers must break these down into a small number of manageable, idealized acoustic environments. The categories into which an environmental classifier sorts the input are defined by each manufacturer, so they are not standardized. However, all systems will at least try to identify environments that are quiet, ones that contain speech, and ones that contain noise. Some may also attempt to further characterize types of noise or to identify music.

DATA LOGGING

Many of today's hearing aids have a feature referred to as data logging. This is more or less an electronic diary that can be used to collect data (1) on hearing aid use, (2) on program/memory and volume control use and (3) to summarize the results of the environmental classification system (e.g., percentage of time the listener was in quiet, noise, and speech in noise). Data logging is not a "processing" feature per se in that it does not treat the incoming sound. However, it can be quite valuable in patient counseling. For one thing, it provides evidence of whether or not the patient has even used the hearing aid. For patients who are using their hearing aids, comparison of what environments the hearing aids have been used in and which programs that were used can serve as a cue for instruction on appropriate program use. Data logging also plays a prominent role in trainable hearing aids that employ learning algorithms; by logging the preferred settings in different environments, the data are subsequently used for automatic switching of parameters and features.

LEARNING ALGORITHMS

Anyone who has used the Internet in recent years is familiar with learning algorithms. They use information gleaned

from your actions and attempt to use the information to customize your experience. For example, if you have searched for tents online, you will likely notice that advertisements for tents and other camping equipment will appear in your browser the next time you open it. Some hearing aid algorithms have been introduced that attempt to do the same sort of thing. That is, they keep track of user actions, make the assumption that these actions represent the user's preferences, and attempt to automatically apply settings that are consistent with these preferences. For example, if the hearing aid user consistently increases the volume of the hearing aid by 3 dB in a listening situation that the environmental classifier categorizes as a speech-only environment, the hearing aid will gradually begin to automatically increase gain when this environment is encountered.

Hearing aids that incorporate learning algorithms are sometimes referred to as "trainable" hearing aids. The learning algorithms currently found in hearing aids are fairly simple and crude, due in part to the limitations of environmental classification and in part to the fact that volume control is the only parameter that lends itself well to include in a commercial product for broad use. Research with trainable hearing aid concepts have demonstrated that users are capable of interacting with learning algorithms to customize other hearing aid characteristics to their preferences, such as frequency response and noise reduction (Dreschler et al., 2008). As new ways of interacting with hearing aids continue to emerge, such as via hearing aid–related apps loaded onto smartphones, it is likely that learning algorithms will play a bigger role.

Tinnitus Management

Tinnitus is a concern for many people and affects approximately 10% of the overall population, with approximately 3% to 5% of the population suffering from clinically treatable tinnitus. Most tinnitus sufferers also have some form of hearing loss. Regardless of what type of tinnitus management protocol is used, sound therapy almost always plays a vital role in the outcome. Therefore it makes sense to combine amplification for hearing loss compensation with sound therapy options for tinnitus management. Sound therapy is simply the introduction of an external sound to help reduce the contrast of the tinnitus against the background acoustic environment. Hearing aids with tinnitus features can generate sounds that are useful in tinnitus management. The simplest of these is actually to use the telecoil program in the hearing aid when there is no signal present, as this creates a low buzzing sound that may be effective for the individual. Other hearing aids are available that generate sound specifically for tinnitus management. These include different noise sounds which at a minimum can be adjusted in terms of spectrum and level. There may also be options for modulating the noise to make it sound like the ocean, rain, or other nature sound or to make the noise

level dependent on the acoustic environment. Tinnitus sufferers who wear digital wireless hearing aids can also make use of audio streaming capabilities to use other sounds from external audio sources that are effective for them. As the memory capabilities of digital hearing aids increases, other types of sounds may become available in the hearing aid itself for tinnitus management.

DIGITAL WIRELESS TECHNOLOGY

In the first quarter of 2013, the HIA started tracking the use of wireless versus non-wireless hearing instruments. These statistics show that wireless hearing aids now constitute 70% of the entire United States' hearing aid market. The phrase “wireless hearing” aids refers to digital wireless technology where wireless transmission is used to either exchange information between two hearing aids or receive information from other sound sources like a TV, MP3 player, microphone, or phone. It should be mentioned that hearing aids have utilized analog wireless technology in the form of telecoils and FMs for many years.

The first digital wireless hearing aids used ear-to-ear data transfer for convenience. When the hearing aid user adjusted the volume control on one hearing aid it would automatically adjust the other hearing aid in the same manner. This would also happen when the user changed the hearing aid memory. Digital wireless hearing aids have advanced to include data transfer for unique signal processing algorithms and connectivity to TVs, phones, and computers. Today's digital wireless hearing aids incorporate one of two types of transmission, near-field magnetic induction (NFMI) or radio frequencies (RFs). Both NFMI and RF systems offer advantages and disadvantages.

NFMI operates in a similar fashion to a telecoil using magnetic induction to transmit. The frequencies used for transmission are between 3 and 15 MHz. NFMI systems have a short range, thus making them near field, because the signal is not radiated beyond 3 to 5 feet. In NFMI, the transmission energy is kept within a localized magnetic field around the transmitting antenna (inductive neck loop). To receive signals from sound sources at greater distances, a relay device using a far-field technology must be used. Most current NFMI systems rely on a propagating RF signal using the open standard Bluetooth protocol for their far-field transmission. In operation, an NFMI system uses a device plugged into the sound source that sends the Bluetooth signal to the relay device. The relay device receives the Bluetooth signals and relays them to the hearing instruments via induction. Figure 38.23 illustrates the architecture of an NFMI-based system. The advantage of NFMI systems to the hearing aid is primarily related to battery life. NFMI has better battery life than RF systems. One other potential advantage for some patients is that the relay device can be used for other functions such as a remote control. The disadvantages of NFMI include having to wear the relay device

FIGURE 38.23 An NFMI digital wireless hearing instrument system. [Courtesy of Oticon.]

because of the short transmission range and a sound delay that is introduced because of using Bluetooth (up to 40 ms) for the far-field portion of the signal transmission. This delay can cause an echo to be heard especially when users are fit with open hearing aid designs or if the hearing aid microphones are simultaneously active and picking up the sound acoustically.

Wireless technology utilizing RF technology uses a frequency to transmit signals a minimum of 30 feet to up to several hundred depending on the antennas size and the power source. RF systems use an antenna to generate and transmit a propagated electromagnetic wave. This type of transmission is referred to as *far field*. The frequencies used in systems today include 2.4-GHz and 900-MHz ISM (Industry Science Medical) bands. The 2.4-GHz ISM band can be used internationally, whereas the use of the 900-MHz ISM band is limited to Region 2 (the Americas, Greenland, and certain eastern Pacific islands). Apart from these regulatory considerations, the choice of frequency for RF systems also impacts the size of the antennas needed for transmission, and thus the size of the devices. There is a fixed relationship between the frequency and the physical dimensions of the antenna, with a lower frequency requiring a longer antenna. Antennas in the hearing instruments must be very small. For a 900-MHz system, this means that the antennas in the transmitting devices must be much larger to compensate. Thus, the wireless accessories of this lower frequency system need to be made larger than are necessary for the higher frequency 2.4-GHz-based system. In operation, an RF system uses an adaptor to connect to sound sources and send to receiving antennas embedded in the hearing instruments.

FIGURE 38.24 An RF digital wireless hearing instrument system. [Courtesy of ReSound.]

No relay device has to be worn around the neck. The architecture of an RF system is illustrated in Figure 38.24. The advantages of RF systems are the long range that the signal can be transmitted, not having to wear a relay device, and the ability to audio stream in stereo. The biggest disadvantage is battery drain because RF requires more power for a given application.

Binaural Processing

Binaural processing in hearing aids refers here to using the exchange of information between the devices to do some unique signal processing with potential benefits for the hearing aid user. In digital wireless hearing aids there are several different ways that ear-to-ear communication is being used. These include synchronizing some signal processing between the ears such as compression, noise reduction, and directionality so that both hearing aids always have the same setting; enhancing the directional patterns by using the input to all four microphones to narrow the directionality; setting different directional microphone configurations for different environments (e.g., using asymmetric directionality in some environment, directionality in others, and omnidirectionality in the rest); determining if feedback is being experienced or if it is another signal because it is arriving at both ears; streaming of sound from one hearing aid to the other; and finally enhancing cues for localization.

Connectivity and Accessories

As discussed above, digital wireless hearing aids create an entire hearing system when combined with accessories to connect the hearing aid user to other sound sources. Today the hearing aid user can be directly connected to his/her TV, phone, computer, MP3 player, and a variety of microphones. This connectivity significantly improves the SNR for the hearing aid user because the sound source is streamed directly to the ear. Connectivity has the ability to help hearing aid users hear in more environments than hearing aids alone. The future will continue to expand in this area of

connectivity. Using 2.4 GHz, digital wireless hearing aids have now been introduced to the markets that directly connect to a smart phone without use of any relay device.

OTHER STYLES OF HEARING AIDS

Earlier in this chapter an overview of the common styles of hearing aids was given. There are other less common styles that will be overviewed here.

CROS/BICROS

Contralateral routing of signal (CROS) and bilateral contralateral routing of signal (BICROS) hearing aids are a special type of hearing aid used when an individual does not have any hearing in one ear that can benefit from a hearing aid. These hearing aids are designed so a microphone is worn on the ear that cannot benefit from a hearing aid and the sound picked up at this microphone is sent wirelessly or via a wire in some cases to the other ear. A CROS hearing aid is worn when one ear cannot benefit from a hearing aid and the other ear has normal hearing. In this case, the sound picked up at the “dead” ear is sent to the aid on the opposite ear with this sound sent to the eardrum. In the case of the BICROS hearing aid, the user has one ear that cannot benefit from a hearing aid and other ear that has some degree of aidable hearing loss. The sound picked up at the “dead” ear is sent to a hearing aid on the other ear where the signal is amplified and delivered to the ear.

Bone-Anchored Hearing Aids

BAHAs are surgically implanted aids that directly stimulate the cochlea through bone conduction. These aids consist of a titanium implant, an external abutment, and a sound processor. These aids are meant to bypass the external and middle ears. The titanium implant is surgically placed into the skull behind the pinna percutaneously (directly coupled to the bone). The sound processor sits behind the ear. This type of aid works by picking up sound at the microphone

FIGURE 38.25 A bone-anchored hearing aid (BAHA). [Courtesy of Cochlear Americas © 2013.]

of the sound processor which is then transmitted to the implant. The implant vibrates within the skull and stimulates the nerve fibers of the inner ear by bone conduction. Recently, a new BAHA-type device was announced that is transcutaneous; part of the device is implanted but the other part is kept outside the skin similar to a cochlear implant. BAHA-type devices are for unilateral deafness, chronic external and/or middle ear conditions, and congenital ear malformations. Figure 38.25 shows a BAHA device.

Bone Conduction

Bone conduction hearing aids are a special kind of hearing aid used when the outer ear cannot wear hearing aids. Reasons for this might include an atresic ear, a draining ear, or any a number of problems with the ear where a hearing aid cannot be worn. In this type of device sound is sent directly to the cochlea via bone vibration, thereby bypassing the part of the ear that is diseased. Bone conduction hearing aids traditionally have used a similar type of vibrator known from bone conduction audiometry and attached to the skull with a metal or elastic band. Some manufacturers are also making use of the bone conduction principle in innovative ways, such as encasing the vibrator in a dental appliance and wearing it in the mouth or encasing it in an earmold and wearing it in an ear canal. In these cases, the microphone and sound processor might be worn on a deaf ear, thus serving the same function as a CROS hearing aid.

Extended Wear

An extended wear hearing aid is one that is placed deep in the ear canal near the tympanic member (see Figure 38.26) by an audiologist or otolaryngologist and can be worn for

several months. These hearing aids were introduced to the market in 2008. The primary advantages of this type of hearing aid are cosmetic and convenience. The technology inside the device is analog rather than digital, but it is digitally programmed for a patient's hearing loss. The only nonsurgical extended wear hearing aid on the market today, the Lyric, is disposable. Once the battery wears out the aid is thrown away and a new hearing aid must be inserted in the ear canal. Candidates for extended wear hearing aids must have ear canals that can accommodate the device which limits the candidacy as some individual's ear canal size is not suited for this device. Extended wear hearing aids can cost significantly more than other types.

Body Worn

Body-worn hearing aids are the largest hearing aids. These aids are composed of a hearing aid worn on the body (usually around the neck) which is connected with cables and earmolds to the ears. Body aids can provide a wide range of gain and output. Body-worn hearing aids were the only hearing aid style available until the 1950s when BTE hearing aids were introduced. These devices are not seen in developed countries today (<1% of the market in the United States and Europe) but are still common in the developing world.

Eyeglass

Eyeglass hearing aids are a combination of eyeglasses and hearing aids. The hearing aids can be located in the frame of the glasses or can be coupled to the frame using an adapter. Tubing then extends from the frames to couple the aids to the earmolds and ear. These types of hearing aids are not very commonly seen today.

SUMMARY

Modern hearing aids can improve the quality of life for patients with hearing loss. Hearing aids using digital wireless technology create hearing systems where hearing aid users can hear in a significant number of listening environments. These systems will continue to evolve in the years ahead providing new benefits to hearing aid users. This chapter has served as a review of the current state of hearing aid technology including many of the features commonly found in hearing aids. These features may have similar goals, but manufacturers use different implementation strategies that can be more or less effective. Audiologists must be critical on behalf of their patients to determine what features provide the best benefit to their patients. It is also important that the audiologist stay up-to-date on technology innovation with regard to hearing aids as technology changes quickly.

FOOD FOR THOUGHT

The Merging of Hearing Aids and Consumer Electronics

Predicting future hearing aid technology is difficult, but there are some emerging trends in the industry. Certainly, wireless hearing aids with connectivity to peripheral devices will continue to be developed and improved. This should lead to better hearing in more environments for hearing aid users. The upcoming releases of hearing aids with direct connections to smart phones will expand options to not only control hearing aids via cell phones, but also adjust the fitting of the hearing aid. Already there are cell phone applications related to hearing aids, but the future will see an increase in these. Applications could lead to greater personalization and ultimately better user satisfaction, but these also open up the controversial issue of self-fitting devices. In particular the role of the professional in these fittings will be debated.

For discussion:

1. What are the pros and cons of the convergence of hearing aids and consumer electronics?
2. How much control over the hearing aid fitting should the hearing aid user be given?
3. How can audiology professionals secure their role as the professional that fits hearing aids to the hearing aid user?

Evidence-Based Practice

Hearing aid manufacturers introduce new hearing aids to the market at an increasingly fast pace. With each introduction, new features are marketed to audiologists that promise greater end-user benefits than current hearing aids. Audiologists should use evidence-based practice when determining the appropriate hearing aid and features; how-

ever, peer-reviewed research in the area of hearing aids is often several years behind the introduction of new features in hearing aids.

For discussion:

1. How can audiologists determine what new features really make a difference to their patients?
2. How much knowledge should the audiologist have about the increasing complex algorithms found in hearing aids?

Market Penetration

It is estimated that of the approximately 34 million hearing-impaired people in the United States, only 24% of them wear hearing aids. There are many reasons given for these low penetration rates, including that many have mild hearing loss and do not have enough problems in hearing to begin to seek out help for the problem. Excluding those with milder hearing loss, there are still many people with hearing loss that need hearing aids that do not wear them.

For discussion:

1. How in the future can we help more people with hearing loss?
2. What do you think contributes to the reluctance of people with hearing loss to use hearing aids?
3. Can hearing aids that can be bought over the counter without seeing an audiologist help with this penetration problem?

How Are Hearing Aids Sold?

Hearing aids have traditionally been sold in a variety of settings from retail shops and audiologist-owned private practices to hospitals and otolaryngology practices. There is a dramatic shift, in the United States today, in how hearing aids are sold. Hearing aid manufacturers are increasingly buying shops and setting up their own retail locations for their products. In addition, big box stores like Costco and Wal-Mart are selling hearing aids.

For discussion:

1. How will the current trend in hearing aid distribution change audiology?
2. How will this trend benefit the hearing aid user?
3. How will this trend hurt the hearing aid user?

Troubleshooting and Testing Hearing Aids

William Cole and Marshall Chasin

INTRODUCTION

Many clients try hearing aids with great reluctance because of social stigma and the high cost associated with the devices. This reluctance is likely to be reinforced when common problems are not minimized or prevented during the prescription and fitting process. In a survey of hearing aid owners in the United States, one in six reported that they did not use their hearing aids at all (Kochkin, 2000). Common complaints included poor fit, occlusion, feedback, wax buildup, poor service, and sweaty ears. This chapter offers prevention and troubleshooting tips for hearing aid problems common among adult clients.

LOOKING FOR PATTERNS

A detailed and up-to-date case history and background are necessary for each client. This is especially important for new clients. Even changes in weight or occupation may affect hearing aid functioning. The clinician needs to determine the client's current level of knowledge and skill regarding the care and use of his/her hearing aids. A reported problem with a hearing aid may not be due to a technically related issue but, in fact, may be caused by a lack of knowledge on the client's part and may possibly be resolved with training and counseling.

The problem can result from many possible sources. The clinician needs to determine the nature of the problem: Physical (pain in the ear); technical (hearing aid static, cutting out); acoustic (feedback); anatomic (occlusion, feedback); psychology (adaptation to hearing aid); or emotional (anxiety/fear about the hearing aid and stigma). Remember that a client's complaint may have multiple underlying causes. Sometimes the problem is straightforward; other times, a client must be questioned closely over a series of visits. Table 39.1 lists a number of questions to guide the clinician in determining the underlying cause of a reported problem.

Patterns may point to the underlying cause of a problem. Problems may occur only in the evening, or when it is humid, or in certain locations. A client may complain that his/her hearing aid goes dead most afternoons or evenings, especially on a hot or rainy day, but usually works again the next morning. This pattern is typical for clients with persis-

tent, dry flaky wax or skin. After several hours, the increasing levels of humidity can cause any dry wax or skin to expand enough to block the receiver tube. Overnight, the wax or skin dries out and shrinks, once again allowing sound to pass through. This pattern is also typical of drops of moisture condensing inside the hearing aid on a hot, humid day, which may cause a short circuit until the humidity level is low enough for the moisture to evaporate.

Another client may complain that whistling or feedback is heard only when he/she is visiting a particular person or location. It is possible that the hearing aid is fine and that what the client is hearing is the feedback of another person's hearing aid or simply some other high-pitched sound.

THE PROCESS OF HEARING AID TROUBLESHOOTING

Table 39.2 provides an overview of the various steps in effective troubleshooting of reported hearing aid problems. It is meant to serve as a step-by-step guide to identifying and solving reported problems.

Performing a Visual Inspection

FIT IN THE EAR

Before proceeding with any other step, the clinician should observe the hearing aid while it is still in the client's ear. It is often possible to see common problems such as improper placement or loose fit. If the hearing aid is not properly placed, the client may experience pain or feedback. Clients

TABLE 39.1

Patterns: Determining the Underlying Cause of a Problem

2. How often does it happen?
3. How long does it last?
4. When did it start?
5. Is there a pattern?

TABLE 39.2

The Steps Used in Troubleshooting Reported Hearing Aid Problems

1. Look for patterns
2. Inspect the hearing aid in the client's ear
3. Disinfect the hearing aid before handling
4. Inspect hearing aid components:
 - Microphone
 - Receiver
 - Volume control
 - Program buttons and switches
 - Battery, battery door, and battery contacts
 - Ear hooks and tubing
 - Vents
5. Listen to the hearing aid
6. Perform American National Standards Institute tests on the hearing aid

require counseling and practice in the insertion of hearing aids. Clients should be counseled to recognize the signs of an improperly placed hearing aid, such as feedback, discomfort, or a decrease in sound quality or volume. If manual dexterity is an issue, a geriatric handle can be added to the aid or mold, or a caretaker can be trained to properly insert the hearing aid. For a full discussion on fit-related issues, see the section later in this chapter titled “Proper Fit.”

Disinfection

Virtually every hearing aid has some kind of bacterial or fungal growth, and most have a combination of several microorganisms. Handling multiple hearing aids risks passing bacteria, molds, and fungus such as *Staphylococcus* and *Candida* between clients. Associated diseases and infections include pneumonia, meningitis, and diphtheria.

The clinician must wash his/her hands using an established infection control protocol before handling any hearing aid. The hearing aid must be thoroughly disinfected with a germicidal wipe. Ultraviolet light of a specific frequency (253.7 nm) is highly effective in infection control and is used in devices such as the Dry & Store chambers. The following list indicates the most common microorganisms found on hearing aids and earmolds (Bankaitis and Kemp, 2003):

- *Staphylococcus* (various)
- Diphtheroids
- *Pseudomonas* (various)
- *Acinetobacter lwoffii*
- *Enterobacter cloacae*
- *Lactobacillus*
- *Aspergillus flavus*
- *Candida parapsilosis*

Inspecting the Hearing Aid and Component Parts

For a review of the basic anatomy of a hearing aid, consult Chapter 38, Hearing Aid Technology. The following sections list procedures for examining different parts of a hearing aid.

HEARING AID SHELL OR EARMOLD

Examine the hearing aid shell or the earmold for cracks or damage. Reshelling or a new mold may be indicated.

MICROPHONE

Check the microphone for debris. If there is a wind screen or wind hood, check to see if it is blocked. Look for signs of exposure to hair sprays or fine dust. Note that there may be moisture present even if water condensation is not visible (see section on moisture). Debris may be removed gently with a suction tool. Blocked or damaged wind screens and wind hoods should be replaced. Behind-the-ear microphone covers should be routinely replaced as specified by the manufacturer.

RECEIVER

Inspect the receiver. Remove any wax guard, and use an otoscope to look all the way down the receiver tube. To improve depth perception, back your eye off the otoscope view finder several inches and look down the otoscope view finder with both eyes. The receiver tube should be clear and the receiver clearly visible. Gently remove any debris, if possible. A vacuum chamber or suction tool can be used to remove small amounts of deeply seated wax, debris, or moisture (see the following section on moisture).

For in-the-ear hearing aids, the receiver is particularly susceptible to damage by wax and moisture. Vigorous cleaning may also cause damage, dislodging the receiver tube and redirecting amplified output into the hearing aid cavity rather than into the ear canal. The presence of a basket-style wax guard can discourage mechanical damage from overzealous cleaning as well as prevent wax from reaching the receiver.

Effects of Moisture on a Hearing Aid

Much like a tropical jungle, the ear canal is hot, humid, and dirty. Humidity is increased because of reduced ventilation caused by wearing hearing aids. In addition, other sources can increase ear canal humidity, such as physical exertion, sweating, high humidity in the environment, and otitis externa (Gray et al., 2005). Behind-the-ear hearing aids are not directly exposed to the heat, humidity, and wax found inside the ear canal; however, they are exposed to sweat from the scalp and head.

The microphone and receiver must remain clear to pick up and transmit sounds accurately but can easily be clogged

or damaged by dirt, wax, sprays, humidity, and sweat. The microphone diaphragm vibrates according to the frequency and volume of the incoming sound and can be significantly dampened by molecules of moisture. Because a wet diaphragm cannot vibrate fast enough to clearly transmit high frequencies, sound quality is compromised.

Moisture and sweat can also cause distortion, intermittent failure, faulty buttons and switches, corrosion of metal contacts and electronics, reduced battery life, and blocked vents, filters, and tubing. The regular use of a desiccant (such as a Dri-Aid kit or Dry & Store) and protective coverings for behind-the-ear hearing aids (such as sweatbands or SuperSeals) can significantly reduce the effect of sweat and humidity on hearing aids, both reducing the need for repair and lengthening service life.

VOLUME CONTROL

Examine the volume control if there is one. It should turn freely and not be too loose or too tight. A stiff volume control is often remedied by application of a contact cleaner. Remember that even if a volume control is present, it may be deactivated or may act as an on/off switch even when deactivated. A listening check will confirm the current functioning of a volume control.

PROGRAM BUTTONS AND SWITCHES

Examine program buttons, switches, or other controls on the hearing aid. Buttons and switches should move freely. Look for a buildup of debris or corrosion around the controls. A small brush will often remove most debris or dirt, and the careful use of a contact cleaner can loosen stiff buttons or switches. During the listening check (discussed later), listen to see if the buttons or switches are functioning correctly.

BATTERY, BATTERY DOOR, AND CONTACTS

The battery contacts should grip the battery snugly but not too tightly. Look for scratches on the battery caused by tight contacts. A battery door should open smoothly and not be too tight or loose. Check for cracks or breaks in the plastic of the battery door. The hinge of in-the-ear battery doors can break fairly easily, requiring replacement. With some practice, battery doors are easy to replace, although care must be taken that the correct replacement door is used. For some makes of hearing aids, there are right-hand and left-hand battery doors that cannot be interchanged. Also, battery doors may change from model to model within the same company. If in doubt, order the required battery door based on the serial number of the hearing aid.

When removing or replacing battery doors, always take great care not to damage the hinge pin. If the metal hinge pin is broken or dislodged, the hearing aid must be sent to the manufacturer for repair. For behind-the-ear and open-

fit hearing aids, the hearing aid may need to be sent to the manufacturer if the battery door needs replacing.

Take a look at the battery and battery contacts for signs of corrosion. Use a cotton swab and contact cleaner to clean dirty contacts, if needed. Occasionally, the battery may be pushed into the internal cavity of the hearing aid rather than placed into the battery door. Typically, this happens with clients with poor vision or when caretakers or friends try to change the battery. Removing the battery can solve the problem; however, it is possible that the internal wiring or circuit may have been damaged. Unless a test of the hearing aid reveals that it is functioning within specifications, the hearing aid should be sent to the company for repair. For more information, see “Batteries” section later in this chapter.

EAR HOOKS (BEHIND-THE-EAR HEARING AIDS ONLY)

For behind-the-ear hearing aids, inspect the ear hook; loose ear hooks should be replaced. Check the tubing for any debris or moisture. If testing shows low gain compared to the manufacturer’s specifications, retest the hearing aid without the ear hook. Ear hooks with filters are particularly susceptible to partial or complete blockage by debris, wax, or moisture and should be replaced as needed. Care should be taken to avoid over-tightening when replacing an ear hook. Some ear hooks cannot be replaced in-house and must be sent to the manufacturer for replacement.

TUBING (BEHIND-THE-EAR HEARING AIDS ONLY)

If the tubing is hardened or cracked, it should be replaced because it can allow sound to cycle back to the microphone, causing feedback.

For open-fit hearing aids, inspect the tubing and dome for blockage or damage. Because the tubing for these hearing aids is so thin, wax blockage is the most common problem and should be cleared with the tool provided by the manufacturer for this purpose. Open-fit tubing and tips should be changed regularly as recommended by the manufacturer. For those models with the receiver in the ear, there is generally a wax guard system that can be changed at the receiver.

VENTS

A vent is a passage through a hearing aid or mold that allows heat to escape from the ear canal, equalizes atmospheric pressure to the ear drum, and allows excess amplification at various frequencies to escape from the ear canal.

Check to see if the vent is occluded with wax or other debris. A plugged vent may cause sweaty ears, uncomfortable pressure, or occlusion. If a client complains that feedback started suddenly and an examination shows that the hearing aid has a large open vent, a vent plug may have been

previously used but has since fallen out. A well-fitting vent plug should not fall out. When a vent plug is used, it should still provide a release of pressure if possible.

Performing a Listening Check

When listening directly to a hearing aid, use a custom listening ear piece for the best sound quality. Disinfect the flexible coupler of the listening piece (as described in the section earlier on infection control) before and after listening to a hearing aid.

With high-power hearing aids, always turn the volume to the lowest setting and do not insert the listening ear piece deep in the ear. Ensure a tight fit between the listening ear piece and the hearing aid to avoid painful feedback. Always remember that the sound pressure levels (SPLs) generated by power hearing aids are capable of causing damage to the clinician's inner ear.

Before doing a listening check, remove any wax guards, microphone protectors, ear hooks, or tubing. This will ensure that you are testing the hearing aid circuit. Always use a fresh battery to rule out battery-related issues. When performing a listening check of a hearing aid, listen for the following:

- Clear and consistent sound
- Smooth increase/decrease of sound when operating the volume control (if activated)
- Obvious distortion
- Cutting in and out
- Static or cutting out when operating the volume control
- Static or cutting out when operating the toggle switches or push buttons
- The hearing aid's frequency response, using the Ling six sound test (Estabrooks and Birkenshaw-Fleming, 2003)
 - /m/ Low and middle frequencies
 - /oo/ Low frequencies
 - /ah/ First and second formants, middle frequencies
 - /ee/ First formant low frequency, second formant higher frequency
 - /sh/ Middle and high frequencies
 - /s/ High frequencies

A listening check may indicate that a hearing aid is functioning well, but it cannot replace a formalized electroacoustic test, which determines whether the hearing aid is functioning according to manufacturer's specifications.

Troubleshooting with Hearing Aid Analyzers

A typical hearing aid analyzer is shown schematically in Figure 39.1. A signal generator [6] provides test signals to a loudspeaker [1]. The level and spectrum of the signal is measured and controlled by a reference microphone [5] in conjunction with the signal generator. The output of the hearing aid [2] is coupled to a measuring microphone [3]

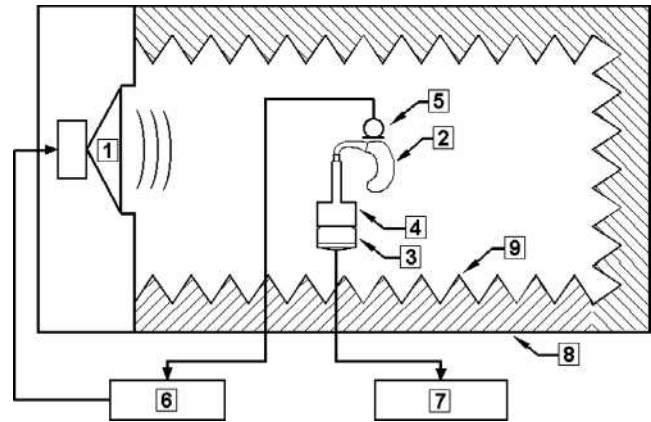

FIGURE 39.1 Schematic representation of a hearing aid analyzer. Acoustic test signals from loudspeaker [1] are generated and controlled by signal generator/control system [6] in conjunction with reference microphone [5]. Output of the hearing aid [2] is coupled to a measuring microphone [3] and measuring system [7] by a coupler [4]. Sound-isolating enclosure [8] is lined with sound-absorbing material [9] to reduce standing waves.

and measuring system [7] by a coupler [4]. To reduce the impact of ambient noise on the intended stimuli or on the operation of the hearing aid, the sound source and hearing aid may be enclosed in a sound-isolating test chamber [8] that is lined with sound-absorbing material [9] to improve sound-field uniformity. In most cases, the stimulus is acoustic, but it may also be magnetic in cases where the performance of a telephone coil is to be tested.

TEST SIGNALS

A variety of test signals are available in the modern hearing aid analyzer. These include steady puretones, steady pseudo-random noise, modulated puretones, modulated noise, and real speech or music. It must always be remembered that, when testing hearing aids with compression or any other adaptive processing features, the results obtained will be valid only for the test signal used. Although it may be tempting and convenient to generalize performance for complex signals from measurements done with simpler signals, the error in doing so will be hearing aid dependent, and this error increases as the difference in signals increases (Henning and Bentler, 2005; Scollie and Seewald, 2002).

In the configuration shown in Figure 39.1, the test signal is controlled by placing a small calibrated microphone very close to the hearing aid microphone port(s) and using the measured SPL to control the signal to the loudspeaker. This is known as the pressure method and is the preferred method in ANSI/ASA S3.22 (ANSI S3.22, 2009). Alternately, a substitution method may be used to control the test signal. In this case, an equalization (leveling) step is performed prior to the test. In this step, the microphone is removed from the coupler and is used to measure the sound

field near the hearing aid microphone port while a known electrical signal is applied to the loudspeaker. For greatest accuracy, all objects should be positioned in the test chamber just as they will be during the test, and a dummy microphone should be installed in the coupler. After the equalization step, the dummy microphone and the coupler microphone are interchanged for subsequent tests.

COUPLERS

The coupler that connects the hearing aid to the measuring microphone also serves as an acoustic load on the hearing aid. This acoustic load has a strong influence on the measured output of the hearing aid, and several have been standardized for hearing aid testing. The most common has a volume of 2 cm^3 and is frequently referred to as a 2-cc coupler. The American National Standard Method for Coupler Calibration of Earphones (ANSI S3.7, 1995) defines this coupler and provides several variations to accommodate different hearing aid configurations. ANSI/ASA S3.22 (ANSI S3.22, 2009) specifies which of these variations is to be used with different hearing aid types.

In-the-ear and in-the-canal devices, including deep-insertion hearing aids, are to be tested in a type HA-1 coupler (Figure 39.2), which has a direct entrance to the 2- cm^3 cavity. The acoustic coupling between the sound outlet of the hearing aid and the coupler entrance must be made airtight by using an appropriate sealant.

Hearing aids that employ a button-type receiver are to be tested using the type HA-2 coupler (ANSI S3.22, 2009). This

FIGURE 39.2 The HA-1 hearing aid coupler. The coupler microphone [2] is concentric with the cavity [1], which has a diameter between 18 and 21 mm and a volume of $2.0 \text{ cm}^3 \pm 1\%$. Hearing aid [3] is sealed to the cavity with putty [4], such that the tip [5] is even with the cavity wall and the sound outlet [6] is approximately centered in the opening. Vent [7] is sealed at the faceplate.

FIGURE 39.3 The HA-2 hearing aid coupler. The coupler microphone [2] is concentric with the cavity [1], which has a diameter between 18 and 21 mm and a volume of $2.0 \text{ cm}^3 \pm 1\%$. Entrance to the cavity is through an earmold substitute [3] having a 3-mm diameter sound bore with a length of 18 mm. The earphone [4] is sealed to the earmold substitute with a suitable sealing mechanism [5].

coupler (Figure 39.3) has the entrance to the cavity through an earmold substitute having a 3-mm diameter sound bore that is 18-mm long. All hearing aids that couple to the ear by means of a length of tubing are to be tested using type HA-2 with entrance through a tube. ANSI/ASA S3.22 permits two variations on the tubing used in this coupler. The first is intended for most postauricular (behind-the-ear) hearing aids and consists of a rigid tube with a 2-mm inside diameter and a length of 25 mm between the earmold substitute and the tip of the ear hook (Figure 39.4). The second variation (type HA-4) is like the first except that both the earmold substitute and the connecting tubing have a 1.93-mm diameter sound bore, creating a uniform sound path with a length of 43 mm. This was originally intended for use with eyeglass hearing aids, which used skeleton-type earmolds and a continuous length of no. 13 tubing (inside diameter of 1.93 mm).

A third variation of the HA-2 coupler is permitted by ANSI/ASA S3.22 for testing modular in-the-ear hearing aids. In this variation, designated the HA-3 coupler, the tubing connects directly from the hearing aid receiver outlet to the entrance to the cavity. This tubing is required to have an inside diameter of 1.93 mm and a length from the receiver case to the cavity entrance of 10 mm.

FIGURE 39.4 The HA-2 coupler with entrance through a rigid tube. The coupler microphone [2] is concentric with the cavity [1], which has a diameter between 18 and 21 mm and a volume of $2.0 \text{ cm}^3 \pm 1\%$. Entrance to the cavity is through an earmold substitute [3] having a 3-mm diameter sound bore with a length of 18 mm. Coupling from the tip of the hearing aid hook [4] to the earmold substitute is via a rigid tube [5] with a 2-mm inner diameter and a length of 25 mm.

The coupler to be used for postauricular hearing aids with the receiver in the ear canal is not explicitly indicated in ANSI S3.22, but the HA-1 coupler is intended to be used with hearing aids having ear tips (ANSI S3.7, 1995), and this is the logical choice for reporting test results for these devices. The tip and coupling system used should be of average size and should be stated.

Vented or Open Fittings

There are no standardized couplers (see the following “Ear Simulators” section) or test methods capable of characterizing hearing aids operating with large vents or in open ear canals. “Open-fit” hearing aids must be tested using one of the closed coupler configurations previously described. Postauricular hearing aids with thin coupling tubes are

often provided with a standard ear hook; thus, they can be tested using the HA-2 coupler. If this is not the case, the open end of the thin tube must be sealed to the entrance of the HA-1 coupler using an adapter or an appropriate sealant. The exact configuration should be specified by the manufacturer, and any required adapters should be available from the manufacturer for test purposes.

EAR SIMULATORS

The 2-cc coupler does not accurately represent the acoustic impedance or resonances of a real ear, and its usefulness as a test load is confined to the 200- to 5,000-Hz range. Ear simulators are designed to more closely approximate the acoustic impedance and resonance characteristics of an average of ears over a wide frequency range. Their use is required when realistic estimates of performance of deep insertion, vented and open fittings, and feedback suppression systems are desired. In some cases, a pinna may be part of the simulator, and the combination may be part of an acoustic manikin.

Simulators are more complex, more expensive, and more difficult to maintain than the 2-cc coupler, and this has confined their use to the laboratory. The Zwislocki coupler (Zwislocki, 1971), which is no longer commercially available, is one such ear simulator. Standards for occluded ear simulators (OES) are ANSI/ASA S3.25 (ANSI S3.25, 2009) and IEC 60318-4 (2010).

AMERICAN NATIONAL STANDARDS INSTITUTE HEARING AID TESTS

In recent years, there has been a concerted effort to harmonize ANSI and IEC standards relating to hearing aids by one organization directly adopting all or part of a standard produced by the other. As a result, there are now few differences between parallel standards and those differences tend to be small.

There are five standards published by ANSI that relate to the testing of hearing aids. These are described here.

First is ANSI/ASA S3.22, Specification of Hearing Aid Characteristics (ANSI S3.22, 2009). This standard describes methods of measuring a number of hearing aid characteristics and provides allowable tolerances for those that are deemed important for the maintenance of product uniformity and compliance with published specifications. The parallel IEC standard is IEC 60118-7 which is currently under revision and has largely been harmonized with ANSI/ASA S3.22.

The use of portions of the 2003 version of this standard is mandated by the Food and Drug Administration (FDA). As of this writing, the use of the 2009 revision has not been mandated by the FDA. This standard also contains procedures for many other tests that are not required by the FDA. The differences between the 2003 and 2009 versions are small, the most significant of which are the inclusion of

a definition of compression, expansion, compression ratio, and expansion ratio, the allowance of the use of a broad-band noise signal for gain measurement if the result does not differ from the gain measured with a puretone by more than 1 dB, and the removal of tolerances on input–output

and attack–release time tests for AGC instruments and their relocation to an informative annex.

All hearing aid manufacturers are required to include in the product brochure or other labeling that accompanies the hearing aid the technical data listed in Table 39.3 with

TABLE 39.3

Data Obtained from ANSI S3.22-2003 that Must be Provided by the Hearing Aid Manufacturer in a Product Brochure or in Other Labeling that Accompanies a Hearing Aid

Requirement	Description of Required Data
Abbreviations	HFA: High-frequency average—the average of values at 1,000, 1,600, and 2,500 Hz SPA: Special-purpose average—the average of values at three frequencies specified by the hearing aid manufacturer that are at one-third octave frequencies separated by two-thirds octave RTS: Reference test setting—setting of the gain control [i.e., volume control, master or overall gain control] required to produce an HFA gain within ± 1.5 dB of the HFA-OSPL90 minus 77 dB for a 60-dB input sound pressure level [SPL] or, if the full-on HFA gain for a 60-dB input SPL is less than the HFA OSPL90 minus 77 dB, the full-on setting of the gain control AGC: Automatic gain control—means for controlling gain as a function of signal level; it includes various forms of compression
OSPL90 curve	Coupler SPL as a function of frequency for a 90-dB input SPL and gain control at full on
HFA-OSPL90	The average of the OSPL90 values at the HFA or SPA frequencies
HFA full-on gain [HFA-FOG]	The average of the full-on gain at the HFA or SPA frequencies
Reference test gain [RTG]	The average of the gain at the HFA or SPA frequencies for a 60-dB input SPL, with gain control at RTS
Frequency response curve	The coupler SPL as a function of frequency for a 60-dB input SPL, with gain control at RTS
Frequency range	The range between the lowest and the highest frequency at which the frequency response curve is 20 dB below its HFA or SPA value
Total harmonic distortion [THD]	The ratio of sum of the powers of all the harmonics to the power of the fundamental
Equivalent input noise [EIN]	The SPL of an external noise source at the input that would result in the same coupler SPL as that caused by all the internal noise sources in the hearing aid
Battery current	The electrical current drawn from the battery when the input SPL is 65 dB at 1,000 Hz and the gain control is at RTS
Induction coil sensitivity [HFA-SPLITS]	For hearing aids with an inductive input coil [telecoil], the average of the coupler SPL at the HFA or SPA frequencies when the hearing aid, with gain control at RTS, is appropriately positioned on a telephone magnetic field simulator [TMFS]
Input–output curve	For hearing aids with AGC, the coupler SPL as a function of the input SPL at one or more of 250, 500, 1,000, 2,000, 4,000 Hz, with the gain control at RTS
Attack time	For hearing aids with AGC, the time between an abrupt change from 55- to 90-dB input SPL and the time when the coupler SPL has stabilized to within 3 dB of the steady value for a 90-dB input SPL, at one or more of 250, 500, 1,000, 2,000, or 4,000 Hz, with the gain control at RTS
Release time	For hearing aids with AGC, the time between an abrupt change from 90- to 55-dB input SPL and the time when the coupler SPL has stabilized to within 4 dB of the steady value for a 55-dB input SPL, at one or more of 250, 500, 1,000, 2,000, or 4,000 Hz, with the gain control at RTS

Food and Drug Administration—Mandated ANSI S3.22-2003 Tests and their Parameters and Tolerances

Test	Gain Setting	AGC	Input	Frequency	Measure or Calculate	Tolerance
OSPL90 curve	Full on	Min	90 dB SPL	200–5,000 Hz	Coupler SPL	Unspecified
Maximum OSPL90	Full on	Min	90 dB SPL	Frequency of maximum	Maximum of OSPL90 curve	+3 dB
HFA- or SPA-OSPL90	Full on	Min	90 dB SPL	HFA or SPA	Average coupler SPL at HFA or SPA frequencies	±4 dB
HFA or SPA full-on gain (HFA- or SPA-FOG)	Full on	Min	50 dB SPL	HFA or SPA	Average gain at HFA or SPA frequencies	±5 dB
Reference test gain (RTG)	RTS	Min	60 dB SPL	HFA or SPA	Average gain at HFA or SPA frequencies	Unspecified
Frequency range	RTS	Min	60 dB SPL	From the lowest frequency (f_1) to the highest frequency (f_2) at which the frequency response curve is 20 dB below its HFA or SPA average		Unspecified
Frequency response curve	RTS	Min	60 dB SPL	From the higher of f_1 or 200 Hz to the lower of f_2 or 5,000 Hz; wider range may be shown	Coupler SPL or gain	±4 dB from the lesser of 1.25 f_1 or 200 Hz to 2 kHz ±6 dB from 2 kHz to the lesser of 4 kHz or 0.8 f_2
Total harmonic distortion (THD)	RTS	Min	70 dB SPL 65 dB SPL	500, 800, or half the lower two SPA frequencies 1,600 or half the highest SPA frequency		+3%
Equivalent input noise (EIN)	RTS	Min	OFF and 50 dB SPL	[Coupler SPL with no input]–[HFA or SPA gain with a 50-dB input SPL]		+3 dB
Battery current	RTS	Min	65 dB SPL	1,000 Hz	Battery current	+20%
SPL for an inductive telephone simulator (SPLITS)	RTS	Min	TMFS	200–5,000 Hz	Coupler SPL. Orient aid on TMFS for maximum output. Place BTE as flat as possible on test surface. ITE and ITC with faceplate as close as possible and parallel to test surface	Unspecified
HFA or SPA SPLITS	RTS	Min	TMFS	HFA or SPA	Average SPLITS values at the HFA or SPA frequencies	±6 dB
Input-output curves	RTS	Max	50–90 dB SPL in 5-dB steps	One or more of 250, 500, 1,000, 2,000, 4,000 Hz	Coupler SPL versus input SPL	±5 dB at 50- and 90-dB input SPL when matched at 70-dB input SPL
Attack time	RTS	Max	Step from 55 to 90 dB SPL	Same frequencies used for input-output curves	Time from input step until coupler SPL settles within 3 dB of its steady value for 90-dB input SPL	±5 ms or 50%, whichever is greater
Release time	RTS	Max	Step from 90 to 55 dB SPL	Same frequencies used for input-output curves	Time from input step until coupler SPL settles within 4 dB of its steady value for 55-dB input SPL	±5 ms or 50%, whichever is greater

AGC, automatic gain control; Min, minimum; Max, maximum; SPL, sound pressure level; RTS, reference test setting; HFA, high-frequency average; SPA, special-purpose average; TMFS, telephone magnetic field simulator; BTE, behind-the-ear; ITE, in-the-ear; ITC, in-the-canal.

measurement conditions and tolerances as given in Table 39.4. When troubleshooting a hearing aid, these required data are the benchmarks against which measured performance should be verified. It should be noted that, when verifying compliance with manufacturers' specifications, the indicated tolerance plus measuring equipment accuracy must be added to the value listed by the manufacturer. For example, if the measurement equipment accuracy is ± 1 dB and the tolerance given in the table for a particular test is ± 4 dB, then a measured value within ± 5 dB of the value listed by the manufacturer would be considered to be within specification.

When interpreting the results of the tests included in this ANSI standard, it is important to remember the following points:

1. ANSI S3.22 is a quality control standard. The data apply only for the puretone signals and measurement conditions, hearing aid settings, and configuration employed when they were generated. They do not predict performance for other signals, conditions, settings, or configurations.
2. Measurements are defined only for the frequency range 200 to 5,000 Hz. A wider range may be shown for informational purposes.
3. Attack and release times include any processing delay through the hearing aid. For digital hearing aids, this will account for some fixed portion of the reported times, typically between 3 and 10 ms. Given the allowed tolerances on these quantities, this is unlikely to be significant.
4. Attack and release times are very dependent on the hearing aid settings and the test protocol. Do not assume they represent times likely to be experienced in actual use.

The second standard is ANSI/ASA S3.35, Method of Measurement of Performance Characteristics of Hearing Aids under Simulated Real-Ear Working Conditions (ANSI S3.35,

2010). This standard provides terminology and techniques for the precise determination of simulated insertion gain, three-dimensional directional response, and directivity index using a suitable manikin and ear simulator. It gives requirements for the test space (typically a large anechoic chamber) and the test equipment. Hearing aids must be placed in a linear, nonadaptive mode of operation. This is a voluntary standard, and its use is not mandated by any government regulation. The parallel IEC standard is IEC 60118-8: Methods of measurement of performance characteristics of hearing aids under simulated in situ working conditions.

The third standard is ANSI/ASA S3.42 Part 1, Testing Hearing Aids with a Broad-Band Noise Signal (ANSI S3.42, 1992). This standard defines the spectrum of a broadband noise test signal and specifies analysis methods for obtaining the steady-state output and gain of hearing aids using this signal. It should be noted that the specified spectrum of the test signal is that of the peaks of speech, not the long-term average speech spectrum (LTASS). As such, it has considerably more high-frequency content than is found in speech-weighted noise based on the LTASS (see Figure 39.5 for a representation of the S3.42 Part 1 noise spectrum and LTASS). As noted in the standard, the steady-state gain and output obtained using this standard are not representative of the gain or output for real speech signals processed by compression hearing aids (Henning and Bentler, 2005; Scollie and Seewald, 2002). This is a voluntary standard, and its use is not mandated by any government regulation. The parallel IEC standard is IEC 60118-0: Measurement of electroacoustical characteristics, which is currently under revision.

The fourth standard is ANSI/ASA S3.42/Part2 (ANSI S3.42, 2012), Methods for Characterizing Signal Processing in Hearing Aids with a Speech-Like Signal. This is a direct adoption of IEC 60118-15 which specifies an International

FIGURE 39.5 The ANSI S3.42-1992 noise spectrum and selected long-term average speech spectra.

Speech Test Signal (ISTS) to be used as the input signal for all tests. This signal was derived by combining segments of recorded speech from six female talkers speaking different languages. The hearing aid output in an ear simulator or 2-cc coupler is analyzed in one-third octave bands and the 30th, 65th, and 99th percentiles of the distribution of SPL in each band are calculated. This is then converted to a coupler or estimated real-ear gain for the three percentiles and the LTASS.

Finally, the fifth standard is ANSI/ASA S3.46, Methods of Measurement of Real-Ear Performance Characteristics of Hearing Aids (ANSI S3.46, 2013). This standard defines terms used in real-ear measurements and provides guidance on procedures for both closed and vented fittings, sources of error, and essential reporting and equipment requirements. A definition and procedure for measuring the real-ear to coupler difference (RECD) and an annex describing sources of error in its measurement and application are among the changes in this revision. This is a voluntary standard, and its use is not mandated by any government regulation.

Troubleshooting Using ANSI/ASA S3.22 Tests

Most commercial hearing aid analyzers provide automated test sequences that make it easy to run the FDA-mandated hearing aid tests of ANSI/ASA S3.22. Although these tests do not represent performance at “use” settings, it is good practice to run them for comparison with manufacturers’ data when a hearing aid is first received, when it has been repaired, or when a malfunction is suspected.

The tests of ANSI/ASA S3.22 are run with all adaptive features disabled and three different hearing aid setups (for more in-depth discussion of some of the hearing aid parameters discussed in the following list, the reader is referred to Chapter 38):

- The output sound pressure level with a 90-dB input (OSPL90) and full-on tests are run with any automatic gain control (AGC) function set for minimum effect (i.e., its most linear operation) and the maximum output and gain set to their highest values. Most programming software provide a setting that accomplishes this. If this is not the case, setting the AGC function for minimum effect may be accomplished by disabling the AGC (if possible), by setting the compression threshold to its highest setting, and/or by setting the compression ratio as close to 1.0 as possible, while still keeping maximum output and gain at their highest values.
- All other tests are run with the gain control at the reference test setting. Most programming software provide a setting for this. If this is not the case, most commercial hearing aid test systems provide automated assistance in making this adjustment.
- Attack and release times and input–output curve tests are performed with the AGC function set to have maximum

effect. Some programming software may provide a setting that does this. If not, setting the AGC function for maximum effect may be accomplished by setting low-level gain as high as possible and setting high-level gain and maximum output as low as possible. This will typically result in a very low compression threshold, a very flat input–output curve above this threshold, and maximum attack and release times. These results should be interpreted as representing the extremes of what is attainable, not what is typical in use.

Manufacturers are required to indicate the control or software settings or provide test programs used for all tests. These settings must be used when verifying performance against test strips or specification sheets.

Before running the ANSI/ASA S3.22 tests, clinicians should do the following:

1. Install a fresh battery, or use the battery substitute in the analyzer.
2. For behind-the-ear aids, ensure that the plastic tubing on the HA-2 coupler is flexible, free from splits, and of the correct length and diameter. The tubing between the tip of the ear hook and the entrance to the earmold simulator should be 2 mm in diameter and 25 mm in length. Some analyzers include all of this tubing within the HA-2 coupler, using a very short piece of earmold tubing only to seal the tip of the ear hook to the internal tubing. Others include varying amounts of the 2-mm section within the coupler, with the remainder (usually 15 to 25 mm) made up of flexible tubing added by the user. In these cases, both the internal diameter and the total length must be as per the ANSI guidelines.
3. For behind-the-ear aids, ensure that the ear hook and dampers are as specified in the manufacturer’s test data and that they are free of obstructions.
4. In-the-ear, in-the-canal, completely-in-the-canal, and other deep-insertion hearing aids should be well sealed to the HA-1 coupler with their tip flush with the entrance to the 2-cc cavity.
5. Any wax guards or microphone screens specified by the manufacturer must be in place and free of obstructions. Any not specified by the manufacturer should be removed.
6. Vents must be plugged at the faceplate (custom aids) or external (behind-the-ear) end.
7. The hearing aid should be set to the omnidirectional mode, its widest frequency response range, greatest high-frequency average (HFA) OSPL90 or special-purpose average (SPA) OSPL90, and, if possible, greatest HFA or SPA full-on gain. The HFA frequencies are 1,000, 1,600, and 2,500 Hz; the SPA frequencies are specified by the manufacturer and are one-third octave frequencies separated by two-thirds octave. Any AGC function should be set to have minimum effect, and any adaptive features should be disabled. Settings or a program

TABLE 39.5

Deviations from Manufacturers' Specifications and their Possible Cause and Remedy

ANSI Test	Result	Possible Cause—Remediation
OSPL90 curve	Large peaks or notches in the low to mid-frequencies [see Figures 39.6 and 39.7]	Open vent— <i>close at faceplate end</i> Poor seal of hearing aid tip to HA-1 coupler— <i>reseal</i> Cracked tubing on HA-2 coupler— <i>replace</i> Defective ear hook— <i>replace</i>
OSPL90 curve	Curve is very jagged	Aid is not set to test program— <i>correct settings</i>

ANSI, American National Standards Institute; HFA, high-frequency average; FOG, full-on gain.

to achieve these conditions should be provided by the manufacturer.

Table 39.5 lists some potential deviations from manufacturers' specifications and their possible cause and remedy.

It is important to make sure that any given test has been run properly, with the hearing aid set exactly as specified, before attempting to draw any conclusions from the test results. Failing to close vents or improper sealing of the hearing aid or earpiece to the HA-1 coupler can result in

curves like those in Figures 39.6 and 39.7. Please note that both curves are output SPL curves versus the typically displayed gain curves when illustrating the effects of venting on hearing aid performance.

Some "rules of thumb" for interpreting ANSI/ASA S3.22 test results are as follows:

- OSPL90 tests generally provide information about the output components of the hearing aid (i.e., receiver, hook, dampers, wax guards) or the power source.

FIGURE 39.6 Effect of an open vent on an OSPL90 curve for an in-the-ear hearing aid. The lower curve [1] is the correct curve, obtained with the vents sealed at the faceplate [outer] end; the upper curve [2] is obtained with the vent open; note that the low-frequency sound enters directly through the open vent unamplified, yielding more low-frequency energy in the output than if the vent was plugged. In addition, the open vent, in conjunction with the 2-cc cavity, forms a resonator for sounds entering directly through the vent, resulting in the boost observed at 500 Hz. This effect depends on vent dimensions, the hearing aid, and its settings.

- Gain tests generally provide information about both the output and the input components of the hearing aid (i.e., microphones, wind filters).
- Distortion tests generally provide information about the receiver or power source.
- Equivalent input noise tests will generally provide information about the microphone(s).
- AGC tests may detect faulty components in analog circuits, but in digital hearing aids, these characteristics are controlled by software. Consequently, for digital circuits,

FIGURE 39.7 Effect of a poor seal to the coupler on the OSPL90 curve for an in-the-canal hearing aid. The smooth curve [2] is obtained with a good seal; the irregular curve [1] is obtained with a poor seal to the coupler. The magnitude of the effect depends on the hearing aid and its settings.

it is extremely unlikely that these tests will be failed by themselves. Failures in digital circuits are more likely to impact many or all of the tests.

TROUBLESHOOTING WHEN ANSI/ASA S3.22 CANNOT BE USED

Sometimes data sheets or test strips are not available, programming software is not at hand, programming connectors are broken, cables cannot be readily obtained, or the hook is not the one used for the ANSI tests. In these cases, test results cannot be directly compared with ANSI specifications to determine if the hearing aid itself is functioning properly. The hearing aid analyzer then becomes a useful tool for probing the hearing aid to determine if it is performing in an acceptable fashion.

Perhaps the simplest deviation from the ANSI test conditions is the use of an ear hook different from the one used to generate the specifications. Running the ANSI tests with a different hook, especially one with different dampers, is likely to change the peaks in the OSPL90 and frequency response curves and the numerical data derived from them. However, the data should still indicate whether the hearing aid is performing reasonably close to expectations. If the ear hook is damaged or permanently blocked and a replacement is not readily available, it is still possible to determine if the hearing aid itself is functioning by replacing the hook with a length of earmold tubing that has the same length as the hook (this gets added to any tubing that would normally be attached to the coupler). Figure 39.8 shows frequency response curves

for a behind-the-ear aid with the proper damped ear hook (lower curve) and with the hook replaced with earmold tubing having the same length as the ear hook but without dampers (upper curve). Although the peaks in the response curve are no longer damped, running an ANSI test battery in this case will still provide data that may be compared to the ANSI specifications to help decide if the hearing aid is functioning properly and simply needs a new hook or if it has more serious problems and needs to be sent for repair.

If it is not possible to disable adaptive features as required for the ANSI tests or if it is simply desired to test the hearing aid at its “use” settings, consideration must be given to the response of the adaptive features to the test signal being used. Adaptive features are most likely to be activated by signals that are tonal or unchanging, and this activation may occur some time after the signal is applied. Running an ANSI test battery in this situation may produce erratic OSPL90 and frequency response curves. Tests of distortion or attack/release time are unlikely to be reliable because the relatively long duration of these tests will likely give the adaptive features time to react.

USE OF ACOUSTIC STIMULI TO ASSESS NONADAPTIVE HEARING AID CHARACTERISTICS

Tests Using Speech-Like Test Signals

There are a number of ways to extract useful information about the condition of the hearing aid without disabling

FIGURE 39.8 Effect of ear hook on frequency response curves. The lower curve [2] was obtained with the manufacturer-specified damped ear hook. The upper curve [1] was obtained with the hook replaced with earmold tubing having the same length as the ear hook and no dampers.

FIGURE 39.9 Using speech to check hearing aid operation with adaptive features enabled. The *hatched area* is the amplified speech region bounded by the peaks of speech at the top and the valleys at the bottom. The *heavy curve* is the long-term average speech spectrum (LTASS), the *circles* are the hearing threshold converted to sound pressure level (SPL), and the *elongated + marks* are the NAL-NL1 real-ear targets for the amplified LTASS. The input was real speech at 65 dB SPL. Ear canal SPL has been estimated by adding an average real-ear to coupler difference (RECD) to the coupler SPL. Noise reduction, feedback suppression, and adaptive directional features are enabled.

adaptive features. The method with the least likelihood of inadvertently triggering noise reduction, feedback suppression, or adaptive directional features uses speech-like signals and determines gain or output. These may be real speech signals or speech-like signals such as the ISTS (ANSI S3.42, 2012), modulated noise, or International Collegium of Rehabilitative Audiology (ICRA) noise, a signal derived by digital manipulation of real speech (Dreschler et al., 2001). The amplified speech-like signal may be compared to the patient's hearing thresholds or to targets for amplified speech generated from the threshold data. Fitting methods such as Desired Sensation Level (DSL) and National Acoustics Laboratories—Nonlinear (NAL-NL1, NAL-NL2) are based on amplifying speech to some desired level and yield targets for the amplified LTASS. Figure 39.9 shows the estimated ear canal SPL produced by a hearing aid amplifying real speech at 65 dB input SPL. The measured coupler SPL has been converted to ear canal SPL by adding the RECD so that it may be compared with the SPL threshold and real-ear NAL-NL1 speech targets. Noise reduction is set for maximum effect and feedback suppression, and adaptive directional features are enabled. In Figure 39.9, the hatched area is the amplified speech region bounded by the peaks of speech at the top and the valleys at the bottom. The circles are the hearing thresholds converted to SPL and the elongated + marks are the NAL-NL1 targets for the amplified LTASS. Most of the speech region is above threshold, and the LTASS of the amplified speech is close to the NAL-NL1 targets, indicating

that this hearing aid is providing adequate amplification for speech at this level. The test may be repeated at other levels to ensure that expansion does not reduce gain for low-level speech signals and that compression keeps loud speech well below levels that might cause discomfort.

It must be emphasized that, when testing hearing aids with compression or any other adaptive processing features, the results obtained will be valid only for the test signal used (Henning and Bentler, 2005; Scollie and Seewald, 2002). Tests using speech-like test signals provide the most reliable indication that audibility goals are being met. If speech-like test signals are not available, the tests described in the following sections may provide estimates of electroacoustic parameters useful in deciding whether a hearing aid is performing as expected.

Tests Using Short-Duration Broadband Noise

If speech-like test signals are not available, tests that use short-duration broadband noise signals may be used to inspect the operation of the hearing aid. Since compression systems typically have millisecond attack times, whereas adaptive features usually have an onset time of several seconds, such signals will frequently show the operation of compression, free of the confounding effects of adaptive features. Figure 39.10 shows the gain obtained with a pink noise signal of 2 seconds in duration presented at (top to

FIGURE 39.10 Using short-duration noise to check hearing aid operation. Curves are the coupler gain for pink noise presented for 2 seconds at [top to bottom] 45-, 60-, 75-, and 90-dB sound pressure level [SPL] for the same hearing aid and same settings used in Figure 39.9. The vertical lines at 500, 1,000, 2,000, and 4,000 Hz indicate one-third to one-half the hearing loss for which this hearing aid was programmed.

bottom) 45, 60, 75, and 90 dB SPL for the same hearing aid and same settings used in Figure 39.9.

- Observe that the gain curves are free from sharp peaks or abrupt dips, and they resemble curves for similar hearing aids.
- The gain for 45 dB input SPL is 4, 18, 27, and 31 dB at 500, 1,000, 2,000, and 4,000 Hz, respectively. The half-gain rule would indicate that this hearing aid might be appropriate for a hearing loss of about 35 at 1 kHz, 55 at 2 kHz, and 60 at 4 kHz.
- The 45- and 60-dB curves are closely spaced, indicating a compression threshold below 60 dB SPL.
- The 60-, 70-, and 90-dB curves are separated by about 7 to 8 dB over much of the useful frequency range. This indicates wide dynamic range compression (WDRC) with a compression ratio (input change/output change) of about 2.
- The 90-dB gain curve can be used to give a rough estimate of the OSPL90 of the hearing aid by adding 90 dB to the gain. This yields an estimated OSPL90 at 500 Hz, 1, 2, and 4 kHz of 90, 97, 102, and 103 dB, respectively, with a peak of about 108 dB at about 2.7 kHz.

These tests provide a good deal of information about this hearing aid and may be used to judge if it is functioning as intended. Refer back to Table 39.5 for a listing of possible causes and remediation of irregular response curves, low gain, and low maximum output.

Tests Using Short-Duration Tones

A test that can shed some light on hearing aid operation when it is not possible to change its programming is an input–output test. This test uses tones that are increased in 5-dB steps every few hundred milliseconds. The levels are maintained long enough to show the operation of compression but change frequently enough not to be attacked by adaptive features. Figure 39.11 shows input–output curves at various frequencies for the same hearing aid and same settings used in Figures 39.9 and 39.10. In each panel, the horizontal axis is the input SPL, and the vertical axis is the output SPL.

1. For a 90 dB input SPL, the output at 500, 1,000, 2,000, and 4,000 Hz is 90, 94, 99, and 99 dB SPL, respectively.
2. The gain is the difference between the output SPL and the input SPL. For a 45 dB input SPL, the gain at 500, 1,000, 2,000, and 4,000 Hz is 5, 18, 28, and 25 dB, respectively.
3. The compression ratio is obtained by dividing a change in input SPL (e.g., 10 dB) by the corresponding change in output SPL. A compression ratio of 1 (a diagonal line) is linear amplification, less than 1 indicates expansion, and greater than 1 indicates compression. The 250-Hz panel shows a compression ratio of about 0.5 (expansion) below 50 dB SPL and about 1 (linear) above about 60 dB SPL input. The 2,000-Hz panel shows a compression ratio of about 2 above 50 dB SPL.

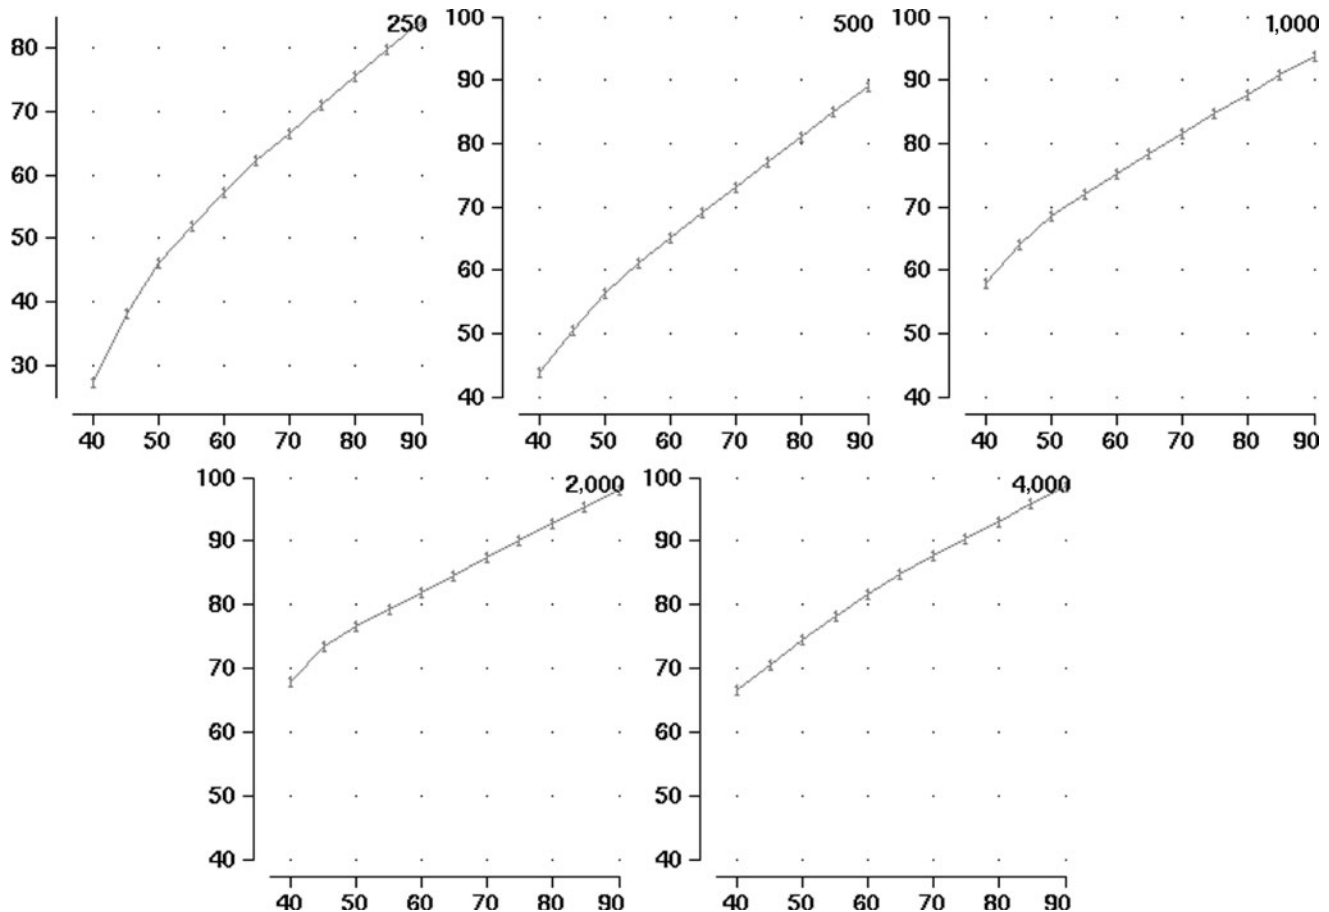

FIGURE 39.11 Using short-duration tones to generate input–output curves to check hearing aid operation. Curves are coupler sound pressure level (SPL; *vertical*) for varying input SPL (*horizontal*). The hearing aid and settings are the same as those for Figure 39.9.

- The lowest input SPL at which the compression ratio exceeds 1 is often referred to as the “compression threshold” or “kneepoint.” The compression threshold at 500, 1,000, 2,000, and 4,000 Hz is about 55, 50, 45, and ≤ 40 dB SPL, respectively.

High-level short-duration tone bursts are sometimes used in real-ear measurement equipment to determine the maximum output capabilities of a hearing aid without causing discomfort to the patient or risking further hearing damage. These tone bursts are typically long enough to activate compression limiting but short enough to avoid triggering adaptive features. If such a signal is available in a hearing aid analyzer, it may be employed to estimate the OSPL₉₀ of the hearing aid without the need to disable noise reduction, feedback suppression, or adaptive directional systems. Figure 39.12 shows the 2-cc coupler SPL in response to a series of 90-dB tone bursts at one-third octave intervals for the same hearing aid and same settings used in Figures 39.9 to 38.11. The estimated OSPL₉₀ at 500, 1,000, 2,000, and 4,000 Hz is 86, 93, 98, and 100 dB, respectively.

Short-duration tone tests may be expected to produce somewhat different estimates of gain, maximum output, compression threshold, and compression ratio than those obtained using brief broadband noise signals because the two signals are likely to be treated differently by compression systems. However, either is sufficiently accurate when the goal is simply to determine whether a hearing aid is functioning as expected and it is not possible or desired to change settings.

VERIFYING DIGITAL FEATURES USING HEARING AID ANALYZERS

The proliferation of digital technology in hearing aids has led to the introduction of features designed to address issues beyond amplification. These features may be significant factors in the selection and successful use of a hearing instrument, and their proper operation should not be taken for granted. These features are disabled for the standard tests of ANSI/ASA S3.22, but most hearing aid analyzers can be used to verify and document the functioning

FIGURE 39.12 Using tone bursts to check maximum output with adaptive features enabled. Tone bursts were 128 ms in duration presented at 90-dB sound pressure level [SPL] at one-third octave frequencies. The hearing aid and settings are the same as those for Figure 39.9.

of noise reduction, adaptive directional microphones, and feedback suppression features. The following tests have been found to work on many current hearing aids but may not be applicable to all hearing aids and may not work with future hearing aids.

Functional Check of Adaptive Noise Reduction

Most noise reduction algorithms operate by reducing gain in frequency bands in which the signals do not exhibit the modulation characteristics of speech (Chung, 2004a). A steady broadband noise signal may be used to verify the functioning of such systems. In Figure 39.13, the upper curve (1) shows the gain for a steady 60-dB SPL pink noise signal when it is first applied, whereas the lower curve (2) shows the gain when it has stabilized 10 seconds later. The noise reduction algorithm has reduced the gain by about 12 dB at 1 kHz. This test also provides some idea of the speed with which the hearing aid responds to the onset of noise. To avoid the confounding effects of adaptive directional response, it may be necessary to set the aid to omnidirectional mode before performing this test.

The noise reduction algorithm should not reduce the gain for a speech signal. This can be verified if the hearing aid analyzer provides speech-like test signals. That is, there should be no change in output for these signals when the noise reduction feature is toggled between minimum (or off) and maximum reduction.

Functional Check of Directional Hearing Aids

Accurately testing directional hearing aids requires a large test space and specialized equipment (ANSI S3.35, 2010). However, it is possible to use a hearing aid analyzer to determine if the directional feature is functioning as expected. Note, however, that such tests performed in a small test chamber will not produce results that can be compared with published specifications. They will generally show less directionality, especially at lower frequencies.

It is usually recommended that the hearing aid be set for linear operation with a fixed directional pattern and to switch off any adaptive noise reduction and feedback suppression algorithms before attempting to measure directional performance. This is because gain or output for sounds from different directions is usually determined by making measurements from different directions at different times. Compression or adaptive features may change the gain or output of the hearing aid between successive measurements, resulting in erroneous measures of directional performance.

To test directional function, the hearing aid is set as indicated earlier, and a gain or output curve for a 50- to 65-dB broadband signal (e.g., pink noise) is obtained, with the hearing aid oriented so that its direction of maximum sensitivity is toward the loudspeaker (within 45°). Next, the hearing aid is oriented so that the direction of maximum sensitivity is away from the loudspeaker, and the test

FIGURE 39.13 Functional check of adaptive noise reduction feature. The upper curve [1] shows the gain for a steady 60-dB sound pressure level [SPL] pink noise signal when it is first applied, whereas the lower curve [2] shows the gain when it has stabilized 10 seconds later.

is repeated. The second curve should lie below the first, at least in the mid-frequencies, with the separation between the curves being an indication that the directional feature is functioning. This is a functional test only, and the curve separation obtained in this way is not expected to correlate with standard measures of directional performance. As an additional check, the tests should be repeated with the hearing aid in omnidirectional mode. In this case, the two curves should be nearly coincident.

Some hearing aid analyzers provide special signals for testing directional function in a test chamber that has two speakers (Smriga, 2004). In this case, the test can be performed without setting the hearing aid for linear operation or switching off adaptive algorithms. This scheme delivers two separate signals, each containing over 500 different tones, from two directions simultaneously. Digital analysis separates the coupler signal into two frequency response curves, one for each direction, and the separation between these curves shows the functioning of the directional microphone(s). The operation of compression or noise reduction impacts both response curves, but their separation remains unaffected. Such a test may also reveal the signal level at which change is initiated and the time required for change to occur. The end result of such a test is shown in Figure 39.14. In each panel, the bold curve is the response from a source in the front hemisphere, whereas the lighter curve is the response from a source in the rear hemisphere obtained using two simultaneous pink noise signals. Panel A shows an omnidirectional response immediately after

signal presentation, whereas panel B shows the directional response after the signals have been presented for 20 seconds. This test may be modified by adding speech to the sound source in the front hemisphere to test hearing aids that change their directional response pattern as a function of signal-to-noise ratio rather than noise level.

A hearing aid may fail to show any appreciable directional function using these tests for the following reasons:

1. The hearing aid has been oriented so that gain is about the same for signals from both directions tested. Some directional patterns have rear or side lobes with gain comparable to the front lobe at some angles. This can be checked by changing the orientation used for the test.
2. The hearing aid is not set for directional operation. This may result from failure of a programming or directional switch, failure to enable the feature in the programming software, an automated decision within the programming software, or a failure of hardware or software.
3. Blockage of the microphone ports on the hearing aid.
4. Microphone drift in two-microphone directional systems. These systems rely on well-matched microphones for their directional performance. Microphone sensitivity changes with temperature, humidity, and time, all of which can degrade directional performance. Some hearing aids self-correct for these changes, but those that do not can cease to be directional hearing aids.
5. Miswired or improperly assembled microphones in the hearing aid.

FIGURE 39.14 Functional check of adaptive directional feature. In each panel, the *bold curve* is the response from a source in the front hemisphere, whereas the *lighter curve* is the response from a source in the rear hemisphere obtained using two simultaneous pink noise signals. **(A)** An omnidirectional response immediately after signal presentation. **(B)** The directional response after the signals have been presented for 20 seconds.

Functional Check of Feedback Suppression Systems

Feedback occurs when the gain through the hearing aid (the forward path) plus the attenuation from the ear canal back to the hearing aid microphone (the feedback path) is greater than 0 dB, with a phase shift that is an integer multiple of 360° . The sum of the gain through the forward path and the attenuation (negative gain) through the feedback path is termed the open loop gain.

Feedback suppression systems operate by reducing the gain of the forward path at frequencies where the open loop gain would otherwise exceed 0 dB. This may be accomplished either through filters in the forward path or by subtracting from the microphone signal an estimate of the signal in the feedback path (called phase cancellation). In some systems, no action is taken to change the forward path gain until feedback, in the form of a persistent tonal signal, is detected. Freed and Soli (2005) have classed these as “detectors.”

Other systems can measure the attenuation of the feedback path during the fitting process by internally applying a known electrical test signal to the hearing aid receiver and measuring the resulting signal at the hearing aid microphone. Freed and Soli (2005) have classed these as “initialized” systems. In the case of forward path filters, this information is used to reduce (or limit) the gain in frequency regions where the open loop gain would otherwise exceed 0 dB. In the case of phase cancellers, the same test signal being applied to the hearing aid receiver is also applied to a digital filter, which is automatically adjusted until its out-

put approximates the signal being measured by the hearing aid microphone. The digital filter then effectively becomes a simulation of the feedback path. In operation, the output of this filter is subtracted from the microphone signal, canceling that portion of the microphone signal that is due to the feedback path. To avoid the initialization step and to accommodate changing feedback paths, some phase cancellers employ an adaptive digital filter that is continuously adjusted to minimize the difference between its output and the microphone signal, using ambient sound rather than an internally generated signal.

A number of laboratory measures have been proposed to characterize feedback suppression systems (Freed and Soli, 2005), but the test described here is intended only to determine whether the suppression system is working. It is based on a test described previously by Smriga (2004) and has been found to work on current hearing aids using different types of suppression systems. The difficulty in performing a test of a feedback suppression system in the test chamber of a hearing aid analyzer is getting feedback to occur on demand. Smriga (2004) described a way to do this in analyzers that provide a headphone for listening to the output of the hearing aid in the coupler. In the steps that follow, this method is used to induce feedback in the presence of a speech-like test signal. A speech-like signal is used to avoid engaging adaptive directional or noise reduction features and to ensure that changes in forward path gain caused by compression and/or expansion are representative of those achieved in actual use. Variations of this test are possible using a low-level noise signal or no input signal at all, but

FIGURE 39.15 Setup for inducing controlled feedback in the test chamber. The monitor headphone [1], which is normally used to listen to the output of the hearing aid in the coupler, is placed near the hearing aid. The monitor gain is adjusted to induce feedback.

it may be necessary to disable adaptive features and expansion, and the results may not represent real-use experience.

1. Program the hearing aid for normal use. Place the hearing aid in the test chamber as if for a standard hearing aid test.
2. Connect the monitor headphone, normally used for listening to the output of the hearing aid, and place it in the test chamber near the hearing aid (Figure 39.15).
3. Present a speech-like signal at 60 dB SPL and display the coupler SPL.

4. Adjust the headphone volume control until one or more peaks appear in the response curve (Figure 39.16).
5. Enable the feedback suppression and observe that the peaks are removed from the response curves. Observe also that there has been no significant loss of output at the frequencies of the peaks. This result may not be observed for some hearing aids that require an initialization step before enabling feedback suppression. In this case, perform initialization after step 4 but with the sound source turned off. The sound source should be switched on before proceeding to step 5.

PROPER FIT

In a survey of hearing aid owners in the United States, the third most common reason for not using hearing aids was fit and comfort (Kochkin, 2000). Clients may complain that the hearing aids “are too big,” “fall out of my ears,” “hurt my ears,” or “are uncomfortable.” An accurate impression and proper fit in the ear are critical for effective hearing aid use.

Proper fit is often more critical and also more difficult to achieve in those with severe or profound hearing losses and for those fit with completely-in-the-canal hearing aids. In some cases, two or three remakes of the hearing aid shell or mold may be required before a good fit is achieved. Depending on the material used and the degree of hearing loss, new molds may be required every 3 to 6 months, whereas others may not need to be remade for a year or more.

FIGURE 39.16 Functional check of adaptive feedback suppression. Shown is the long-term average speech spectrum for speech at 60-dB sound pressure level (SPL) obtained with the setup of Figure 39.15. *Curve 1* was obtained by adjusting the gain of the monitor headphones, with feedback suppression disabled, until feedback occurred. *Curve 2* was obtained after enabling feedback suppression without changing the gain.

Pain

Hearing aids and earmolds should never cause pain or aching even after a full day of use. Clients should be cautioned to remove the hearing aid if there is pain and return as soon as possible to ensure a proper fit. Whereas new users are more likely to give up when there is pain, some long-term users cannot manage without their hearing aids and will persist in wearing a painful hearing aid until there is a visible red, swollen sore that may take weeks to heal.

If proper placement in the ear is observed, it should be determined whether the pain experienced happens immediately or after a few hours of use. The ear needs to be inspected. Is a sore or red spot present in the helix, concha, or canal? Is the pain in one particular spot (indicating a possible pressure sore) or all over (indicating that the aid may be slightly too large and needs to be reduced in general by a small amount)? If the client experiences pain almost immediately or if the pain is felt in a widespread area, a complete remake of the shell or mold from a new impression is indicated. However, if the pain occurs only after a few hours or only in one particular spot, then grinding and buffing the shell or mold is worth doing. Note that, with open-fit behind-the-ear hearing aids, pain may be caused by inappropriate tubing size or dome size.

If a sore is present, it is important to advise the client to leave the hearing aid out until all soreness, redness, or swelling is gone. Pressure sores can take days or weeks to heal completely and will not heal unless the hearing aid is not worn at all during the recovery period.

Excessive Hair in the Ear

Excessive hair growth in the concha or ear canal may cause chronic fit problems. The client may choose to keep the ear hair trimmed or switch to a behind-the-ear or open-fit model, if appropriate.

Change in Client's Weight

A change in the client's weight can affect the fit of a hearing aid. The shape and size of the ear can change with a weight increase or decrease of 10 pounds or more. In the case of weight loss, the hearing aid may become too loose and fall out of the ear or cause feedback. With significant weight gain, the hearing aid may become too tight and cause pain or sores. Reshelling for in-the-ear hearing aids or making a new mold in the case of behind-the-ear hearing aids usually alleviates the problem.

Effect of Climate

Hearing aids made from an impression in one season or climate may cause problems in another. To determine whether this may be a problem for a particular client, ask if rings and

TABLE 39.6

Seasonal and Climate Problems

Summer issues

- High humidity can cause condensation in in-the-ear hearing aids, resulting in a short circuit
- High humidity can cause condensation in the tubing of behind-the-ear hearing aids, resulting in a blockage
- Client's ear tissues may swell (fluid retention), making fit snug or painful
- High temperatures [$>122^{\circ}\text{F}$ or 50°C] (common in cars on a hot day) may impair batteries

Winter issues

- Dry air due to heating may shorten battery life
- Dry air due to heating may increase static electricity, which could damage the hearing aid circuit
- Cold or dry air may shrink client ear tissues, making the fit too loose and/or causing feedback
- Low temperatures [$<-14^{\circ}\text{F}$ or -10°C] may impair batteries

wrist watches are tighter in the summer and looser in the winter. This can be an issue for clients traveling to different climates. For behind-the-ear hearing aids, some clients may require a winter mold and a summer mold. For in-the-ear hearing aids, a shell made from an impression taken in the winter may feel tight in the summer but may avoid feedback or a loose fit in the winter. Table 39.6 lists various seasonal and climate problems.

Grinding and Buffing Shells and Molds

A hearing aid should be reshelled if the shell is quite thin or if there are cracks, holes, or signs of extensive grinding or previous application of coatings. However, sending a hearing aid, or mold, out for a remake means that the client will be without the hearing aid for several days or more. If a remake of the shell or mold is not required, grinding and buffing can be done in the office while the client waits. A Dremel-type tool with a flex-shaft is ideal for this kind of fine, delicate grinding and buffing. If one or two adjustments do not resolve the problem, it is advisable to take a new impression and have the shell or mold remade.

There is a wide variety of materials available for earmolds such as acrylic, silicone, and polyvinyl chloride (PVC). The hardness (or Shore rating) of a material will determine the appropriate bit type and speed for grinding and buffing. Shore ratings and material descriptions are available from companies that make molds. For hard materials such as acrylic, a small bit and a medium speed are best. Hard

materials are more difficult to smooth and need to be buffed well. For soft materials such as PVC, a medium bit and a higher speed work well and reduce the amount of shredding. Super-soft materials such as silicone require a larger bit and higher speed, and the mold must be braced to reduce vibration and increase the effectiveness of the grinding; softer materials, however, do not require buffing. If a large amount must be removed, soft materials such as PVC and silicone can be cut or trimmed before grinding, but care must be taken to ensure that there are no sharp edges.

OCCLUSION AND AMPCLUSION

“My own voice is too loud,” “It sounds like I am shouting,” and “Everything is hollow and echoing” are complaints often heard from clients trying new hearing aids. Sometimes the subjective discomfort is so pronounced that the client refuses to wear the hearing aids.

Shell-related occlusion is a common side effect of placing an object into the ear canal, particularly with binaural fittings. When talking, the voice projects primarily through the mouth, but some of the energy normally escapes through the ears. With the ears “plugged,” however, a client’s voice may resonate more within the head.

Ampclusion occurs when certain frequencies are over- or underamplified by the hearing aids, causing a hollowness or echoing effect. Some of the common causes of shell-related occlusion and ampclusion include

- Too little venting in the hearing aid
- Inappropriate length of hearing aid in the canal
- Physical blockage of canals (e.g., wax, blocked vent)
- Inappropriate gain for hearing loss in low frequencies (“ampclusion”)

Adapting to Initial Shell-Related Occlusion

Some shell-related occlusion effect should be expected when trying hearing aids for the first time. Clients should be counseled that their own voice and sounds, in general, will sound different at first. Mild cases of shell-related occlusion can disappear within a few minutes, although a few days of regular use are often needed as the client adapts to the new sound.

Persistent Occlusion: Shell-Related or Ampclusion?

When occlusion persists, the underlying cause must be determined. If the sense of occlusion is less when the hearing aids are turned off while still in the ear (by opening the battery door), then the problem is ampclusion (over- or underamplification provided by the hearing aids). If the occlusion effect is worse with the hearing aid off, then the

problem is either underamplification (ampclusion) or shell-related occlusion. If the occlusion is unaffected by the hearing aids being on or off, then shell-related occlusion is the problem.

One needs to check whether the occlusion is present with just one hearing aid or with two. If the occlusion is primarily present in one ear, adjustments may be needed only in that ear. If the occlusion is observed only when both hearing aids are in place but not with either one alone, then the occlusion may be due to an increase in the resonance of sound within the head or underventing, both of which result in overamplification of low frequencies. Although the origin is shell related, if shell-related solutions do not solve the problem, then it should be treated as ampclusion because of overamplification of the low frequencies.

Nonacoustic Occlusion due to Cranial Nerve Stimulation

The trigeminal nerve (cranial nerve [CN] V), vagus nerve (CN X), facial nerve (CN VII), glossopharyngeal nerve (CN IX), and many intermediary branches of nerves course through and around the external auditory canal, the tympanic plexus at the eardrum, and around the middle ear and Eustachian tube. Stimulation of any of these can trigger reflexes that may occasionally cause nonacoustic occlusion when fitting hearing aids. The vagus and trigeminal reflexes in particular may contribute to occlusion in some people; however, there is currently no easy way to determine whether this may be an underlying cause. Until a clinically feasible method for predicting and testing for cranial nerve stimulation is developed, this should be treated as a shell-related problem.

RESOLVING SHELL-RELATED OCCLUSION

During the assessment and prescribing process, the optimal venting for the hearing loss can be determined (Table 39.7)

TABLE 39.7

Optimal Venting to Minimize Occlusion

Hearing Loss at 500 Hz	Optimal Vent Size
<20 dB HL	Open fit (>3 mm)
20–30 dB HL	2–3 mm
30–40 dB HL	1.5–2 mm
>50 dB HL	<1 mm
With CICs	Reverse horn vent

Source: Adapted from Kuk F. [2005] Developing a hierarchy to manage the “own voice” problem. Session at American Academy of Audiology Conference, Washington, DC, April 2005. HL, hearing level; CIC, completely-in-the-canal.

to minimize shell-related occlusion. Shell-related occlusion may result from inappropriate venting in the hearing aid, too long a canal in the hearing aid, physical blockage of the hearing aid, or pressure on nerves in the ear canal, which, in turn, requires physical alteration of the hearing aid shell or earmold. An open-fit behind-the-ear hearing aid may solve occlusion for clients whose hearing loss is in the appropriate range.

Very deep insertion in the canal may also significantly reduce the occlusion effect, but the effective depth is 4 mm beyond the second bend, which is usually physically uncomfortable for the client (Pirzanski, 1998). The difficulty in inserting and removing these hearing aids, combined with physical discomfort, limits the clinical usefulness of very deep fits in the canal for reducing occlusion.

RESOLVING AMPCLUSION

Ampclusion may be resolved by adjusting low-frequency gain according to a client's perception of his/her own voice. If the problem is worse when the client speaks louder, overamplification is the issue, and low frequencies should be reduced. If the problem is worse when the client speaks softer, underamplification is the issue, and low frequencies should be increased.

FEEDBACK

Although many clients will persist in wearing a hearing aid that causes pain, most will refuse to wear one that squeals or buzzes. Feedback may occur with every head or jaw movement or may be occasional such as when putting on a hat or hugging family or friends.

Clients should be advised that there are times when feedback is expected and normal, such as when inserting or removing a hearing aid with both the power and volume on, or when the microphone is covered, such as by a hand, hat, or telephone. Some clients use feedback to confirm that the hearing aid is working and that the battery is good and to judge when the hearing aid has been correctly inserted based on when the feedback stops.

Understanding Feedback

A hearing aid is an amplifying system with a microphone, an amplifier, and a speaker (receiver). If the sound leaves the receiver and re-enters the microphone, it becomes reamplified and creates an oscillation. Low levels of acoustic feedback may not cause actual squealing but can disrupt frequency response and reduce speech clarity by creating an echo sensation. Feedback can progress into self-sustaining oscillation, which is the well-known, embarrassing whistle. When feedback drives the hearing aid into saturation, it generates multiple intense oscillations that are clearly audible and usually extremely uncomfortable for the wearer.

Although both high- and low-frequency sounds can easily escape from the hearing aid through venting or poor fit, the shorter wavelengths of the high-frequency sounds allow them to more easily reflect off surfaces such as the pinna and concha, increasing the likelihood of re-entering the hearing aid at the microphone. High-frequency sounds exiting the receiver are also more likely to be in phase with the incoming sounds at the microphone.

In hearing aids with greater high-frequency gain, the escaping sound is more likely to be louder than the initiating sound when it finds its way back to the microphone. In addition, higher gain hearing aids may produce oscillations of multiple frequencies that result in a faster onset of acoustic feedback. Because peaks in the real-ear frequency response often occur at high frequencies and such peaks are often associated with rapid phase changes, it is clear how these factors interact to produce the oscillation of feedback.

Because high-frequency hearing loss is most common, clients may not hear the acoustic feedback even though it is audible to others around them.

IS IT REALLY FEEDBACK?

In some cases, it may be difficult to determine whether a problem experienced by a client is feedback. Clients will use a bewildering variety of terms and phrases to describe the problem, and it is not often clear what the actual issue is. Clients may describe a squealing and whistling that appear to indicate the presence of feedback or a buzz or other odd sound that could be an issue with the telephone coil in the hearing aid or the presence of a real sound in their environment. The various possibilities must be investigated to determine the underlying cause. One way to determine if feedback is the problem is to induce feedback by covering the hearing aid while it is in the client's ear. If the client reports that this is the sound he/she has heard, then feedback has been confirmed.

Patterns may help identify the source of feedback-related issues. If a client hears the disturbing sound in question only when he/she smiles or bends over, then feedback is likely the issue. However, if the sound in question is only heard at certain times or in certain locations, then the client may be hearing an unfamiliar sound in the environment. Main sources of feedback include

- Improper fit in the ear
- Effect of impression materials
- Anatomy of the ear
- Improper placement in the ear
- Cracked or loose tubing in earmold
- Orientation of sound bore results in aiming sounds at the canal wall
- Presence of wax in the ear canal
- Reduced tympanic membrane compliance

- Large venting with high gain
- Low kneepoint (WDRC circuit)
- Inappropriate style of hearing aid for the degree of hearing loss
- Distance between the microphone and the receiver

Improper Fit

It is important to ensure the best physical fit possible in the ear before resorting to the application of software feedback managers. The more severe the hearing loss, the more amplification is usually prescribed and the more critical the fit will be in preventing feedback. With a new hearing aid or mold, it is worth the investment of time, energy, and resources in the first few months to achieve optimal fit and minimize future problems.

Feedback can be a major issue with older hearing aids, as well. Over time, the ear often changes slightly, and there may also be some shrinkage in the hearing aid shell or mold, depending on the properties of the material used and the chemistry of the ear canal skin. Materials such as PVC can shrink significantly over 2 or 3 years. The fit of a hearing aid tends to become less precise after 2 or 3 years, usually getting looser in the ear over time. The resulting gaps between the hearing aid and the ear canal can allow sound to leak out of the ear and cause feedback. In some cases, the hearing aid becomes so loose that the shifting in the ear can easily be seen with normal jaw movement. One easy test is to apply a soft expanding material, such as Comply Soft Wraps, around the canal portion of the hearing aid. If the feedback is eliminated by the presence of the Comply Soft Wrap, then poor fit is likely the primary cause of the feedback, and a recoating or reshelling of the hearing aid often corrects the problem. If the hearing aid is 5 years old or older, it may be preferable to purchase a new hearing aid since repair and reshelling costs are higher for hearing aids over 5 years of age. With behind-the-ear hearing aids, a new earmold should be made if the fit is loose in the ear.

A significant change in the client's weight can also affect the fit and cause feedback. See earlier "Proper Fit" section.

Effect of Impression Materials

The type of impression material used for taking impressions can affect the ultimate fit in the ear. Standard-viscosity silicone tends to give a more accurate impression of the ear, resulting in a better fit and less feedback. When using injector guns for impression taking, keep in mind that many guns do not have enough power to push standard-viscosity silicone; therefore, a standard syringe may be required. Low-viscosity materials reduce stretching of the ear tissue and can make a more comfortable though less accurate fit, increasing the chance of feedback in the hearing aid. If feedback is a problem for a hearing aid made from a

low-viscosity impression material, a reshelling from a medium- or high-viscosity material impression is worth trying.

Open-Jaw versus Closed-Jaw Impressions

Hearing aids and molds made from closed-jaw impressions or impressions taken while the client is chewing may lack a proper acoustic seal and result in retention and feedback problems. Hearing aids and molds made from open-jaw impressions tend to have better anatomic definition of the ear, a more secure fit, less feedback, and better comfort (Chasin et al., 1997). Open-jaw impressions should be done one ear at a time, with a bite block as far back as possible on the same side and the longest axis kept vertical to maximize the openness of the jaw.

Anatomy of the Ear

Sometimes the cause of intermittent feedback can be traced to jaw movement. Look for patterns such as feedback that occurs after a meal or only later in the day. In some clients, the temporomandibular joint (TMJ) may significantly amplify the effect of jaw movement while talking and eating, resulting in the hearing aid shifting in the ear (Oliviera et al., 2005). Sometimes, the cumulative effect of chewing over several meals is needed before the jaw movement displaces the hearing aid enough to create feedback. In this case, the feedback tends to be experienced only later in the day. This effect is often greater in one ear than the other. A very straight ear canal tends to result in poor retention of the hearing aid as well, and jaw movement may shift the hearing aid out of the ear canal in some cases.

There is currently no way to predict whether the anatomy of a client's ear will have a negative effect on the fit of a hearing aid. For experienced users, ask if feedback has ever been a problem with previous hearing aids. If the problem is chronic ("I've always had problems with hearing aids in my right ear"), then the anatomy of the client's ear may be the root cause, and an open-jaw impression is recommended. For some clients, adding a canal or helix lock to in-the-canal or completely-in-the-canal hearing aids may solve the problem by improved retention.

Improper Placement in the Ear

Improper placement in the ear can cause feedback. See "Performing a Visual Inspection" section earlier in this chapter.

Cracked or Loose Tubing in Earmold

Cracked or loose tubing in earmolds allows sound to escape freely from the ear causing feedback. See "Inspecting the Hearing Aid and Component Parts" section earlier in this chapter.

Orientation of the Sound Bore

The orientation of the sound bore of the mold or hearing aid shell is also important. If the sound bore is pointed toward the wall of the ear canal rather than toward the eardrum, some of the sound may be reflected back toward the receiver, increasing the chance of feedback.

Presence of Wax in the Canal

The presence of a significant amount of wax in the ear can cause feedback. The sound from the receiver tube of the hearing aid can be deflected by the wax back toward the hearing aid. The sound can exit the ear via the vent and cause feedback. This can be exacerbated by an imperfect fit in the ear canal or improper placement of the hearing aid in the ear. In many cases, removal of the wax reduces or eliminates the feedback. If there is a significant amount of wax present, it should be removed before other causes of feedback are investigated and before other solutions (such as reshelling or running a software feedback manager) are attempted.

Open-fit behind-the-ear hearing aids are particularly susceptible to blockage by wax because of the small diameter of the tubing. Manufacturers provide a tool to keep the tubing clear.

Venting with High Gain

If acoustic feedback is a problem, a vent may need to be reduced or closed completely; however, this may result in an increase in occlusion and humidity in the ear canals.

One way to retain some venting in a high-gain hearing aid is to choose a hearing aid with a smooth real-ear response or enough channels to achieve a smooth response. Feedback is less likely to occur if the peaks of the frequency response are minimized.

The large venting of open-fit behind-the-ear hearing aids allows high frequencies to escape easily, increasing the risk of feedback. More occlusive ear pieces are available from some companies for use with open-fit tubing that restrict the escape of high frequencies from the ear canal. Software feedback management can also be used to reduce feedback (see “Software Feedback Reduction Managers” section later in this chapter).

Feedback in Wide Dynamic Range Compression Circuits

Hearing aids using WDRC or other compression schemes that provide more gain for low-level input signals and less for higher level signals are more prone to feedback than linear hearing aids (Olsen et al., 2001). This is especially true when the input levels to the hearing aid are low. A hear-

ing aid may be in feedback for quiet situations because of the relatively high gain, but the feedback may cease in noisier environments because of the lower amounts of gain (Chung, 2004b). Feedback in quieter locations can be partially reduced by increasing the threshold kneepoint, by increasing the amount of expansion, or by a binaural fitting (through loudness summation, thus reducing the amount of amplification required).

Inappropriate Hearing Aid Style for the Degree of Hearing Loss

Sometimes a person with a severe or profound hearing loss in the high frequencies is fit with an in-the-canal or completely-in-the-canal hearing aid. This can be an issue for persons with very straight ear canals or poor retention of the hearing aid. Feedback can be reduced or eliminated by increasing the distance between the microphone and the receiver by increasing the canal length or switching from an in-the-ear model to a behind-the-ear model. Moving to a larger hearing instrument may increase the surface contact in the ear, thereby providing a more efficient seal. A behind-the-ear model also allows for use of softer materials, such as PVC or silicone, that can reduce feedback by providing a more snug fit in the ear.

Feedback can occur when open-fit behind-the-ear hearing aids are used with a severe hearing loss. A hybrid open fit with the slim tube attached to a custom-made earpiece may be effective in this case. The increasing effectiveness of software feedback managers may make the open-fit behind-the-ear hearing aid more useable for severe hearing losses (see earlier “Venting with High Gain” section; see also “Software Feedback Reduction Managers” section later in this chapter).

Distance between the Microphone and the Receiver

If feedback persists with a behind-the-ear model, it is possible to route the signal contralaterally between two behind-the-ear hearing aids. In this configuration, the sound from the right hearing aid is routed to the left ear and vice versa. This can be accomplished by either a wire or a wireless (e.g., Wi-Fi) routing. The distance between the microphone and the receiver will be significantly increased and often eliminates feedback completely.

Body aids work on the same principle of maximizing the distance between the microphone and the receiver, with the microphone typically being worn at chest level. However, body aids are being phased out and are difficult to purchase.

The use of a frequency modulation (FM) system will also reduce or eliminate feedback, again because of the increase in distance between the microphone and the receiver.

Malfunctioning Battery

Batteries occasionally cause unusual problems with hearing aids, including feedback. Some hearing aid circuits will experience more feedback as the battery is about to expire. If no obvious cause for the feedback can be found, try a new battery from a different batch and/or brand.

Improper Mounting of Microphone and Receiver

In the course of normal operation, receivers generate a small amount of vibration. Any vibration transferred to the shell of the hearing aid may generate a small amount of sound that is sensed by the microphone, potentially causing feedback. If proper fit and venting have been ensured, persistent feedback may be due to the microphone or receiver not being mounted optimally to minimize vibration. In this case, the hearing aid would have to be returned to the manufacturer for verification.

Software Feedback Reduction Managers

Software feedback reduction managers should be the last resort for addressing persistent feedback problems. When running the feedback manager in a manufacturer's software, one needs to be aware of what the program is doing. There are many different methods employed within software feedback managers. Feedback management programs typically work by gain reduction, notch filtering, or phase shifting. It is well worth some investigation to determine the specifications of any software feedback manager before using it.

Gain reduction can eliminate feedback by reducing the gain in the high frequencies, but such a broad range of reduction can also decrease the ability to clearly understand speech, particularly for unfamiliar voices, for foreign accents, or in competing noise. For this reason, the gain reduction method of feedback reduction should be a last resort.

Notch filters work by gain reduction, but the frequencies reduced are limited to those known to cause feedback. This can be implemented at the hearing aid fitting, and there are some models of hearing aids that attempt to "seek out and destroy" the offending feedback signal. To date, this adaptive approach has met with limited success. A very narrow notch filter can reduce feedback without greatly altering the final output from the hearing aid. However, if the feedback occurs at multiple frequencies, several notch filters or a much wider notch filter may be required, and the resulting gain may be significantly lower than that required for the level of hearing loss.

Phase shifting or phase inversion, also known as "feedback cancellation," eliminates or reduces acoustic feedback without significantly reducing the prescribed gain of the

hearing aid across the frequencies. This preserves the ability to hear speech and other sounds as clearly as possible. In phase shifting, the phase of any detected feedback is mirrored in a 180° phase shift, resulting in destructive interference. The goal is to achieve an exact 180° shift within an extremely short time to achieve near or complete cancellation of the feedback signal.

Feedback can build to saturation within 200 ms, so the ideal feedback-canceling system must be able to negate audible oscillations in real time. Some digital hearing aids incorporate high-speed real-time feedback cancellation systems that claim to completely stop feedback. As of yet, however, there are no independent, large-scale studies to substantiate these claims.

EAR WAX

An existing hearing loss can be exacerbated by the presence of ear wax. Ear wax can significantly reduce the transmission of sound by blocking the ear canal, blocking the sound from exiting the hearing aid, or causing damage to internal components of the hearing aid. Hearing aid manufacturers report that the majority of all hearing aid repairs are due to damage from ear wax.

What Is Ear Wax?

Ear wax is a normal product of the ear. Ear wax is primarily composed of keratin (derived from dead skin) with a mixture of cerumen (secretions from the ceruminous and pilosebaceous glands), sweat, dust, and other debris. The amount and consistency of ear wax vary from person to person. Ear wax can vary in color from yellow to orange or reddish-brown to dark brown or almost black. It may be nearly liquid or thick, sticky or dry, or soft or hard. Wax type is genetically inherited, although the appearance of wax may vary from time to time in the same person. Cerumen type has been used by anthropologists to track human migratory patterns, such as those of the Inuit. There are two main types, wet and dry. Dry flaky wax is common in persons of Asian descent and Native Americans (Overfield, 1985). Dry wax contains by weight about 20% lipid. Wet wax is common in people of Western European descent (Caucasians) and people of African descent (Overfield, 1985) and consists of approximately 50% lipid (Burkhart et al., 2000). Wet wax can be either soft or hard, with hard wax being more likely to be impacted.

Why Do We Have Ear Wax?

Various hypotheses have been advanced as to the purpose of ear wax. It has been proposed that wax provides protection against foreign objects, assists in cleaning the ear canal, acts as a lubricant, acts as an antibacterial and antifungal agent, and promotes a healthy immune response.

Debris is removed from the ear canal by a “conveyor belt” process of epithelial migration that is aided by jaw movement. Cells of the tympanic membrane migrate outward from the umbo (at a rate equivalent to that of fingernail growth) to the walls of the ear canal. The speed of cell migration accelerates as the cells move outward to the entrance of the ear canal. The cerumen in the canal is also carried outward, taking with it any dirt, dust, and particulate matter that may have gathered in the canal. Jaw movement tends to dislodge any debris attached to the walls of the ear canal, although vigorous chewing may actually stimulate wax production in some people.

Wax can also act as a lubricant, preventing drying and itching of the skin in the ear canal (asteatosis). In wet-type cerumen, the lubricating effect is due to the presence of cholesterol, squalene, long-chain fatty acids, and alcohols produced by the sebaceous glands (Harvey, 1989).

Studies have found that cerumen can provide protection against some strains of bacteria. Chai and Chai (1980), among others, have found cerumen to be effective in reducing the viability of a wide range of bacteria (sometimes by up to 99%), including *Haemophilus influenzae*, *Staphylococcus aureus*, and many variants of *Escherichia coli*. These antimicrobial properties are due to the presence of saturated fatty acids, lysozymes, and the relatively low pH of cerumen, which is typically around 6.1 in normal ear canals (Roland and Marple, 1997). Sirigu et al. (1997) also showed evidence of an antibody-mediated local immune response in the ear canal associated with the production and presence of cerumen, whereas Fairey et al. (1985) found that too little ear wax increases the risk of infection.

Removal of Ear Wax

If wax is hard and impacted in the ear canal, it may cause damage to the skin as it is removed and thus should be first softened. Wax removal is often more difficult for older people because their wax tends to be drier and harder. Ear wax can be softened by applying a few drops of mineral oil, baby oil, or glycerin in the ear for several days in a row. Oil should be administered at night time so that it can be absorbed into the wax and skin overnight. If oil is administered in the morning, the oil will likely get into the hearing aid when inserted and possibly disable the hearing aid.

Over-the-counter drops claiming to soften wax are available, most commonly with carbamide peroxide as the active ingredient. Other common active ingredients found in commercial wax removal preparations are triethanolamine oleate and docusate sodium. However, a recent study (Roland et al., 2004) found that triethanolamine oleate and carbamide peroxide were no more effective than a placebo (an isotonic salt solution) in aiding the removal of cerumen from occluded ear canals in an office setting. Docusate sodium and sodium bicarbonate have also been studied with conflicting results.

Once the ear wax has been softened, it can be removed with a minimum of discomfort. A standard protocol should be developed that includes obtaining informed consent and proper safety measures. The removal of wax may cause minor trauma to the ear canal, resulting in small amounts of blood. Since blood is a bodily fluid capable of transmitting various diseases, appropriate infection control measures should always be taken during cerumen removal.

SYRINGING WITH WATER

Syringing with water can be done by a client at home, by a trained audiologist, by a family doctor, or by another qualified person. Water pressure may, however, push the wax deeper into the canal (possibly touching the eardrum), whereas significant amounts of water may remain in the ear canal after syringing. When hydrogen peroxide (H_2O_2) is used, oxygen bubbles off, leaving water in the ear canal. A problem with wet, warm ear canals is that they make good incubators for growth of bacteria. In these instances, the ear canal may be flushed with isopropyl alcohol to displace the water and dry the skin but should be used sparingly to avoid excessive drying and itching.

PLASTIC SCOOPS

Small, flexible plastic scoops are commonly used by audiologists trained in wax removal. A good hands-free magnifier and light source are required. The basic technique is to gently scoop built-up wax from the canal. Care must be taken to minimize discomfort or trauma to the ear canal and to avoid contact with the tympanic membrane. This method is not recommended if wax is deeply impacted. Hairs in the ear canal may be embedded in the wax and can leave small amounts of blood in the canal when they are pulled out with the wax.

SUCTION

Suction is an effective way to remove wax and debris; however, there is a risk of damage to the ear canal and/or tympanic membrane. This method can be uncomfortable for the client, both physically because of the suction and acoustically because of the high SPLs. Suction should be used only by a qualified practitioner such as an otolaryngologist.

COTTON SWABS

Using cotton swabs to clean the ears is not recommended. Swabs tend to push wax deeper in the canal and may stimulate the production of more wax. Swabs irritate the skin of the ear canal and may damage the ear drum.

EAR CANDLING

Ear candling or coning is an ineffective and potentially dangerous method of cleaning the ears. A hollow candle

is placed at the entrance of the ear canal and lit, supposedly sucking out ear wax. Despite many claims that ear candling is effective for wax removal, it has been proven that the substances appearing within the cone originate from the melted candle, not from the ears (Seely et al., 1996). The suction supposedly created by the candle's flame is insufficient to remove wax and there is a substantial risk of burns, infection, obstruction of the ear canal, and perforation of the eardrum (Seely et al., 1996). Ear candling is not recommended at any time, and federal health warnings have been issued (FDA Important Alert #77-01; FDA, 1998).

Cleaning Hearing Aids

Hearing aids should be cleaned regularly as a preventive measure. A thorough cleaning every 6 months is usually sufficient to reduce repairs due to wax damage. Some clients require deep cleaning of their hearing aids every month or even more frequently, whereas others may never have a problem with wax.

A vacuum chamber with a suction tip for cleaning hearing aids is essential for any hearing care practice. The vacuum chamber loosens and removes small particles of dust and wax, whereas the suction tip removes more recalcitrant debris. Care must be used when using a suction tip because the receiver can be easily damaged.

Prevention: The Use of Wax Guards

Wax guards are the first line of defense against wax damage in a hearing aid. Different kinds of wax guards have been developed, including covers, metal springs, vented plastic plugs, and vented plastic baskets. One of the most effective is the vented plastic basket type, which is also the simplest for clients to change on their own. When clients cannot change the wax guard themselves, encourage them to bring their hearing aids in for regular cleaning and to change the wax guards.

HEARING AIDS AND TELEPHONES

The speech signal exiting from the receiver of an ordinary telephone is already slightly amplified to about 70 dB SPL, which may be sufficient for people with a mild hearing loss. For people with a severe hearing loss, using a telephone can be a frustrating experience because of a lack of amplification and visual cues and/or poor word recognition.

Feedback is also a common complaint for clients using a telephone. Feedback is generated when a hearing aid microphone is covered by the telephone receiver.

Foam Pads

For hearing aids without telecoils or acoustic telephone programs, feedback can be reduced or eliminated by adding

a foam pad to a telephone receiver to increase its distance from the hearing aid microphone.

Telecoils

Hearing aids with telecoils can eliminate feedback caused when using a telephone by turning the hearing aid microphone off and allowing the telecoil to pick up the magnetic signal from the telephone receiver instead. The Hearing Aid Compatibility Act of 1988 required “essential” telephones made in the United States or imported into the United States from August 1989 onward to be compatible with telecoils. The act defines “essential” phones as “coin-operated telephones, telephones provided for emergency use, and other telephones frequently needed for use by persons using . . . hearing aids”; this definition includes workplace telephones, telephones in hospitals and nursing homes, and telephones in hotel and motel rooms. For more information on telecoils, please refer to Chapter 38, Hearing Aid Technology.

Clients using telecoils may still run into problems using the telephone. Clients may have trouble operating the program button on their hearing aids, or the pressure of the telephone receiver can toggle the program button accidentally. With behind-the-ear hearing aids, a client must be shown how to hold the telephone to the hearing aid rather than to the ear for the telecoil to maximally pick up the magnetic signal. Also, there may be instances in which an older telephone model with insufficient electromagnetic leakage is used and, in turn, may result in a weak or nonexistent signal when used with the telecoil of a hearing aid.

Autocoils

Hearing aids with autocoils are switched into the telecoil mode automatically whenever a magnetic field is detected. The magnetic field must be very close to the hearing aid to trigger the autocoil. A typical problem with autocoils is that clients may not hold the phone close enough to trigger the autocoil. Counseling the client to hold the phone right up to the hearing aid should solve the problem. The initial feedback the client may hear should disappear quickly as the autocoil switches modes and the microphone is turned off.

A client may have a phone that does not have a strong enough magnetic field to trigger the autocoil. Adding a magnet to the telephone receiver may solve the problem, and a larger magnet or a second magnet may be added if required.

Magnetic Interference and Telecoils

When a hearing aid is in the telecoil mode, any strong or nearby electromagnetic signal may be detected and amplified, producing a buzzing sound. Common sources of electromagnetic interference include fluorescent lights, microwave ovens, televisions, tube-type computer monitors, power lines, and electrical transformers.

Because the strength of an electromagnetic field often varies considerably with small changes of position, it is sometimes possible to minimize interference by moving the head a few inches to one side. In some places, effective telephone communication with a telecoil is simply not possible given the strength of the interference.

Cell Phones

Historically, cell phones were not required under US law to be compatible with hearing aids; however, Section 255 of the US Telecommunications Act of 1996 requires a phased improvement of compatibility according to ANSI PC63.19, (2011) in new cell phones sold after 2005.

For hearing aids with telecoils, a special neckloop may be plugged into the headset jack of the cell phone to transmit the signal to one or both of the hearing aids.

Bluetooth wireless technology can bridge the gap between hearing aids and cell phones. Hearing aids with Bluetooth can automatically receive wireless signals from Bluetooth-enabled cell phones. FM systems with Bluetooth can wirelessly forward signals from a Bluetooth-enabled cell phone to a hearing aid with an FM receiver. The future may see new technologies being used to communicate with cell phones.

Modified Telephone Use

Modifications have been made to telephones to make them more accessible to the hearing aid user. There are many amplified telephones with built-in volume boost controls and high-quality speaker phones that allow for binaural listening. A direct connection from a telephone to a hearing aid via direct audio input (DAI) is also possible if the telephone has an output or headphone jack.

Frequency-Modulated Systems

FM systems provide another way to access the telephone via a hearing aid as well as allow for binaural listening. Binaural listening on a telephone can significantly improve clarity and efficacy of communication for many people with hearing loss. With the correct connector cord, any telephone with an output or headphone jack can be routed to the auxiliary input of an FM transmitter. Many FM systems can be set to automatically switch into the telephone mode when the phone rings.

Acoustic Telephone Programs

Hearing aids without a telecoil may allow for an acoustic telephone program. Because telephones only transmit information at 3,000 Hz and below, amplification of the higher frequencies in the hearing aid can be reduced sufficiently to eliminate feedback. Significant reduction of higher frequen-

cies may, however, impair effective speech discrimination. Therefore, hearing aids should have two or more programs with the primary program left unchanged.

Alternatives to the Telephone

Some people with severe hearing loss or poor word recognition cannot use the telephone at all. Many text-based alternatives are available including voice carry over (VCO) telephones, e-mail, teletype devices, Blackberry communicators, pagers, and fax machines. The Blackberry and pagers usually have a vibration option to alert the owner to incoming messages.

BATTERIES

Clients may be shocked to learn that a battery will only last days or weeks—typically 150 hours of use. It might be useful to mention to a client that a battery would also only last 150 hours in a flashlight or radio as well. Chips for high-end hearing aids have become more and more sophisticated, incorporating more sound-processing features such as noise reduction, speech enhancement, adaptive directionality, and feedback cancellation, which, in turn, put a higher demand on the battery. However, even though the demands placed on batteries have increased, batteries have improved in strength and current drain, thus keeping overall battery life fairly constant.

The current standard is zinc air batteries. These are significantly more efficient than mercury or silver batteries and can be safely disposed of, unlike the mercury-based batteries.

How Do Batteries Work?

Zinc air batteries require oxygen to produce energy. Since they contain tiny air holes, environmental factors such as humidity can affect battery life. The batteries come with tabs to cover the air holes and may require several minutes to fully activate after the tab is removed.

TESTING BATTERIES

When using a battery tester, count to three slowly and look for any sign of decrease in power. A battery that initially appears to be at full power may begin to fade after several seconds.

Most hearing aids have a low-battery warning; however, clients may not hear the warning beep if the hearing aid is blocked with wax or if the battery dies before emitting the warning signal. Clients should be advised to check for bad batteries and to recognize any low-battery warning given by their hearing aids. Most clients would benefit from purchasing their own battery tester.

Corrosion

Clients who sweat a lot or who live in a hot humid climate can experience chronic sweat-induced corrosion, a dark residue forming on the battery that has been described as “rust.” This corrosion occurs when sweat enters the battery compartment and bridges the positive and negative terminals of the battery. Salty sweat serves as an electrolyte that promotes ionic conduction, causing the battery to corrode. The corrosion is rapid, and severe “rusting” may be observed in a matter of minutes in some individuals. This problem is mostly associated with behind-the-ear hearing aids because the location of the aid allows for easy sweat access. A protective covering over the hearing aid, such as sweatbands or SuperSeals, or a waterproof or water-resistant hearing aid, such as the Rionet line, may solve the problem.

Clients who are regularly exposed to certain chemicals, such as high levels of chlorine in an indoor pool, may experience chronic chemical corrosion of their batteries. If the hearing aid must be worn in this environment, the use of a waterproof or water-resistant behind-the-ear model, such as the Rionet series, may be required.

Malfunctioning Battery

Batteries occasionally cause unusual problems with hearing aids. Some hearing aid circuits will experience increased distortion or feedback when the battery is about to expire. If no obvious cause for a problem can be found, a new battery from a different batch and brand may eliminate the problem.

Maximizing the Life of Batteries

Hearing aid batteries should be stored at room temperature and will operate best within the humidity range of 50% to 60%. When humidity is above 60%, clients may use a dry-aid kit for both their hearing aid and batteries. Batteries should also not be kept in locations where they may short out against metal objects.

Replacing the tab on the positive side of the battery may be beneficial if the typical battery life is longer than 10 days.

A tight-fitting battery compartment in a hearing aid that is made airtight by debris buildup can result in shortened battery life. Several manufacturers now have water-resistant and waterproof hearing aids to avoid this problem by using a ventilation window covered by a membrane on the battery compartment, which allows air to pass freely but repels liquids. In addition, nano-coating of hearing aid circuitry is now widespread in the hearing aid industry.

PREVENTION

The importance of preventing common problems before they happen cannot be overstated. A positive, trouble-free experience for the client will reinforce the audiologist’s mes-

TABLE 39.8

Prevention of Common Problems

Evaluation of listening needs and prescription	Assess listening needs and physical abilities to ensure optimum prescription
	Choose style and venting to minimize occlusion, sweat, and pressure
	Include directional microphones whenever possible
	Choose a circuit with fast real-time feedback cancellation whenever possible
	Order appropriate wax guards
	Take deep, accurate open-jaw ear impressions
	Add canal or helix lock to overcome poor retention in the ear
	Set adaptation levels as appropriate for each client
Expectations and training	Discuss expectations with the client
	Provide thorough training to the client during the initial fitting
	Recommend regular cleaning for both the hearing aids and the client’s ears
	Provide Dri-Aid kit, battery tester, and appropriate accessories
	Recommend the use of devices such as Dry & Store
	Provide documentation and written instructions for new users
	Provide aural rehabilitation (orientation classes, counseling, reading materials, etc.)
Follow-up	Insist on timely and thorough follow-ups within the first months
	Set up a callback system to see how clients are doing during the first few days
	Encourage clients to call if they are having any trouble

sage that hearing aids are supposed to make life easier and improve communication and the quality of life. Many of the common problems that discourage hearing aid use can be minimized or avoided during the prescription and fitting process. Table 39.8 lists a number of ways in which common problems with hearing aids can be prevented.

CONCLUSIONS

This chapter discussed many troubleshooting tips for hearing aids, as well as proper hearing aid assessment protocols. These included both formal and informal assessment of the hearing aids. Formal testing involves the use of hearing aid analyzers, different couplers, various test stimuli, different measures for testing digital hearing aids and advanced

functions, and the appropriate ANSI standard. Informal assessment focuses on visual assessment of the hearing aid and its components, the ear itself, and the fitting of the hearing aid to the ear.

As with a hearing assessment, a detailed up-to-date case history and background are necessary for each client. This is especially important for new clients. Even changes in weight or occupation may affect hearing aid functioning. The strategies, tips, and testing protocols in this chapter will assist you in helping your clients receive optimal benefit from their personal amplification.

FOOD FOR THOUGHT

1. There appears to be a harmonizing of the hearing aid test standards internationally. Will this trend continue and will it affect other areas of the hearing aid industry? For example, in the United States the FDA has approved the use of personal sound amplification products (PSAPs). Will these (or similar standards) be applied to the manufacture and testing of these products?
2. The standards mentioned in this chapter are reporting standards—a delineation of how to test hearing aids, tolerances of the tests, and how to report the data on specification sheets. To date there are no performance standards—how a hearing aid should perform, rather how a hearing aid does perform. What are your views about the future development of performance standards?
3. In the most recent suggestions by ANSI/ASA there is a recommendation to remove tests such as attack time and release time from the standard and place them in an informative (but optional) annex. Yet, data such as attack and release times can affect the ultimate hearing aid fitting. Why do you think that attack time and release time tests will be relegated to the annex and what other measures might follow in their path in the future?

IN MEMORIAM

This chapter is dedicated to the memory of Moneca Price, whose sudden and unexpected death during the final revisions of the sixth edition of this handbook shocked and saddened all those who knew her. Although much of this has been updated in this current edition, the spirit of Moneca will not be forgotten.

Hearing Aid Fitting for Children: Selection, Fitting, Verification, and Validation

Susan Scollie

INTRODUCTION

Audiologists who provide hearing aids for children serve infants, toddlers, preschoolers, children, teens, and their families. This wide-ranging population has specific needs for listening, language acquisition, and the physical fit of hearing aids. This chapter will outline the key differences for the pediatric population and introduce best practices for hearing aid fitting and follow-up by audiologists.

PEDIATRIC VERSUS ADULT HEARING AID FITTING

Recently, the American Academy of Audiology issued a Pediatric Amplification Guideline (AAA, 2013). This document stresses nine ways in which children and adults differ in their needs for listening and hearing aid use. Specifically, the nature of childhood hearing loss is unique: It is more likely to be variable between ears, between children, and over time within a child, and more likely to be associated with other health conditions. Also, children's hearing must be tested using different methods and their small but growing ear canals change the assessment and the hearing aid fitting over time. Further, children's listening needs frequently include the use of aided listening as a support for speech and language acquisition and development. This limits their ability to use top-down processing and increases their need for level, signal-to-noise ratio (SNR), and bandwidth of the signal. Finally, children's hearing aids may require that a caregiver initiate and/or monitor device use, meaning that both caregivers and children are the recipients of our care. All of these realities impact our protocols and service delivery to the pediatric population, particularly in infancy.

Clinical practice in pediatric amplification follows a sequence of events as shown in Figure 40.1. Not shown in Figure 40.1 are the many feedback paths that occur throughout, including the important link between assessing outcomes, defining next steps, and revisions to device selection, physical fit, or signal processing decisions. Because there are no "typical" children, it should be a fluid family-centered

and child-centered practice, with revision of decisions in response to changes. The steps illustrated in Figure 40.1 will serve as an overall organization for this chapter.

Identifying Hearing Loss

Many children who have permanent congenital hearing losses are now identified in infancy because of universal newborn hearing screening programs and associated early intervention initiatives (JCIH, 2007, 2013). In this service route, children are referred for a full audiologic assessment based on a screening result, and hearing assessment takes place in infancy. For infants, the main tools for hearing assessment are auditory-evoked potentials. Both the frequency-specific auditory brainstem response (FS-ABR) and the auditory steady-state response (ASSR) are used to predict the behavioral audiogram. Corrections are applied to achieve a more accurate prediction of hearing thresholds. This occurs *after* testing in some FS-ABR protocols (Figure 40.2) or *as part of the test setup* in ASSR and other ABR protocols. The corrections generate an estimated audiogram which is then used

FIGURE 40.1 Components of the clinical pathway for pediatric amplification.

FIGURE 40.2 Estimated audiogram from frequency-specific auditory brainstem responses [FS-ABRs] for a 5-month-old infant. Values are shown for both uncorrected [*light*] and corrected [*dark*] threshold estimates.

as the basis for further discussions with families, including whether or not the infant may be a candidate for hearing aid use, and subsequent calculation of prescribed hearing aid gain and output. Accuracy of these corrections is therefore an important precursor to accurate infant hearing aid fitting.

Assessment of hearing loss continues past early infancy, transitioning from electrophysiological methods to behavioral testing once conditioned procedures are possible. For older infants and young children assessment of hearing uses behavioral methods (visual reinforcement audiometry, conditioned play audiometry, or standard procedures). In the early months and years of life, behavioral measures of threshold may be best described as minimum auditory response levels (MRL), which are up to 25 dB above true threshold in children with normal cochlear sensitivity (Sabo et al., 2003). Infants and young children may cease responding prior to test completion on a given day, so repeated assessments may be required before behavioral estimates of thresholds are available, via air and bone, for each ear. Obtaining high-quality assessment of a child's ear-specific and frequency-specific hearing before making candidacy decisions is important because children have higher incidence of asymmetrical, progressive, and conductive/mixed hearing losses (Gravel, 2002; Pittman and Stelmachowicz, 2003; Tharpe, 2008). Specifically, the results of sound field threshold testing are not considered sufficient information for hearing aid fitting, because they are not ear specific. It is possible to perform audiometry with insert or TDH headphones, thus obtaining ear-specific threshold data. In general, insert phones are preferred, because their lighter

weight permits easy head movement. Also, they prevent collapse of the external ear canal, provide better attenuation of room noise, and reduce the need for masking in air conduction audiometry because of increased interaural attenuation (Clemis et al., 1986; Wright and Frank, 1992).

Supporting Families

Family-centered and child-centered practice includes working with families to support their choices in communication development, and to support them in modifying these choices over time. In structured family-centered programs, many children are provided with hearing aids, either in support of oral language acquisition, or in support of environmental sound awareness or bimodal communication, or as part of an assessment for cochlear implant candidacy. Audiologists can support families in making amplification-related decisions by providing clear information about the nature of a child's unaided hearing, realistic expectations about aided hearing abilities, trial fittings, best practices, and an overall family-centered approach that builds trust between the professional and the caregiver. Early hearing aid fittings are typically simple, with the focus on orientation to the device, getting started with device use, and monitoring the newly fitted infant or child for their responses to aided sound. These topics will be covered in more detail later in this chapter.

Key messages to families in the early days include reasonable expectations for clinical processes and behavioral outcomes based on the link between auditory input and the development of oral speech and language. Clinicians communicate the typical frequency and type of appointments to expect, as well as the types of procedures that will be completed. Although this will vary with the age of the child and the nature of their hearing loss and other health conditions, good generic descriptions, pictures, and videos are available from evidence-based, parent-focused web resources (www.babyhearing.org) or from books that share stories from other families of children who have hearing loss (e.g., Waldman and Roush, 2009). Parent-to-parent organizations can provide valuable support to families, regardless of their choice of oral and/or manual communication modes (DesGeorges, 2013).

Assessing Hearing Aid Candidacy

When families choose to pursue hearing aids for their infants or children, they may do so to support oral language development or to support sound awareness, or they may wish to explore whether or not hearing aid use will be helpful to their child. In cases of uncertain candidacy, either because the hearing loss is mild, profound, or unilateral, the fitting may be done on a trial basis to determine candidacy for continued use. In all cases, the idea behind hearing aid fitting is to provide the child with more access to the

auditory world than what is available without hearing aids. To understand this, we should consider what may help about hearing aids as well as any barriers to and potential negative side effects of hearing aid use.

Barriers to consistent hearing aid use can include the financial costs to families. These include the direct and indirect costs of attending appointments, including time off work, child minding for siblings, parking, travel, and appointment fees, as well as costs associated with device use including device purchase, earmolds, batteries, accessories, and insurance. Assistance with financial costs is often within the scope of the pediatric audiologist, by supporting families in applications and with temporary devices while funding access is in process.

Negative side effects that have been considered in the literature are rare and diverse, and prevention strategies are available (AAA, 2013). Certain ear impression and earmold materials may sensitize the hearing aid user to contact dermatitis, but we can avoid the use of these materials (AAA, 2013). We can protect the child's pinna from harm if struck during hearing aid use by ordering earmolds made of soft materials. We can protect the child's hearing from over-amplification by fine tuning and verifying to ensure that the child's hearing aids do not exceed prescribed levels of sound from a validated prescription (more on this later in this chapter). Further protection from overamplification is available by including signal processing technologies that reduce the levels of loud sounds, such as output compression limiting and wide dynamic range compression. Finally, we can minimize the impacts of additional noise and/or distortion by choosing hearing aids with low noise and low distortion, performing careful listening checks, and using venting whenever possible and indicated.

Candidacy-related conversations with families will typically focus more on whether positive effects of hearing aid use are expected. Families will need to know the type and nature of the child's hearing loss, that hearing may not be the same across frequencies, and that the child's audibility of speech will be affected in a frequency-specific way according to their hearing thresholds. An understanding of these basic concepts will help to support understanding of how hearing aids should help: By amplifying more in some frequencies, hearing aids overcome some of the effects of the specific shape and degree of hearing loss for the child. Realistic expectations for auditory development should be built for the child-specific case, taking into account current evidence on outcomes, the child's degree of hearing loss, the effects of support, daily use, and room acoustics, and the importance of engaging in appropriate interventions. Answering parents' questions as they are asked and providing written materials to take home are two of many strategies for supporting families as they receive this new information.

At early stages, audiologists can help parents understand (un)aided speech acoustics through the use of visual depictions of speech and from listening to filtered speech

demonstrations. One example of this is the familiar sounds audiogram, which can be used to relate audiometric data to the audibility of specific phonemes and environmental sounds, keeping the audiometric and phonemic information on a common dB HL scale. Another example is the SPLogram, which was developed to assist explanations of audibility of speech, by demonstration with and without a hearing aid. SPLograms display the audiometric and spectral information on a common dB SPL scale. Whether the clinician chooses to use an HL or SPL approach during informational counseling, it is wise to remember that the change between HL and SPL is confusing at first, so care should be taken when moving between display formats. Displays are available in most hearing aid fitting and verification software, and in more detail within the Situational Hearing Aid Response Profile (SHARP; Boys Town National Research Hospital, 2013). A sample unaided SPLogram (Figure 40.3) provides an example of unaided speech versus a child's hearing thresholds and upper limits of comfort (ULC), with normal hearing sensitivity plotted for comparison. The region between thresholds and ULC is the *auditory area*. This example uses the same case shown in Figure 40.2 and assumes average ear canal resonances for a 5-month-old infant. The audiogram and field levels of speech have been converted to ear canal SPL using established procedures (Bagatto et al., 2005). The unaided long-term average speech spectrum (LTASS) is the middle spectrum, with the two other lines indicating the peaks (top line) and valleys (bottom line) of the amplitude distribution around the LTASS. A level of 60 dB SPL was used to represent average conversational speech (Olsen, 1998). Comparing these levels

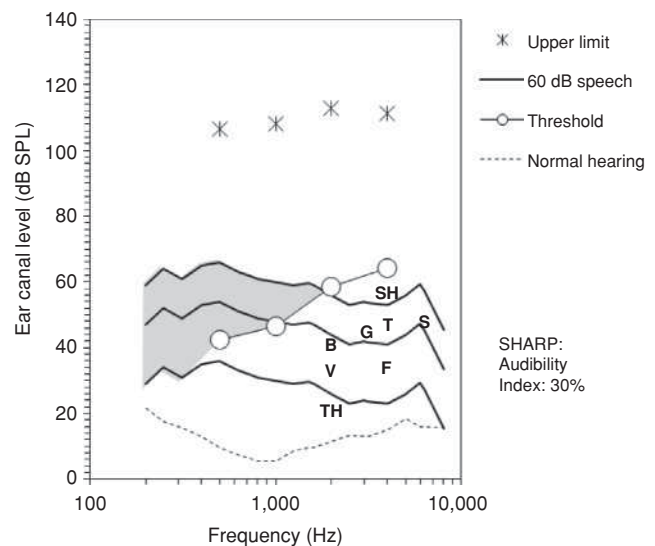

FIGURE 40.3 SPLogram for unaided conversation-level speech for a 5-month-old infant with the audiogram shown in Figure 40.2. The *shaded region* indicates speech energy that is audible. *Overlaid letters* indicate the spectral peaks of each phoneme.

to the normal thresholds, we see that all of the unaided speech amplitude distribution is above threshold. In contrast, only the shaded region is above threshold for this child. The SHARP version 7 (Boys Town National Research Hospital, 2013) was used to estimate the audibility index for this SPLogram resulting in an estimate of 30%. This value should be interpreted according to the speech cues available for the audible bandwidth, rather than as an estimate of the percentage of speech that might be understood correctly (Gustafson and Pittman, 2010). In this case, the 30% of audible speech contains only low-frequency energy, which will allow detection of most broadband environmental sounds and recognition of some vowels, nasals, liquids, glides, and certain mid-frequency consonants. However, high-frequency environmental sounds as well as fricatives, upper vowel formants, and high-frequency bursts or plosives may be inaudible. Explaining these distinctions to families is important, because a child with this degree and configuration of hearing loss will most certainly be aware of sounds in the environment but is at risk for poor oral language development without appropriate amplification. If the family chooses hearing aid intervention as a support for oral language development, bandwidth of audibility is an important factor to consider in candidacy. Limited bandwidth from children's hearing aids restricts access to some phonemes (see review by Stelmachowicz et al., 2004) and may impair word learning (Pittman, 2008).

Children who have similar hearing loss in both ears are likely candidates for binaural hearing aid fitting. Selection decisions can be more complex when the hearing profile is asymmetrical. Children are generally considered candidates for a trial with amplification even when hearing loss is mild or confined to only the high frequencies. Children with unilateral cochlear implants are generally considered candidates for amplification in the nonimplanted ear unless contradictions are present. Further guidance and evidence review on specific profiles is available from the AAA (AAA, 2013) and from evidence-based practice guidelines (e.g., Cincinnati Children's Hospital Medical Center, 2009). When candidacy for amplification is uncertain, offering a trial with loaner devices with monitoring of outcomes is an important tool that can assist families in determining whether or not hearing aid use is desired.

SELECTING AND PRESCRIBING HEARING AIDS

Physical Characteristics

The AAA provides good general guidelines for the selection of physical characteristics of hearing aids (AAA, 2013). They emphasize that most children's needs will be met with binaural, flexible fittings that offer direct audio input, usually in the form of behind-the-ear (BTE) casings attached to soft earmolds or soft-cased receiver tips. Soft casings are used to

protect the external ear from injury. Earmold venting is used, when the ear's size permits it, to allow airflow into the ear canal and possibly to provide access to timing cues for localization, depending on the configurations of hearing thresholds in both ears (Johnstone et al., 2010). Other physical configurations should be considered as warranted by the child's hearing level, manual dexterity, age, and other factors. For example, signals may be routed via a remote microphone to an open-fitted receiver instrument coupled to the better ear of a child with unilateral deafness, rather than providing a power hearing aid fitting to the ear with profound hearing loss. Another example is fitting a bone-conducted hearing aid for use while candidacy for either bone-anchored or middle-ear implants is not yet an option because of skull growth.

For air-conducted devices, choice of an appropriate earhook can affect both frequency response and physical retention of the device on the infant or child's small ear. A full-sized unfiltered earhook on a BTE hearing aid adds resonant peaks to the electroacoustic response of the hearing aid's receiver. Simulated and real earhook resonances have not been shown to decrease speech intelligibility or quality ratings for average-level speech in adult hearing impaired listeners (Cox and Gilmore, 1986; van Buuren et al., 1996). However, there may be other reasons to remove earhook resonances through the use of filtered ("damped") earhooks. First, earhook resonances may increase the risk of acoustic feedback (Agnew, 1996) and/or loudness discomfort (van Buuren et al., 1996) for the hearing aid user, because they can add roughly 10 dB to the output of the device at approximately 1,000 Hz. Second, the peak in the hearing aid response often governs the maximum output setting of the hearing aid. If an audiologist adjusts the hearing aid to meet the target output levels, the off-peak frequencies will be unnecessarily lower than the target maximum output level. The response from a damped or filtered earhook will be smoother, allowing a broader band of audible sound to be made available. In many cases, filtering the earhook is desirable. Earhook filters may have less effect with some newer earhook designs: Some recently introduced shorter earhooks are about half the length of a traditional hook. This reduces the magnitude of the earhook resonance, resulting in less need for damping or filtering. If in doubt, test the frequency response of the hearing aid both with and without a damped hook and compare the two. Small earhook designs for pediatric uses are particularly important for infant hearing aid fitting. Pediatric earhooks are typically designed to be smaller and more tightly curved than those intended for adult pinnae. They "hug" the top of the pinna and aid in retention of the hearing aid. When combined with other retention strategies, such as two-sided tape or hearing aid retention cord systems, they can have a significant impact on hearing aids staying on rather than flopping off. Together with tamper-resistant battery doors to prevent the infant or toddler from ingesting toxic batteries, a pediatric earhook is a common physical feature of hearing aids for very young children.

A well-fitted, comfortable soft earmold or a soft custom casing for a receiver-in-the-ear is also a key requirement for most children's hearing aid fittings. Either of these requires that an accurate ear impression is taken and that earmold fit is closely monitored over time, particularly during ages 0 to 2, when rapid growth of the external ear is expected. This continues at a slower rate to about age 5 or 6. Ear impression techniques require good distraction of the child (with videos, toys, or games) while the clinician ensures the ears are clear, places a tight otoblock, and injects impression material into the ear canal. Remember that the child will not be able to hear you while the ear impression material is in his or her ears. The ear canal should be examined following impression taking to ensure that all material has been removed and that no injury or skin reactions are observed and the results should be documented. Pediatric ear impression supplies are available, including low-capacity syringes that hold less ear impression material (for smaller ears) and come in bright colors. Thick-walled tubing in an earmold can reduce the risk of feedback. However, in very small earmolds, tubing may be a narrower gauge and/or extend only halfway through the mold to prevent high-frequency roll-off caused by tube crimping at the end of the earmold (AAA, 2013). Colorful earmolds with sparkles, swirls, and pictures of favorite characters are all options that young children like to choose. Teens and tweens may continue to choose bright colors or may wish to change styles and colors to minimize contrast with skin and hair tones. Matte tubing or receiver-in-the-ear options may facilitate continued acceptance of BTE or mini-BTE styles and therefore maintain options for high-gain fitting and/or remote microphone coupling via DAI or other routings.

Signal Processing

Modern hearing instrument technology includes signal processing to control the level of sound, to split it into multiple channels with channel-specific processing, to use one or more microphones to aim a beam of sensitivity to a particular direction, to attenuate noisy signals, and to use two hearing aids as a team if they are linked wirelessly. Hearing aid features allow effective feedback control, delivery of telephone signals to both ears simultaneously, and incorporation of small external microphones to enhance SNRs. Fitting software has become similarly complex, with many software-guided fitting algorithms that attempt to aid the clinician in choosing options and fine tuning the strength of some features. In this chapter, general guiding principles will lend insight into pediatric-specific issues within this landscape.

Audibility Technologies

Hearing aids improve the audibility of speech and other sounds by providing amplification of the incoming sound energy and by shaping the amplification according to the

listener's hearing loss. Shaping is typically performed according to a prescription, discussed below. We can pair this shaped amplification with one of three other ear-level audibility strategies: Amplitude compression, frequency lowering, and beamforming microphone technology. In addition, we can pair ear-level technologies with remote microphones to enhance listening across distances and in the presence of competing signals. Each of these options can be considered from a pediatric perspective.

Amplitude Compression

Historically, hearing aids provided one level of gain for any level of input, until the hearing aid reaches its saturation point. This type of linear gain system is now uncommon in modern hearing aids. More commonly, the hearing aid monitors the level of the incoming sounds using a frequency-domain analysis and makes automatic adjustments to the gain of the hearing aid. This type of processing is called *amplitude compression* and is recommended for use in most pediatric fittings to improve audibility of low-level sounds (AAA, 2013; McCreery et al., 2012a). Specific products that offer amplitude compression may differ in the magnitude and the speed of the change, as well as the frequency range affected, because the frequency-domain analysis allocates unique compression parameters to each channel within the hearing aid. Alternatives to amplitude compression also exist, with systems monitoring the levels of the incoming signal in the time domain rather than in the frequency domain. With either type of system, a frequency-shaped automatic volume control is achieved: When sounds get softer, the hearing aid turns the gain up and vice versa. Specific products may combine amplitude compression with either input compression limiting (to prevent microphone distortion), input expansion (to lower the gain applied to the microphone noise floor), and/or output compression limiting (to prevent receiver saturation). Combinations of these nonlinear technologies are common in today's products and are often used in children's hearing aids.

Frequency Lowering

Some hearing aid users may have limited access to the high-frequency portions of the incoming signal, even with well-fitted conventional hearing aids. If this could limit the benefit derived from amplification, these hearing aid users may be considered candidates for frequency-lowering systems. These devices apply signal processing to move high-frequency energy from the input into a lower-frequency range within the aided signal. Fitting procedures are often aimed at providing enough lowering effect to move the aided lowered signal to a usable region of hearing. There are several ways that this may be accomplished. Early commercial devices divided the incoming frequency range into two frequency ranges and transposed the higher-frequency inputs

into the lower-frequency range. This used different frequency range definitions depending on whether the input signal was judged as vowel like or consonant like by the device's processor. More recently introduced devices include other strategies, such as frequency compression, spectral warping, and others (Alexander, 2013). All of these are encompassed by the umbrella term "frequency lowering," but they may provide different types and strengths of frequency lowering when compared with one another. Some confine their effects to only the very high frequencies, some are adaptive processors, and some create nonlinearities, mixing of lowered with unlowered energy, and/or have significant filtering effects on the signal. To varying degrees, these side effects of frequency lowering have been viewed with skepticism, resulting in more cautious acceptance of frequency lowering at this time than is present for older technologies such as amplitude compression.

Research studies are emerging that present profiles of candidacy and outcomes with various frequency-lowering schemes (Auriemma et al., 2009; Glista et al., 2009; McCreery et al., 2012c; Parsa et al., 2013; Wolfe et al., 2010) and/or that propose or illustrate the efficacy or rationale for fitting methods. These methods underscore the importance of avoiding excessive strengths of frequency compression processors (Glista and Scollie, 2009; Kuk, 2013; McCreery et al., 2012; Scollie and Glista, 2011). Benefits for children with hearing losses that are severe to profound in the high frequencies are likely attainable with well-fitted frequency-lowering hearing aids, particularly following a period of acclimatization (Glista et al., 2012; Wolfe et al., 2011). Children who can achieve good audibility of high-frequency phonemes such as /s/ without frequency-lowering signal processing may not be candidates for this category of processor. Determining candidacy for this technology requires the audiologist to strike a balance between two of the fundamental requirements for signal processing: Avoiding unnecessary distortion and providing sufficient frequency shaping to meet prescriptive requirements (AAA, 2013). If high-frequency prescriptive requirements cannot be met, frequency lowering may be indicated. Monitoring of outcomes from frequency-lowering fitting is recommended practice (AAA, 2013).

Directional Microphones

Modern directional microphones use beamforming technology, which combines signals from more than one microphone to create a beam of sensitivity that may be steered to a specific direction. Sounds outside of the beam area are attenuated. Beamforming technology is commonly used in a wide range of microphone applications. In hearing aids, this takes the form of two or three microphone ports along the top edge of a BTE hearing aid with signal processing to combine the multiple inputs. Wireless microphone hearing aid accessories may also use multiple microphones to create a beam. Signal processing is used to steer the beam,

such as in front of the listener for conversations in noise, or to adapt the beam to the location that provides the best SNR. Some beams can be pointed behind the listener, to serve the user in situations like driving a car with conversation partners seated one behind the other. Beamforming microphone arrays on hearing aids are known to provide SNR enhancement when used appropriately, which usually requires the listener to point their nose to the target talker. Children are able to derive substantial benefit from the beam when it is correctly oriented, but less is known about how children can appropriately use these technologies in real-world environments (Crukley and Scollie, 2013; McCreery et al., 2012b; Ricketts et al., 2007; Ricketts and Picou, 2013). Children orient their heads to the target talker less than half of the time (Ching et al., 2009; Ricketts and Galster, 2008), and directional decrements in performance are possible when the beam is aimed away from the target talker, such as when listening to someone seated to the side or rear (AAA, 2013; Ching et al., 2009; Ricketts et al., 2007; Ricketts and Picou, 2013). The age, motor abilities, and cognitive abilities of the children may factor into their ability to use a directional system appropriately. It should also be cautioned that ear-level beamforming systems are designed for use when the listener is in close proximity to the target signal. Ear-level beamformers are not a substitute for the long-distance SNR advantages available from systems with remote microphones, such as FM systems. These complex issues lead to specific pediatric recommendations: Consider technology use on a case-by-case basis, consider avoiding full-time directional use, consider adaptive directional systems if their properties are well understood, and consider omnidirectional fittings with remote microphone support to improve SNRs in specific environments (AAA, 2013; Foley et al., 2009).

Remote Microphone Systems

Remote wireless microphone technologies, such as FM systems, are an important consideration in the pediatric population. The purpose of a remote wireless microphone is to pick up a signal of interest and send it wirelessly to a receiver that is connected to a loudspeaker (soundfield configuration) or connected to the hearing aid (personal configuration). This sends a clear, high-level signal that is less contaminated by reverberation and/or background noise than the signal received at the hearing aid microphone. By sending this cleaner signal to the hearing aid, we can overcome many of the deleterious effects of distance, reverberation, and noise that often occur in everyday communication environments. In educational environments, it is possible to configure these systems to support clear access to a teacher's voice, yet also allow for multiple talkers and interfacing with equipment such as computers and room projection systems (AAA, 2008). In home use, caregivers can use these systems to support clear access to a caregiver's voice, and use the

remote microphone in the car, on playgrounds, in shopping centers, or other situations where distance, noise, and reverberation can inhibit effective communication (AAA, 2008). Historically, remote microphone systems typically used FM signal transmission and were referred to as “FM systems.” More recently, alternatives to FM signal transmission have come to market, and these use various types of digital signal encoding and transmission. Some types use Bluetooth transmission or other encoding schemes for transmission only, whereas others combine this with digital noise reduction and level-dependent processing in an attempt to deliver a cleaner signal. Some are designed as adult-focused hearing aid accessories and may not be designed for the more rigorous school environment in terms of breakdown or options for interfacing other talkers. More details on the remote microphone systems are discussed in Chapter 37.

Pediatric protocols for selecting, programming, verifying, and validating remote microphone systems are available and specify required equipment and decision considerations for children who do and do not use hearing aids (AAA, 2008). For children who use hearing aids coupled to personal remote microphone systems, protocols focus on ensuring that the remote microphone transmitter/receiver is successfully sending the signal from microphone to hearing aid, often using an SPLogram and comparing to the hearing aid fitting as a reference signal. Fitting protocols also include ensuring that systems in adjacent classrooms do not interfere with one another and allocating signal processing to the microphone to enhance audibility of the target talker.

Prescription and Verification of Audibility

Prescription and verification of the gain, output, and amplitude compression of a child’s hearing aid are intended to assist the pediatric audiologist in ensuring that the fitted hearing aids provide appropriate amplification across children. Prescription involves the use of a computational formula via software to compute target levels of gain or output across input levels, signal types, and frequencies that are tailored to the individual child’s ear acoustics and hearing. Verification involves the use of electroacoustic test equipment to evaluate whether or not the hearing aid closely approximates the target levels. The audiologist performs fine tuning as needed to optimize the match to targets or to make other adjustments as required to meet the listening needs of the child. Because modern hearing aids use amplitude compression, verification and fine tuning are typically completed for more than input level. The use of calibrated speech during verification is increasingly preferred for its robust nature and high face validity.

An example of a basic verification and fine tuning for conversation-level speech is shown in Figure 40.4. Prescriptive targets for the case shown in Figures 40.2 and 40.3 were developed using the Desired Sensation Level (DSL) v5 pre-

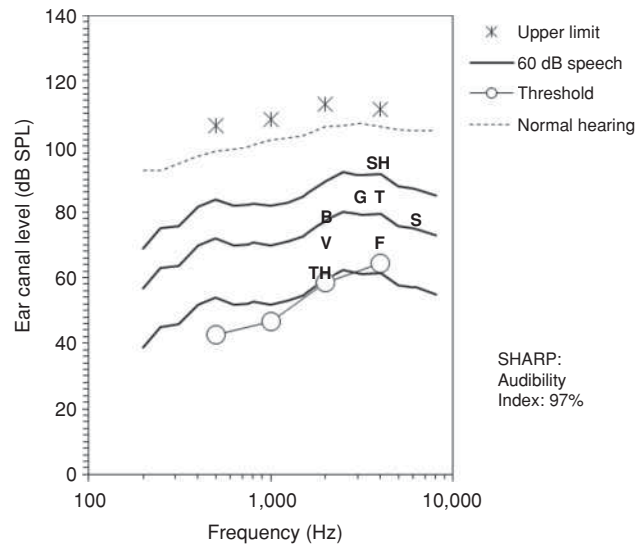

FIGURE 40.4 SPLogram for aided conversation-level speech for the same 5-month-old infant assessed in Figures 40.2 and 40.3. Format generally follows that of Figure 40.3.

scriptive method (Scollie et al., 2005). Figure 40.4 shows verification curves that meet the target levels. The maximum output curve shows hearing aid output for a 90 dB SPL puretone sweep: This curve is at a lower SPL level than the predicted ULC for this child. This is an acceptable fitting and a typical outcome for fittings that use amplitude compression. The aided speech curves for speech at an input level of 60 dB SPL show that the peaks, LTASS, and valleys of speech have been amplified to suprathreshold levels, resulting in audibility of the peaks of the various phonemes shown and an increase of the SHARP audibility index from the unaided level of 30% to an aided level of 97%. The audible bandwidth covers the entire range of the measurement, for the peaks and LTASS of speech, with some possible inaudibility in the very low frequencies. This fitting would be expected to support access to the important cues of conversation-level speech and should support speech sound awareness in a quiet environment.

This simple example attempts to illustrate the purpose and outcome of prescription and verification: A well-fitted hearing aid that provides access to a comfortable, beneficial amplified speech signal. Clinical use of this strategy requires a more detailed understanding at a deeper level, including the rationale and differences between varying target prescriptions, the specific methods used for multilevel verification, and the use of verified fittings within the context of multimemory hearing aids.

PREScriptive FORMULAE

Historically, many prescriptive formulae have been proposed, all with the goal to harness the correlation that exists

between hearing thresholds and the level of hearing aid gain or output that might be helpful. The ratio of prescribed gain to hearing thresholds has ranged between about 30% to 66%, with some variation across prescriptive methods, and variables in addition to hearing thresholds being used within some methods. In contemporary practice, two prescriptive methods offer pediatric-specific solutions that include infant-friendly features. The sections below will review these methods.

The National Acoustic Laboratories Formula

The National Acoustic Laboratories (NAL) family of formulae have been under development for more than 30 years and are the most common prescriptive formulae used in adult hearing aid research. The original NAL formula was developed and modified by Denis Byrne and colleagues, resulting in the NAL-R prescription which aimed to amplify all bands of speech to the most comfortable level (Byrne, 1986a, 1986b; Byrne and Dillon, 1986; Byrne and Murray, 1986). Byrne et al. (1990) proposed a modification of the NAL-R formula called “NAL-RP” for use when auditory thresholds are greater than 95 dB HL at 2,000 Hz. The NAL-RP formula adds extra low-frequency gain and reduces high-frequency gain. Prescriptions for hearing aid output limits have also been proposed (Dillon and Storey, 1998). Both NAL-R and NAL-RP are linear gain prescriptions and therefore do not prescribe targets for amplitude compression.

NAL prescriptions for amplitude compression hearing aids have been developed in two subsequent versions by Harvey Dillon, Teresa Ching, Gitte Keidser, and colleagues. Both methods provide multilevel targets that are appropriate for use with amplitude compression hearing aids. A hallmark of the NAL-NL methods is a method of reducing gain and output when limits of “effective audibility” are predicted to have been reached. Effective audibility includes stimulation levels that can be used well by adults for the purposes of speech recognition (Ching et al., 1998, 2001). For example, a listener with normal hearing will have increased speech recognition scores as the level of speech increased from threshold to suprathreshold levels, until they achieve the maximum score of the test. This typically occurs when the speech signal is fully audible, usually when the peaks of speech are about 30 dB above threshold. For a listener with sensory/neural hearing loss, maximum performance may not reach the maximum possible score of the test, and this may occur at sensation levels less than about 30 dB because of the listener’s reduced auditory area. This limits effective audibility. The NAL-NL methods combined experimentally derived limits with a model of loudness. An iterative algorithm was used to find hearing aid frequency responses that would allocate loudness of aided speech to those frequency regions that demonstrated greater effectiveness in a sample of adults. In NAL-NL1, this target deri-

vation resulted in missing targets at frequencies with limited effectiveness, thus limiting the prescribed bandwidth of the fitting. In NAL-NL2, the effectiveness limit was revised to prescribe less gain rather than a missing target, allowing the prescription to compute a target across frequencies (Keidser et al., 2011). Although this makes it more difficult to see where effectiveness limits have been reached, it makes clinical use of the prescription more feasible, particularly with hearing thresholds in the severe to profound range. In the NAL-NL2 procedure, children are provided with more hearing aid gain than adults, and normative data are included that estimate and incorporate pediatric ear canal acoustics.

The Desired Sensation Level Formula

The DSL family of formulae have also been under development for many years and are the most common prescriptive formulae used in pediatric hearing aid research and in clinical practice (Jones and Launer, 2011; McCreery et al., 2013). The original DSL formulae up to and including version 3.1 were developed by Richard Seewald and colleagues. These were developed for use with linear hearing aids and included a prescription for hearing aid output limiting (Seewald et al., 1985; Seewald, 1991). Similar to the NAL-NL formulae, Seewald sought to prescribe a comfortable level of speech that was associated with maximum speech sound recognition performance in children. These early versions of DSL incorporated children’s ear canal acoustics and child-friendly verification procedures and tended to prescribe more gain than the same-era NAL prescriptions.

DSL prescriptions for use with amplitude compression include the DSL[i/o] and DSLm[i/o] algorithms. These algorithms underlie versions 4 and 5 of the DSL method in software-based tools. DSL[i/o] computes targets for gain and output across frequencies and can be adjusted for use with linear or amplitude compression hearing aids (Cornelisse et al., 1995). The DSL[i/o] algorithm was updated in 2005 to include multichannel amplitude compression targets, infant-focused features, corrections for conductive and bin-aural fittings, and targets for adult listeners (Bagatto et al., 2005; Scollie et al., 2005). DSL version 5 continues to prescribe pediatric target listening levels that are similar to those used in the linear gain version, which aim for a broad band of audible conversation-level speech placed within the midpoint of the child’s auditory area. Targets for adults receive a similar frequency shape but at a lower level of output and gain. If amplitude compression is selected, compressive target input/output functions are fitted through the conversation-level target. Infant features include normative data and incorporation of ear canal acoustics across ages, and embedded corrections from nHL to eHL if hearing assessment was performed with frequency-specific ABR (Figure 40.1).

Studies of Prescriptive Formulae

Studies evaluating outcomes with NAL, DSL, and other prescriptions have been completed for the linear gain era formulae either in isolation or when comparing the effects of linear and nonlinear prescriptions (e.g., Snik and Stollman, 1995; Snik et al., 1995; Ching et al., 1997; Jenstad et al., 1999; Scollie et al., 2000). One series of studies compared DSL[i/o] and NAL-NL1 and incorporated double blinding and a period of acclimatization to each prescription (Ching et al., 2010a, 2010b; Scollie et al., 2010a, 2010b). These studies revealed that individual children may have preference or performance advantages with one prescription or another, with children who had increased loudness sensitivity being more satisfied with the lower gain provided by NAL-NL1. Situational preferences were also common, with most children in the study preferring to use the higher gain from DSL[i/o] when listening to sounds from behind or soft sounds and some children preferring the lower NAL-NL1 gain when listening in loud or noisy environments. More recent studies have evaluated outcomes from children either with DSLm[i/o] (e.g., Bagatto et al., 2011; Crukley and Scollie, 2012, 2013; Sininger et al., 2010) or including comparisons between DSLm[i/o] and NAL-NL2 (Ching et al., 2013). On average, outcomes are generally appropriate with either prescription, provided that the hearing aids use amplitude compression and are routinely verified and fine-tuned by a pediatric audiologist who incorporates the child's ear canal acoustics. Exceptions may occur for children with severe to profound hearing losses, who perform significantly better with DSLm[i/o] than with NAL-NL1 (Quar et al., 2013). Because the two prescriptions differ most markedly when losses are severe or poorer in any frequency region, it may be the case that children with either flat, severe/profound, or steeply sloping losses are those who

may have differing outcomes depending on the prescription used. The use of a validated prescription with routine verification and fine tuning of amplitude compression hearing aids appears to provide more consistent outcomes across large caseloads than fitting by other methods and is recommended practice for that reason (AAA, 2013; McCreery et al., 2013). In part, this consistency arises because pediatric prescription/verification methods are designed to take into account the pediatric principles discussed below.

BEST PRACTICES IN LINKING ASSESSMENT AND VERIFICATION

During hearing assessment, an individual's ear canal adds a unique acoustic signature to levels of sound reaching the child's eardrum, middle ear, and cochlea. Calibration in the dB HL scale assumes an average adult ear; therefore, the ear of an infant or young child may differ substantially from those assumed in calibration standards. As the child grows, this changes. This issue presents a problem for consistency and accuracy of hearing prescription, both at any one time and over time. There are two proposed solutions to this problem.

One solution is to convert the child's thresholds from HL to real-ear SPL or coupler SPL, which may be compared directly to hearing aid verification curves on an SPLogram as shown in Figure 40.4. Procedures for these conversions are well established and require either measurement or age-appropriate prediction of the child's ear canal acoustics (Figure 40.5, Table 40.1). The generic procedure is to obtain an HL audiogram, measure or predict the ear canal resonance that is appropriate for the specific procedure used during audiometry, and sum these together with the reference equivalent threshold sound pressure level (RETSPL;

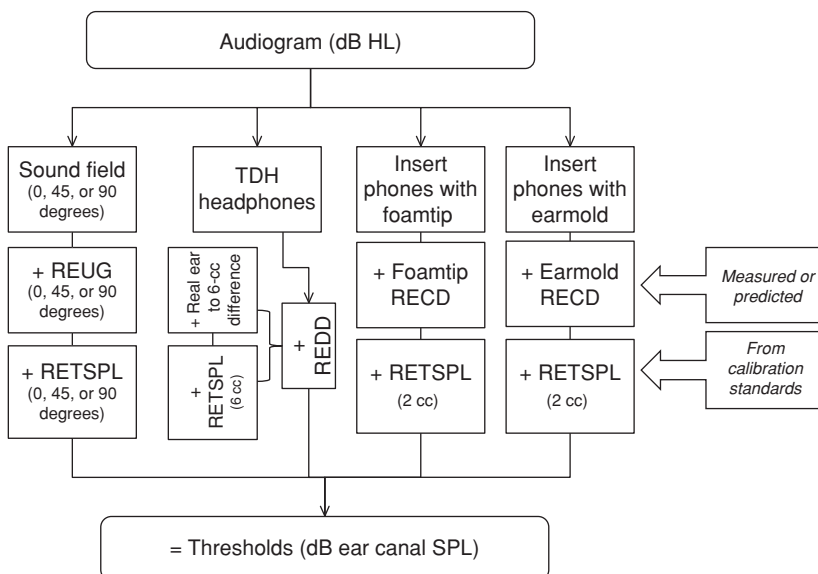

FIGURE 40.5 Computation path for converting HL assessment data to ear canal sound pressure level [SPL] across audiometric transducers. Refer to Table 40.1 for definitions of transform components.

TABLE 40.1

Summary of Transforms Used in Hearing Aid Prescription and Verification, with Acronyms and Definitions for Each

Variable	Acronym	Description
Reference equivalent threshold sound pressure level	RETSPL	The level per frequency [dB SPL] at 0 dB HL for audiometric test signals delivered to either a coupler or a field via a calibrated audiometric transducer. The coupler type and specific levels vary with audiometric transducer, and for sound field calibration also varies with head azimuth and whether or not thresholds are tested binaurally or monaurally
Real ear unaided gain	REUG	The difference [dB] between a signal in free field versus the level measured in the ear canal from the same loudspeaker. Varies with head azimuth
Real ear to dial difference	REDD	The difference [dB] between a signal in the ear canal and the audiometric dial level used to generate the signal. Typically measured with TDH headphones
Real ear to coupler difference	RECD	The difference [dB] between a signal routed to the ear and the same signal routed to the coupler. Typically measured with an insert transducer. Results vary with the specific transducer used, the coupling type [foamtip or earmold] and coupler used [HA1, HA2]
Microphone location effects	MLE	The difference [dB] between the free field levels of a signal, and the level at the hearing aid microphone. Varies with style of hearing aid [BTE, ITE, ITC, CIC]
Transform for estimating real ear output	TEREO	The sum of the RECD and MLE. This is added to 2-cc hearing aid output to predict output levels in the ear canal. Some software systems may compress the MLE portion of the TEREO because MLEs are present within the input to the hearing aid. This can also be done by filtering MLEs into the input signal during coupler-based verification

ANSI, 2010). The result is a prediction of ear canal SPL at threshold (Gustafson et al., 2013). If the HL audiogram was derived from frequency-specific ABR, a correction to estimated HL should precede the conversion to SPL. These procedures are used within the DSL method, before prediction of ULC and target calculations, so that the child's ear canal acoustics are incorporated (Bagatto et al., 2005). If the child's ear grows, the ear canal size increases and the magnitude of the ear canal resonance will change accordingly. This is intended to ensure consistent serial prescriptions, particularly if the ear canal acoustics are remeasured as the ear and earmold change over time.

Normative trends have been defined for children's real ear unaided gain (REUG; Kruger, 1987) and for both definitions of the real ear to coupler difference (RECD; Bagatto et al., 2005), but not for the real ear to 6-cc transform or real ear to dial difference (REDD; Cole and Sinclair, 1998). Within DSL, the clinician can enter measured thresholds and either RECDs or REUGs. If no measured transforms are available, age-predicted values are used. The most commonly measured transform is the RECD, which defines the difference between levels in the child's ear canal and the levels in the standard 2-cc coupler used for audiometer calibration or hearing aid measurements. Care must be taken to ensure that the correct coupling/coupler definition of the RECD is used (Gustafson et al., 2013). Appropriately developed software tools will automate this. Average adult

values are applied for the REDD. Measured values may be used but clinical options for measuring this transform are rare.

Another solution is to convert the child's thresholds from raw dB HL values to equivalent adult hearing levels (Ching and Dillon, 2003). In this procedure, the child's own ear canal resonance is compared to the corresponding average adult ear canal resonance. The difference between the two is a correction. The correction is used to adjust the measured audiogram to levels that would have been measured in an average adult ear canal. These equivalent adult hearing levels can be used for computing prescriptive targets. This may ensure consistent serial prescriptions, especially when used together with repeated ear canal measurements as the child matures. This method is used by NAL-NL2 for insert phone and soundfield audiograms. As with DSL v5, age-dependent corrections for TDH headphones are not available in NAL-NL2, and the details in Table 40.1 are included in transducer-dependent corrections.

For either of the two methods just discussed, assessment of hearing thresholds with insert phones allows incorporation of ear canal acoustics and measurement of ear-specific hearing. Insert phones are the preferred audiometric transducer for this reason. One important facilitator of insert phone audiometry in older infants and young children is the child's own earmold. Fabricated to fit the ear, the soft earmold is comfortable and retains well in the ear during

FIGURE 40.6 Illustration of a method for coupling children's custom earmolds to insert earphones for use during audiometry and RECD measurement. **Panel 1:** Trim the earmold tubing to length for daily use. **Panel 2:** Trim about 5 mm of tubing from a standard foamtip. **Panel 3:** Couple the black tubing to the end of the insert phone connector and insert it fully into the earmold tubing. The black tubing ensures a tight seal even if the earmold tubing has expanded to the size of the BTE earhook.

audiometry. The earmold may be attached to insert phones using the three-step procedure shown in Figure 40.6. Once the earmold tubing is trimmed to the correct length, a small portion of black tubing may be trimmed from an insert phone foamtip. This is placed on the end of the insert phone connector, allowing it to be firmly coupled to the earmold, even when the earmold tubing end has been stretched to a larger bore by the BTE earhook. This strategy prevents the insert phone from “popping out” of the child's ear during head turns, because the earmold fits the child's ear more snugly than a standard-sized foamtip. The insert phone plus earmold combination can then be used for both audiometry and for RECD measurement, allowing accurate incorporation of individual ear canal acoustics within assessment, prescription, and verification.

One important facilitator of incorporating ear canal acoustics is the measurement and correct definition of the RECD (Table 40.1). The RECD is measured by delivering a test signal to the ear using an insert transducer, measuring the SPL across frequencies, and then repeating this procedure in a standard coupler. The difference between the ear levels and the coupler levels is the RECD. Within software systems, clinicians are asked to define the RECD by coupling type (either a foamtip or an earmold), coupler type (HA1 or HA2), and whether the RECD was measured or should be predicted from normative data. These parameters need to be defined because the normative data for foamtip and earmold RECDs are different, especially in the high frequencies where the longer earmold tubing rolls off the high frequencies (Bagatto et al., 2005). The type of coupler also affects the

RECD, because the HA2 coupler includes an earmold simulator. Measuring an RECD accurately involves the ability to correctly place a probe tube within the ear of a young child and troubleshoot it for accuracy. Placement techniques vary by age and child state. For a young, sleeping 4-month-old infant, an approximate insertion depth of 11 mm from the opening of the external auditory meatus may be a reasonable estimate (Bagatto et al., 2006). An active toddler will be seated up and will require entertainment or distraction (a video, bubbles, a toy, a mirror, a ball of tape) to occupy their interest while probe placement and RECD measurement are completed. Insertion depth guidelines from the intertragal notch for children include (1) at least 5 mm deeper than the end of their earmold; or (2) placed using otoscopy to the start of the third bend of the ear canal; or (3) placed using the 6,000-Hz notch method (Dillon, 2012). Combinations of these strategies are common: Clinicians may premark the probe relative to the earmold, then use otoscopy or notch methods to confirm correct placement in the child's ear. The clinician then measures the RECD and evaluates the result, checking for common problems: (1) Child vocalizing during measurement requiring remeasurement while the child is silent; (2) unintentional slit leak because of lack of seal by the eartip/mold causing negative RECD values in the low frequencies; and (3) shallow probe placement causing notches in the high frequencies. Correct tube placement ensures accurate estimates of ear canal pressure to about 4,000 Hz. Above this frequency, standing waves cause large changes in SPL with only minor changes in probe location. Although alternatives to measurement of ear canal SPL have

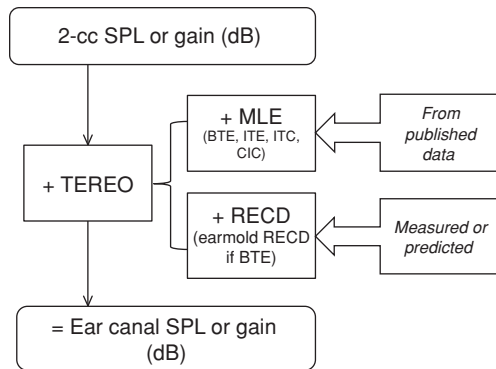

FIGURE 40.7 Computation path for converting coupler output or gain to ear canal output or gain. Refer to Table 40.1 for definitions of transform components.

promise for addressing this issue (McCreery et al., 2009), clinical tools for their implementation do not yet exist.

Verification of the child's hearing aid also incorporates individually measured or predicted ear canal characteristics. Clinically, we can choose to verify and fine-tune hearing aids using measures made on a coupler or on an ear. Coupler measures of fit to targets can incorporate the child's ear canal characteristics and the hearing aid's microphone location effects (Table 40.1) to create a reasonably accurate prediction of hearing aid output in the ear. This "coupler approach" to verification is also sometimes called "simulated real-ear verification" and uses the procedures shown in Figure 40.7 (Bagatto et al., 2005). The coupler approach is feasible for use with infants and young children because they are not required to sit up and be still in front of a loudspeaker for repeated real-ear measurements. However, the coupler approach does not account for venting effects. Real-ear evaluation is therefore preferred for older children who can comply, particularly if venting plays a major role in the fitting. Also, the fitting should be checked on-ear for feedback following the fitting on the coupler, because the full seal on the coupler does not mimic the true feedback path when worn. If significant changes are made to the hearing aid's frequency response while managing feedback, remeasurement on the coupler may be warranted to ensure accurate clinical documentation of the audibility provided from the fitting.

Real-ear evaluation can take several forms. Traditional adult-focused protocols have commonly used the real ear insertion gain (REIG) format (ANSI, 2007; Table 40.1). However, there are several problems with using the REIG as the primary measure in hearing aid fittings. Most importantly, REIG measurements are not directly comparable to auditory threshold or loudness discomfort level (LDL). Therefore, it is difficult to use REIG hearing aid responses to determine if the aided response is either inaudible or exceeding the ULC. For infants and young children, comparison between aided responses and thresholds/ULC acts as a surrogate for wearer feedback and is therefore an essen-

tial component of interpreting the adequacy of a hearing aid fitting (Figure 40.2). A more technical problem with the REIG arises because of how it is conventionally calculated. In many prescriptive, fitting, and verification systems, the target insertion gain curve is calculated using an average adult REUR, whereas the measured insertion gain curve is calculated using the client's measured real ear unaided response (REUR). If the client is lucky enough to have a "typical" REUR, this will not pose a problem. However, infants and young children are rarely in this situation, which can add substantial error to the process. Although this problem was addressed in the development of DSL v5, insertion gain tends not to be the preferred option, because clinicians prefer the more meaningful format of the SPLogram. The SPLogram is based on either direct measurement or prediction of the real ear-aided response (REAR; ANSI, 2007). Measures of the REAR have several practical challenges that should be addressed to ensure accuracy. First, patient and observer vocalizations will be included in the measurement: The clinician must take steps to capture the measure while the child and caregivers are not speaking. Second, low-level measures may be contaminated by room noise, and measures at any level may include room reflections, rendering real-ear measures less smooth in appearance than corresponding coupler measures. One solution to these problems is to locate the verification equipment within a sound booth. Third, measures in REAR format require correct probe microphone placement for accurate high-frequency measurement, particularly in comparison to the REIG procedure. Practice and use of clear markers on the probe tube to indicate target insertion depth are helpful strategies for ensuring accurate probe microphone placement.

Tailoring the Hearing Aid Options

Once the hearing assessment, ear canal acoustics assessment, prescription, fine tuning, and verification for output limiting and average speech audibility have been completed, an initial hearing aid fitting of one ear is nearly complete. Checking that both ears have loudness balance with one another is also important. Also, today's hearing aids have many options, so the next steps will include reviewing the setup of audibility for multiple input levels of speech, the setup of user controls and alerts, and the setup of multiple programs. Verification across multiple input levels of speech is recommended to ensure that the amplitude compression (and possibly other features) allows access to soft and/or distant speech and avoids excessive outputs for loud speech. Soft conversational speech is usually 50 to 55 dB SPL in overall level (Olsen, 1998), whereas loud speech is usually in the range of 75 to 80 dB SPL, with shouted speech exceeding this level. Evaluating the fit to targets across two or three levels spanning the range of 55 to 75 dB SPL is common practice. Enhanced multilevel verification is available from the SHARP software system.

User controls such as volume controls, on-off switches, battery compartment locks, and remote controls require planning and consideration of the wide range of uses and users that span infancy through the teenage years. Whereas a teen's hearing aid may provide full access to these, as would an adult's, an infant's hearing aid typically provides locked or restricted-range volume controls and locked battery compartments to prevent inadvertent adjustments and prevent battery ingestion. These decisions are typically software adjustable and can be revisited to promote the child's ownership and responsibility for their own hearing aids as their developmental status permits. Similarly, program alerts and low battery alerts may be irrelevant for a young infant's hearing aid (unless needed for use by parents during listening checks) but may be essential for older children and teens.

Multiple program profiles in hearing aids typically offer a program for listening while in a quiet place alongside programs intended for use in noise and on the phone. Programs for use with remote microphone systems are also common. When programming, it is useful to link these programs while fine tuning of the main program is taking place, so that changes to the frequency-gain response carry over to the others. Providing alternative programs for use in noise for children may improve loudness comfort (Crukley and Scollie, 2013) and improve learning through listening (Pittman, 2011), while maintaining speech recognition in noise and possibly improving it if paired with a directional or remote microphone (AAA, 2013; McCreery et al., 2012b). Audiologists can configure and reconfigure the program structure over time, adding in new features as the child's lifestyle and outcomes warrant change. For example, we can support telephone use in young children by providing hearing aids that automatically switch into a phone program when exposed to the telefield of a landline phone.

Amplification for Children with Conductive Hearing Losses

Some children have permanent or transient outer and/or middle-ear conditions that may require assistance through amplification. Transient conductive hearing losses are often because of otitis media and may or may not warrant the use of either hearing aids or remote microphone systems depending on the expected duration of the conductive loss and the child's needs. Children who have permanent conductive hearing losses, however, are considered candidates for hearing aid use in many cases (AAA, 2013). Some may be able to use air-conducted hearing aids, which can be fitted using corrections for conductive hearing loss within modern prescriptive methods (see Johnson, 2013 for comparison and review). Others may be candidates for one of several device types that provide sound via bone conduction. These include bone conduction devices, which send vibrations through the skin from a smooth hearing device

that has a vibration plate. The transmission path of these devices is similar to that of a bone conduction oscillator used in audiometry. Modern bone conduction hearing aids are designed to be worn with a soft headband that can be adjusted to a comfortable tension. Surgically mediated devices that anchor either to the skull or to the middle-ear system are also available. Use of these devices in children typically requires waiting until skull growth is nearly complete, at approximately age 5. One recent study reviewed benefits of such devices in children with unilateral or bilateral permanent conductive hearing losses (deWolf et al., 2011). Procedures for prescribing, fitting, and verification of bone-anchored devices are under development and may offer systematic approaches particularly for the adjustment of the frequency response to maximize audible bandwidth (Hodgetts et al., 2011). More information on bone-anchored hearing aid technology can be found in Chapter 38.

Hearing Aid Orientation

Although a well-fitted hearing aid is an excellent first step in a child's habilitation program, it represents the point of entry into the long-term habilitation process. Hearing aids do not replace ongoing care and therapy. Nor do they maintain themselves, and thus we need to ensure that some person in the child's life is trained to do this important job. Early infant hearing aid fitting appointments are usually focused on completing a hearing aid fitting and emphasize supporting caregivers in being the enablers of routine hearing aid use by their child. Coaching sessions are necessary to train caregivers on insertion and removal of earmolds, device cleaning, battery maintenance and safety, hearing aid retention devices and strategies, and begin focusing caregiver observations on infant behaviors that may indicate responses to aided sound. Supplies and training on daily hearing aid checks are provided to help caregivers prevent or detect the regular malfunctions that may occur because of battery failure, moisture or wax blockage in the earmold, and electroacoustic malfunction. One recent survey indicates that roughly half of parents reported inadequate coaching on how to perform daily checks of children's hearing aids (Muñoz et al., 2013), so repeated coaching sessions may be necessary until caregivers feel fully competent at this important activity. Let's face it: There's a lot to learn in the early days and we don't remember it all from only one session. Daily use logs during the first weeks of hearing aid use may help in identifying problems and establishing a pattern of daily use. Typical use times in children vary with a child's age and degree of hearing loss, but on average is about 8 hours per day for the 0 to 2 age range once regular use is established (Walker et al., 2013). Supportive information about preventing hearing aid damage and provision of cost-effective and long-lasting warranties against damage are essential. Providing written information for caregivers to take home and offering a drop-in service when problems

arise may ease the burden of having to remember all of the information received the first time it is given.

Validation and Monitoring of Hearing Aid Outcome

Validation of hearing aid fittings typically follows an initial trial period, evaluates whether the hearing aid(s) change the child's ability to detect sound and understand sound, and may consider the child's perception of loudness, comfort, or ease of listening. Perceptual tests, questionnaires, or checklists are all commonly used to elicit this type of feedback, either directly from the child and/or from caregivers or others in the child's life. Collaborative team meetings with other professionals are another source of information on outcome, particularly reports on progress and performance in therapy sessions from speech-language pathologists and auditory-verbal therapists or on performance in the educational setting from teachers, educational audiologists, or their colleagues. The section below will focus on measures that the audiologist can make to monitor outcome following hearing aid fitting.

The Aided Audiogram

One common outcome measure is the *aided audiogram*, which assesses the lowest level of sound that can be detected by the child. If this is compared to the child's unaided threshold, the result is called *functional gain*. The aided audiogram and functional gain are not used for verification of hearing aid frequency responses, but are recommended as a potential outcome measure for children aged 0 to 3 years (AAA, 2013; Scollie et al., 2012). This can confirm that the child is hearing aided sound and that an improvement in sound detection has been achieved. The major limitation of aided threshold testing is that it does not assess suprathreshold use of aided sound.

SUPRATHRESHOLD PERCEPTUAL TESTING

Although speech intelligibility and loudness perception are commonly used as objective outcome measures in the adult population, their use with the pediatric population may not be possible or may require modification. For example, a cartoon-based LDL rating scale may be used to measure aided loudness in children (Crukley and Scollie, 2013) and any age-appropriate word recognition materials may be used in an aided format. For example, child-appropriate materials exist for measuring perception of sentences in noise (AAA, 2013) and word-final fricatives for assessing bandwidth of audibility (Glista and Scollie, 2012). Choice of materials requires selection of tests that are appropriate for the developmental status of the child, contain stimuli that probe the hearing aid signal processing of interest, and

can be feasibly administered in the equipment available. A list of age-appropriate speech tests is available (AAA, 2013). Some clinics choose a set of materials that will be used consistently over time, which can lead to the development of local trends of expected outcomes. Another common practice is to use live voice to assess the child's ability to recognize and discriminate the Ling 6 sounds (/m/, /u/, /a/, /i/, /sh/, /s/) by the clinician—this procedure is used most often with young children, by parents as part of a daily check and by SLPs or AVTs prior to sessions to check device function. This surprisingly simple test has a number of internet videos illustrating how to perform and interpret it (e.g., Alberta Health Services, 2012).

Questionnaires, Checklists, and Standardized Tests

Structured, evidence protocols exist for using subjective reports from caregivers for outcome measurement in children who use hearing aids. Some use nonstandardized checklists, such as the longstanding battery of functional assessment tools developed at the Marion Downs Center (<http://www.mariondowns.com/assessment-tools>) and by Karen Anderson (<https://successforkidswithhearingloss.com/tests>). The UWO PedAMP protocol uses age-appropriate parent-report questionnaires to monitor the auditory development and performance of the child in real-world situations. It pairs these measures with assessments of the quality of the hearing aid fitting, allowing programs and clinicians to track hearing aid adequacy alongside outcomes. This battery was developed using a combination of evidence review and clinician review and includes typical performance ranges for the specific questionnaires (Bagatto et al., 2011). Other comprehensive batteries of standardized and laboratory measures have been developed for research purposes (<http://www.uiowa.edu/~ochl/index.html>, <http://www.hearingcrc.org/research/projects/r462>). These examples are from large-scale longitudinal studies that should be monitored for their contribution to the literature in the upcoming years.

Regardless of the specific protocol used for validation and monitoring of outcome, it should continue the pattern of family-centered care established in the choice of whether to use hearing aids described earlier in this chapter. The measurement of outcomes is not an end unto itself: The results should inform both the audiologist and the family and facilitate good dialogue on how things are going and what the next steps should be. For example, a hearing aid review session could include a review of parent-report questionnaire, a review of hearing thresholds and ear acoustics, minor adjustments to hearing aid frequency response, and a discussion of goals for the next visit. It is possible that the outcomes of the fitting and the parent-report questionnaire may be shared with parents and other professionals at a team meeting to facilitate planning and goal setting. At this appointment, the audiologist

and family may decide to revise the hearing aid options to include more or different features, perhaps because they have set the goal to introduce the child to telephone use. They may decide to increase the target number of hours of hearing aid use per day, perhaps because the child has stopped napping and is awake more hours per day. Perhaps ear impressions are taken for the next set of earmolds. These ongoing revisions are normal in the pediatric population, because change is continuous. The interested reader is referred to Chapter 44 of this book for information on ongoing intervention, education, and therapy for children with hearing loss.

CHAPTER SUMMARY AND CLINICAL CHALLENGES

Pediatric hearing aid fitting procedures combine family-centered care with evidence-based procedures to provide consistent, comfortable access to the auditory world through the use of modern hearing aid technology. The cornerstone procedures for ensuring accuracy and consistency across children and across ages are the use of high-quality assessment procedures, the use of validated prescriptions together with speech-based verification and individualized ear canal acoustics, and follow-up with monitoring of outcomes and ongoing review. Signal processing options are available for both younger and older children to ensure audibility of speech signals and to manage listening requirements in noisy places. Coupling of hearing aids to remote microphone systems in educational settings is required to overcome the effects of distance and room reverberation.

Challenges in clinical practice abound in every area of pediatric amplification. Because our technologies and fitting procedures improve regularly, the candidacy ranges for these interventions change as well. One interesting example for discussion includes whether or not to fit an older child with a traditional earmold, versus an in the ear/canal product, versus a slim-tube, versus a receiver-in-the-canal mini-BTE. If the child has a moderate hearing loss, all of these products will be considered in the child's fitting range but each offers its own cosmetic details, low-frequency response characteristics, high-frequency response characteristics, and options for coupling to accessory devices. This is a complex decision for any professional to consider, let alone to explain to families. Which styles would you recommend and why? Which option is most cost-effective? Which parameters are the most important to the family?

Another important clinical challenge comes in serving families of children who have multiple medical conditions. Comprising about one-third of our clinical caseload (Bagatto et al., 2011), these children are more likely to experience delayed onset of hearing assessment and intervention because of multiple medical interventions that may take both priority and time. In family-centered practice, audiologists will likely join teams of professionals for collabora-

tive planning of care with one another and with the family. These meetings require that audiologists work as consultants and collaborative case managers. We are required to explain hearing, hearing loss, the child's needs for auditory access, hearing technology, and current progress to our team members in ways that they can understand. If we are new to this situation and accustomed to "talking in jargon" with our hearing professional colleagues, we may need to develop some new skills in interprofessional communication. These and many other issues identified in this chapter are worthy of probing more deeply than can be explored here. Remembering that the family is our context for service delivery is an important touchstone in navigating the challenges of service delivery in our world of rapid changes, both in the child and in technology.

FOOD FOR THOUGHT

1. What is one strategy suggested in this chapter that can be used in cases of children who have borderline audiometric candidacy for hearing aid use, but for whom oral language development is a goal?
2. What are the listening situations in which either directional microphones or remote microphone systems are expected to provide benefit?
3. What aspects of hearing aid programming are expected to change between the first hearing aid fitting in infancy versus follow up hearing aid fittings during the school age years?

Hearing Aid Fitting for Adults: Selection, Fitting, Verification, and Validation

Michael Valente and Maureen Valente

INTRODUCTION

Audiologists have a responsibility to achieve hearing aid fittings that provide the best possible “benefit” and “satisfaction.” Surprisingly, these goals can often contradict each other. For example, patients commonly request hearing aids providing the best performance in noise (i.e., benefit), but this is immediately followed by the need for the hearing aids to be “invisible” (i.e., satisfaction). At this point, a conflict can present itself because the technology capable of providing the greatest benefit in noise (i.e., directional microphone and/or personal listening devices) may be in conflict with the desire for “invisibility” (i.e., completely-in-the-canal (CIC) or a Lyric® hearing aid or similar hearing aid that is deeply seated in the ear canal). The audiologist must either educate the patient on the technologies available that provide the best benefit in noise and “convert” the patient to this technology, or simply surrender to the patient’s demand for cosmetic appeal knowing the fitting may not provide the best benefit in noise. Ultimately, this patient may be fit with bilateral behind-the-ear (BTE) hearing aids with directional microphones at one clinic, whereas the same patient could have been fit with bilateral smaller hearing aids at another clinic. One fit may satisfy the goal of hearing better in noise, whereas the other fit may satisfy the cosmetic concerns of the patient.

To address the concern of “cosmetics,” BTE open-fit hearing aids with a directional microphone using either a thin tube or a wire connected to a receiver placed in the ear canal are now readily available as are hearing aids deeply seated in the ear canal. Kuk and Keenan (2005) and Valente and Mispagel (2008) reported on the performance of open-fit BTEs using directional microphones. Kuk and Keenan (2005) evaluated 8 participants with one manufacturer’s open-fit BTE, whereas Valente and Mispagel (2008) evaluated 26 participants with another manufacturer’s open-fit BTE. Kuk and Keenan (2005) examined the Hearing in Noise Test (HINT) reception threshold for sentences (RTS in decibels). The HINT sentences were presented at 0° azimuth whereas HINT noise was presented at 75 dB

SPL with loudspeakers at 90°, 180°, and 270°. Valente and Mispagel (2008) measured RTS with HINT sentences presented at 0° and uncorrelated restaurant noise presented at 65 dBA from eight loudspeakers set 45° apart. Results from both studies reported no significant differences between unaided and aided omnidirectional conditions, but a directional benefit of slightly less than 2 dB relative to omnidirectional and unaided performance. These results suggest that when communicating in a noisy listening environment, patients require at least a directional microphone with an open-fit hearing aid if aided performance is to be better than unaided performance. Assuming a 10% per decibel improvement in sentence intelligibility of HINT sentences, the directional microphone improved performance in noise, re: Unaided and omnidirectional performance, by approximately 20%.

The above-mentioned examples illustrate one of the issues confronting audiologists when selecting hearing aids for their patients. To help the reader achieve the “best fit” for his/her adult patients, this chapter will provide a comprehensive overview of clinical procedures audiologists can implement when selecting, fitting, verifying, and validating hearing aid fittings for adults. The procedures will be presented chronologically in the manner that hearing aids are typically selected, fit, verified, and validated by us.

This process often requires four visits at our clinics. The *first* visit includes a comprehensive case history and audiologic evaluation, counseling, and informally assessing patient’s motivation toward amplification. The *second* visit may include loudness judgments for puretones measured in dB SPL near the tympanic membrane, extensive counseling on fitting options, taking impressions of the ear canal(s), and obtaining an unaided outcome measure (e.g., Client Oriented Scale of Improvement (COSI), Dillon et al., 1997; or Washington University questionnaire (Wash U)) (Figure 41.1). If time allows, the first and second visits can be collapsed into a single visit. The *third* visit includes verifying real-ear performance of the hearing aids and obtaining aided loudness judgments for speech. This visit also includes counseling on the use and care of the hearing aids

and the method of coupling the hearing aids to the ear(s). In addition, the patient is contacted within two working days to determine his/her initial experiences to the fitting. If problems are present, the patient is immediately scheduled to return to the clinic so the issue(s) can be resolved. The *final* visit, scheduled approximately 30 days after the initial fitting, includes obtaining the “aided” measure using the COSI or Wash U questionnaire. Recently, we added EARtrak® as another outcome measure of hearing aid usage to obtain greater information about the satisfaction of our patients in varying listening situations (11 situations), hearing aid features (12 features), and service providers (7 situations) (Figure 41.2). This computer-based outcome measure is accessed by our patients via our website (<http://hearing.wustl.edu>) and has proven to be a very valuable tool. This visit may also include fine-tuning the hearing aids in response to the patient’s assessment of performance during the 4-week trial period. Finally, the patient is provided a Zephyr® Dry & Store to help remove moisture from the

hearing aids and reduce the number of patient visits related to the problems caused by excessive moisture.

PREFITTING DATA (FIRST VISIT)

Comprehensive Audiometry and Assessing Motivation

During this visit, a comprehensive case history is taken and puretone and speech audiometry are assessed in the conventional manner. Immittance tests are administered, including tympanometry, acoustic reflex thresholds with contralateral and ipsilateral stimulation, and reflex decay if the results from puretone and/or speech audiometry warrant ruling out conductive, mixed, or retrocochlear pathology. If the results from these measures suggest that amplification is appropriate, then candidacy for amplification is suggested to the patient. The patient is counseled to schedule an appointment with his/her physician to obtain

Your responses for Question 12 - Satisfaction with Listening Situations

medical clearance for amplification. If the audiologist is questioned about the need for a medical examination, it is best to inform them that it is in the patient's best interest, but the patient has the right to sign a medical waiver. This signed form is placed in the patient's electronic medical record (EMR) and later attached to the fee ticket as required by law in the state where we reside. It is crucial during this initial visit that audiologists informally assess the patient's motivation toward amplification. We believe that dispensing hearing aids to unmotivated patients can do significantly more harm than good. If the experience with amplification is unsatisfactory, these feelings of dissatisfaction will probably be transferred to friends and/or family members who may also be considering amplification. Therefore, it would not be surprising if these other "potential" patients no longer pursue amplification because of the negative expression of their friend or family member. Dispensing hearing aids to an unmotivated patient is strongly discouraged, because this practice may lead to far more than simply a "return for credit." When counseling unmotivated patients, we suggest this may not be the best time for them to consider amplification. Rather, we urge such patients to make an appointment when they feel more motivated and the hearing loss is negatively impacting quality of life (QOL).

HEARING AID EVALUATION (SECOND VISIT)

Following the audiologic evaluation, a hearing aid evaluation (HAE) is scheduled. The HAE is the appointment dedicated to discussing all aspects of hearing aid use, hearing aid technology, and hearing aid styles. For the HAE, the patient

is encouraged to bring family members. During this visit, the audiologist will

1. Counsel the patient, once again, on the results from the audiologic evaluation because several weeks may have passed since the initial audiologic examination. Experience has shown that patients may not accurately recall the counseling that was completed at the initial audiologic evaluation and a review is often very helpful.
2. Counsel the patient on anatomy and physiology of the ear using figures from a wide variety of resources. This review allows the patient to have a greater appreciation of how the hearing loss is related to anatomical changes in the ear.
3. Calculate the patient's Speech Intelligibility Index (SII) using free software available at www.sii.to. This is a very helpful tool to provide a greater understanding of the impact of the patient's hearing loss on the audibility of speech. Calculation of the SII for unaided and aided performance is also available with most real-ear analyzers.
4. Counsel the patient, when appropriate, on the advantages of bilateral amplification for improved sound quality, hearing in background noise, and localization. This is described in greater detail in a section that follows.
5. Counsel the patient on the realistic expectations of amplification. Aided performance in noise should be better than unaided performance in noise, but aided performance in noise will probably not be as good as aided performance in quiet. It is emphasized that even listeners with normal hearing perform poorer in noise than quiet. This is described in greater detail in a section that follows.

6. Demonstrate different hearing aid styles. This may include custom in-the-ear (ITE), in-the-canal (ITC), CIC, conventional BTE instruments, BTE using a thin tube to direct the amplified sound to the ear canal, or BTE using a wire connected to the receiver placed in the ear canal. The patient may also be shown examples of custom earmolds, or manufacturer domes and custom earmolds that can be used to deliver the amplified sound to the ear canal.
7. Counsel the patient on different features of hearing aids such as volume control, program button, remote control, and directional microphones. Also, discuss wireless communication to cellular and landline telephones, computers, televisions, hearing-assistive technology (HAT), and a wide variety of other auditory inputs.
8. Counsel the patient on the importance of the telecoil (t-coil) for communication on the telephone and HAT. Emphasize that with current hearing aids it is possible for the hearing aid to automatically switch to the t-coil when a telephone is placed near the ear. Also, with some current hearing aids, the signal from the telephone placed over one ear can be heard, automatically, in both hearing aids.
9. Counsel the patient on the relationship between the “levels” of hearing aid technology and the associated charges. This is described in greater detail in a section that follows, but these differences in “levels” include
 - a. The number of available “bands” which is related to the flexibility of the audiologist to “match” a validated prescriptive target using real-ear measures (REM).
 - b. The number of “channels” which is the effectiveness of the signal processing in the hearing aid(s) to process environmental noise and feedback as well as the effectiveness of the directional microphones.
 - c. The number of automatic features.
 - d. Warranty for repair (1 to 3 years).
 - e. Warranty for loss and damage (1 to 3 years).
10. Administer a questionnaire to assess what the patient may expect his/her hearing aid(s) to provide. For example, a patient may want the hearing aids to improve the ability to recognize (a) female and child talkers, (b) speech while watching television, (c) speech in noisy listening situations, and (d) communication on the telephone. This information will assist the patient to establish realistic goals. This also is described in greater detail in a section that follows.
11. Measure the patient’s loudness discomfort levels (LDLs) to determine when signals are “loud, but OK.” These LDLs will serve as the target when measuring the output of hearing aids to a loud input during the hearing aid fitting (HAF). This is described in greater detail in the next section.
12. Take impressions of one or both ear canals to order custom earmolds for BTEs or custom hearing aids. On the other hand, some hearing aids may be coupled to the ear using noncustom “domes.” Again, this is described in greater detail in a section that follows.

Real-Ear Measures of Loudness Discomfort

One of the most important facets of successful hearing aid fittings is to ensure that the amplified signal does not exceed the level where the patient reports the amplified sound to be “loud, but OK.” Munro and Patel (1998) reported that if the measured real-ear saturation response with a 90-dB SPL puretone sweep ($RESR_{90}$) is below the individually measured LDL, then participants did not report “real-life” listening to be uncomfortably loud. This contrasted with participants whose $RESR_{90}$ exceeded the individually measured LDL. Jenstad et al. (2003) reported that the primary complaint of patients newly fit with hearing aids, who returned to the clinic for fine-tuning, was the amplified sound was too loud.

As part of the HAE, measures can be made to determine the intensity level (in dB SPL measured near the tympanic membrane) where sound is “loud, but OK.” To accomplish this, a probe-tube, attached to a probe microphone, is placed in the ear canal approximately 4 to 6 mm from the tympanic membrane to directly measure the dB SPL near the tympanic membrane. To assure that the end of the probe-tube is within 4 to 6 mm from the tympanic membrane of an adult male patient, the probe-tube is marked 30 mm from the tip (26 mm for an adult female). This mark is placed at the intratragal notch of the outer ear and taped into position.

Using this method, calibrated TDH-series or ER-3A insert earphones are connected to the earphone output of a calibrated audiometer (ANSI-2004) and placed in the ear canal along with the probe-tube from the real-ear analyzer (Figure 41.3). At this point, a continuous puretone at 500 to 4,000 Hz in octave and mid-octave intervals is presented to the patient. The patient is asked to judge the loudness of the signal with choices of “very soft,” “soft,” “comfortable, but

FIGURE 41.3 Placement of a probe-tube, probe microphone, and insert earphone for measuring individual LDLs.

Washington University School of Medicine				
Loudness Measures				
Patient Name: _____		DOB: _____		
Date: _____		Audiologist: _____		
Right Ear				
	HL	SPL	REDD	ANSI-1989
500 Hz	85	96	11	12.0
1 kHz	85	95	10	9.0
2 kHz	90	105	15	15.0
3 kHz	95	106	11	15.5
4 kHz	95	105	10	13.0

FIGURE 41.4 Example of a report form used to document a patient's measured LDL in dB HL and dB SPL and REDD at 500, 1,000, 2,000, and 4,000 Hz. The data to the right are the average REDD. This form is placed in the patient's chart for future reference when measuring the RESR₉₀.

slightly soft," "comfortable," "comfortable, but slightly loud," "loud, but OK," and "uncomfortably loud."

Using an ascending procedure, the audiometer attenuator is increased in 5 dB steps to determine the intensity level (in dB HL and SPL) where the patient consistently reports that the puretone signals are "loud, but OK." This level is read in dB SPL from a video monitor of the real-ear analyzer and is recorded as the patient's LDL_{spl} at each test frequency and these values are placed in the patient's chart (Figure 41.3). In Figure 41.4, the LDL in dB HL is placed in the first column (85 to 95 dB HL for this patient) and the measured LDL_{spl} is placed in the next column (96 to 106 dB SPL for this patient). The difference between these two measures is the real ear to dial difference (REDD) and these values are placed in the third column (10 to 15 dB for this patient). The last column to the right reports the average REDD. As part of the hearing aid fit at a subsequent visit, the audiologist uses the real-ear analyzer and measures the output (in dB SPL) from the hearing aid at the tympanic membrane in response to a puretone sweep presented at 90 dB SPL (i.e., RESR₉₀; Figure 41.5). On completing the RESR₉₀,

FIGURE 41.5 Example of the measured RESR₉₀ [solid curve] below the individually measured LDL in dB SPL [dots]. The \uparrow symbol at 1,000 and 2,000 Hz reports that the measured LDL in dB SPL, in this case, was greater than 120 dB SPL [upper line on the ordinate].

the audiologist can determine the relationship between the measured RESR₉₀ and the previously measured LDL_{spl}. The audiologist must verify that the RESR₉₀ is below the measured LDL_{spl}; if so, this suggests the patient will not judge loud environmental sounds to be uncomfortably loud. As can be seen in Figure 41.5, this goal has been achieved for all test frequencies.

Patient Counseling on Realistic Goals

It is important that patients obtain information that will portray a realistic "picture" of the benefits they can expect from amplification; this may vary somewhat across patients. With these goals in mind, the patient is counseled on some or all of the following points:

- Performance with hearing aids in "quiet" will be significantly better than performance without the hearing aids. At this point, the patient is reminded that the final judgment of "significant benefit" does not rely on the outcome of the numerous measures described in this chapter. Rather, the final decision concerning benefit lies exclusively with the patient.
- Performance with the hearing aids in "noise" must be significantly better than the performance without the hearing aids (at least for patients with mild-to-moderate hearing loss). Achieving this goal is very important because most patients seek amplification because they experience difficulty recognizing speech in noise. Currently, it is our experience that fitting hearing aids incorporating directional microphones significantly increases the likelihood of achieving this goal (Kochkin, 2000; Valente et al., 1995).
- Patients should not expect performance in "noise" to be as satisfactory as performance in "quiet." We explain that even listeners with normal hearing do not recognize speech as well in a "noisy restaurant" as they do in a "quiet living room." Therefore, the patient is reminded there is no reason to expect his/her hearing aids to perform as well in "noise" as in "quiet."
- Input signals of a "soft" input level (i.e., 40 to 50 dB SPL) should be perceived as "soft, but audible."
- Input signals of an "average" input level (i.e., 60 to 70 dB SPL) should be perceived as "comfortable."
- Input signals of a "loud" input level (i.e., 80 dB SPL or greater) should be perceived as "loud, but not uncomfortable."
- Earmolds or custom shells must be comfortable.
- The patient's voice should not sound as if he/she is speaking at the bottom of a barrel (i.e., occlusion effect).
- The patient should not experience acoustic or suboscillatory feedback.
- It is common for patients purchasing "new" hearing aids to expect to hear as well as their normal-hearing friends in a noisy restaurant. To address this expectation, we ask

the patient to mentally “score” the percent of the conversation understood from his/her “normal”-hearing friend(s) when communicating in noisy situations. Next, the patient then asks his/her normal-hearing friend(s) what percent of the patient’s conversation did the friend understand. It has been our experience that very often the difference between these two “scores” is often not as great as the patient previously predicted they might be. The patient then has a greater appreciation that even friends with “normal”-hearing experience significant difficulty in noisy environments. After completing this simple exercise, the patient typically has a better “feel” for the benefit achieved with the aids and his/her expectations are more realistic. Moreover, audiologists should counsel that even greater benefit in noise can be achieved with HAT (Lewis et al., 2004) and auditory rehabilitation.

- k. If these expectations are not fulfilled, the patient must return to the office so that the hearing aids can either be readjusted or replaced with another form of technology. If these problems cannot be addressed in a satisfactory manner, then the hearing aids must be returned for credit. We counsel patients that it is not our intent for these hearing aids to be another set of hearing aids lying in a dresser drawer.

Bilateral versus Monaural Amplification

Next, and when appropriate, we counsel on the advantages of bilateral amplification. At our clinic, we strongly promote bilateral fittings to eliminate the *head shadow effect* and to yield a more “natural” amplified sound. During the 30-day trial period, patients are counseled to use the hearing aids equally as a monaural and bilateral fit. We want the patient to assess whether or not the addition of the second hearing aid proves beneficial. Using this approach, approximately 85% of patients in our practice have decided that the second hearing aid provides significant benefit and to keep the second hearing aid. The remaining 15% feel that performance was equal with one hearing aid in either ear in comparison to two. These relatively few patients decide to return one hearing aid for credit. Using a different strategy, we found that if the initial monaural fitting was found to be successful, only 15% of our patients returned to convert their monaural fitting to bilateral. For these reasons, when the audiometric results and case history profile are appropriate, we typically fit bilaterally at the time of the initial fitting.

Hearing Aid Style, Technology, and Signal Processing

We counsel the patient on

- a. Style: Conventional BTE, BTE with a receiver in the ear canal (RIC), BTE with a thin tube, ITE, ITC, CIC, and a “Lyric®-type” device described earlier.

- b. Microphone technology: Omnidirectional, fixed directional, adaptive directional, automatic adaptive directional, and automatic multichannel adaptive directional microphone. An adaptive directional microphone is designed to automatically apply the most effective polar design depending on the azimuth and input level of the noise. A cardioid design will automatically be in place when the noise is directly behind and a bidirectional polar design will be in place if the noise moves from the back directly to the side. An automatic adaptive directional microphone is similar with the exception that the microphones will automatically change from directional to omnidirectional when the environment switches from noisy to quiet. The patient is not required to press a switch to change the hearing aid from omnidirectional to directional and vice versa. When in the directional mode as described above, the microphone is fully adaptive. Thus, an automatic adaptive microphone can theoretically provide the greatest benefit if patient convenience is a consideration.
- c. Various benefits of digital signal processing (DSP): Feedback management, expansion to reduce/eliminate circuit noise for those patients with normal low-frequency hearing, noise reduction (NR) for improved comfort in noisy listening situations, and multiband processing for greater precision in shaping the frequency-gain/output response.
- d. Telephone communication: Programmable t-coil, wireless Bluetooth communication, automatic t-coil, and bilateral t-coil to a telephone signal placed at one ear.
- e. HAT: Our facility has a fully stocked HAT display in two counseling rooms. In these rooms, patients can see and experience the benefits provided by such devices. In these rooms, there are infrared television listening devices, amplified telephones, wireless Bluetooth communication systems, FM devices, alarm clocks, and other devices. Also, both counseling rooms are induction looped so patients may experience the benefits of looping using the t-coil(s).
- f. When applicable, we cover special applications:
1. Wireless CROS/BICROS.
 2. Auditory osseointegrated system (AOIS), SoundBite, transcranial CROS, and TransEar for patients with unilateral hearing loss (UHL).

For additional information on the various types of hearing aid technologies and signal processing, the reader is referred to Chapter 38.

Counseling Goals

The overall goals of this extensive counseling are threefold. First, the audiologist must determine a hearing aid fitting that is the most appropriate for the patient in terms of addressing (a) the patient’s goals (i.e., “hear better in noise,” “improved communication on the telephone”), (b) style

(BTE, ITE, ITC, CIC, deeply seated style such as the Lyric®), and (c) technology (number of channels and bands, feedback management, adaptive directional microphone, expansion, cost, and other features). Second, the authors believe that a well-informed patient will more likely result in greater user satisfaction than an uninformed or underinformed patient. Third, the patient needs to feel that he/she is as much a part of the decision in selecting the “appropriate” hearing aids as is the audiologist. The final decision of which hearing aids to pursue is based on the interaction of such issues as

- a. The magnitude, configuration, and symmetry of the hearing loss.
- b. Listener lifestyle and the demands on communication.
- c. The patient’s need or demand for the “best and/or most convenient” signal processing technology to reduce the deleterious effects of background noise. We cannot remember a single patient reporting he/she hears better in “noise” than in “quiet.” Therefore, our primary goal is to counsel the patient on the available technology that has been proven via research to improve the recognition of speech in noise.
- d. Importance of communication on the telephone and the sensitivity of the telecoil.

Unaided Outcome Measure

It is imperative that a comprehensive hearing aid fitting process must include some outcome measure assessing the patient’s impressions of hearing aid benefit (i.e., the degree of perceived improvement in the aided vs. unaided listening conditions). Numerous self-assessment questionnaires are available to consider. These include the Communication Profile of Hearing Impairment (Erdman and Demorest, 1990), Hearing Performance Inventory (Giolas et al., 1979), Hearing Handicap Inventory for the Elderly (Newman et al., 1990), Abbreviated Profile of Hearing Aid Benefit (APHAB) (Cox and Alexander, 1995), Glasgow Hearing Aid Benefit Profile (Gatehouse, 1999), Satisfaction with Amplification in Daily Life (Cox and Alexander, 2001), and COSI (Dillon et al., 1997). Currently, APHAB and COSI are available on the latest HIMSA module as well as several manufacturers’ NOAH modules.

To satisfy the above-mentioned goal and as mentioned earlier, we ask the patient to initially complete the “unaided” portion of either the COSI or the Washington University questionnaires. With the COSI, the patient generates as many as five specific expectations (goals) he/she wants to achieve with the hearing aids. For example, “hearing better in noise,” “hearing better in church,” “hearing better on the telephone,” or “hearing better while communicating around the dinner table.” By being “forced” to focus on his/her goals, the counseling can focus on the hearing aid technology that will most likely allow the patient to achieve his/her goals. In addition, the responses allow the clinician to gain further

insight into the patient’s expectations and, in turn, allow the clinician to determine if these expectations are realistic and attainable. After the patient has had the opportunity to wear the hearing aids for 4 weeks, he/she is asked to check the box on the COSI form that asks, “to what degree have the hearing aids changed your expectations?” The choices are “worse,” “no difference,” “slightly better,” “better,” or “much better.” In addition, the patient is asked to check the correct box on the COSI form completing the statement “if, by using the hearing aids, you can hear satisfactorily: “Hardly ever (10%),” “occasionally (25%),” “half the time (50%),” “most of the time (75%),” or “almost always (95%).” The COSI has proven to be a very useful clinical tool, because it is easy to use and the goals are set by the patient rather than by the clinician.

With the Washington University questionnaire (Figure 41.1), the patient is asked to mark (placing a check in a column) the magnitude of difficulty (“always,” “often,” “sometimes,” “rarely,” “never,” or “not applicable”) under the unaided condition (“X” in Figure 41.1). The patient is furthermore asked to rate his/her current aids (if experienced user; “O” in Figure 41.1) for 14 listening situations divided into 3 areas (difficulty at home, difficulty at work, and difficulty in social situations). After the patient has had the opportunity to wear the hearing aid for at least 4 weeks, he/she is asked to check the column corresponding to his/her perception of the performance of the new aids relative to the unaided condition and, if applicable, to his/her current hearing aids (“+” in Figure 41.1). In this manner, the audiologist can quickly determine if the patient perceives the aided performance as being better than either the unaided condition or with his/her current hearing aids. This is because the check mark would be placed in a column further to the right than was marked for the unaided and/or current aids. The Washington University questionnaire has proven to be an efficient and useful clinical tool, because of its ease of use for both the patient and the audiologist.

Earmold Impressions

Finally, and at the end of this second visit, impressions are made for the purpose of ordering earmolds for BTE fittings or custom products. Figure 41.6 illustrates an important point concerning the benefits of ordering a Libby 3- or 4-mm horn for a BTE fitting. In this case, the first author was fitting a patient who arrived at the clinic from another facility with a BTE coupled to the earmold with No. 13 tubing. Initial real-ear insertion gain (REIG) measures were performed to verify if the measured REIG reasonably matched the prescribed NAL-RP (solid curve) target. The initial REIG (lower curve) with the No. 13 tubing revealed that the measured REIG was significantly below gain of the prescribed formula. Rather than attach the hearing aid to the programmer to increase the gain to match the target, it was decided to remove the No. 13 tubing and drill the bore

FIGURE 41.6 Difference in measured REIG between No. 13 tubing and 4-mm Libby horn. The *wider curve* represents the NAL-NL1 prescriptive target for a 65-dB SPL input level.

to make it wider to accept the wider outside diameter of the 4-mm horn. A repeat REIG with the 4-mm horn (upper curve in Figure 41.6) clearly indicates that the REIG with the 4-mm horn arrives much closer to the prescribed REIG than was possible with the No. 13 tubing. More importantly, the amplifier in the hearing aid was not programmed to achieve the greater required gain (i.e., the clinician was able to maintain greater headroom). This leaves the amplifier available for future increases in gain, should the patient's hearing loss decrease. By not programming the amplifier to provide greater amplification, there was probably less distortion at the output of the hearing aid and the amplified sound was crisper. It is our strong belief that almost all patients should be fit with hearing aids coupled with a 3- or 4-mm horn unless the hearing loss is of a rising configuration. In our clinics, virtually all of our patients are fit with a 3- or 4-mm horn! Also, we order earmolds and custom products with a select-a-vent (SAV) to provide greater flexibility for controlling the low-frequency response to reduce or eliminate the occlusion effect and maintain some control over feedback.

One significant advance in earmold technology has been the manner in which impressions are being processed after the impression has been made. In the past, the impression was made and placed in a box with the order form and forwarded to the hearing aid manufacturer or earmold laboratory. At this point, a cast of the impression was made to create the end product. This process is still completed, but with one major change. Advances in computer and software technology in the past several years allow most manufacturers to scan the received impression and store it in their computers. The scanned impression is then modeled and decisions are made by the software for deriving the final product. Initially, scanning technology was only available for the leading hearing aid manufacturers and earmold laboratories for the purpose of modeling custom products. A few years ago, one manufacturer allowed audiologists to scan the impression within the clinic and download the scanned image to the manufacturer via the Internet. Now, several

laboratories provide similar technology. One of the obvious advantages of this method is that it is no longer necessary to remake impressions when a problem is present with the initial impression. The remake can be manufactured from the scanned image. A more recent advance from at least two manufacturers is the ability for audiologists to directly scan the ear and ear canal (i.e., no impression is made) and send the scanned image immediately over the Internet to earmold laboratories and hearing aid manufacturers. Using this process, the concerns and issues of placing otodams and impression material into the ear canal will soon be a process of the past.

Coupler Measures (between the Second and Third Visits) with ANSI-2003 (Revised in 2009)

When the hearing aids arrive from the manufacturer, they are placed on an HA-1 or HA-2 coupler and their performance is compared to the ANSI-2003 (Figure 41.7) measures supplied by the manufacturer. Recently, ANSI-2003 was revised to ANSI-2009, but we experience, at the time of preparing this chapter, no hearing aid analyzer has the software to implement its use and no hearing aid manufacturer is delivering hearing aids measured using ANSI-2009. The performance of the hearing aid must adhere to the specifications provided by the manufacturer. If not, the hearing aid is sent back to the manufacturer to be replaced by another unit. See Chapter 39 for a detailed discussion of the ANSI-2003 standard and any impending changes.

In addition to measuring the performance of the hearing aids re: ANSI-2003, the authors may also evaluate the "smoothness" of the frequency-gain response to input levels of 50 to 90 dB SPL, in 10-dB steps (ANSI-1992). Figure 41.8 illustrates the frequency-gain response of one hearing aid measured for input levels of 50 dB (upper curve) to 90 dB SPL (lower curve) in 10-dB steps. Notice how the "smoothness" of the frequency-gain response for the 90 dB SPL input is the same as the "smoothness" of the frequency-gain response for the 50 dB SPL input. On the other hand, if the hearing aid yielded significant intermodulation distortion, one would expect the frequency-gain response obtained with the 80 to 90 dB input (lower curves) to be "irregular" or "jagged" when compared to the frequency-gain responses at 50 to 70 dB SPL. Revit (1994) reported that the appearance of a "jagged" frequency-gain response at higher input levels is an indication of the presence of intermodulation distortion, which in turn can result in reduced recognition of speech or poor sound quality. We feel that clinicians should return any hearing aid to the manufacturer for which a "jagged" frequency-gain response is obtained and a copy of the coupler printout verifying the presence of the jagged frequency-gain response should be sent along with the repair form.

FIGURE 41.7 Example of ANSI S3.22-2003 coupler measure for a hearing aid with nonlinear signal processing and a telecoil.

FIGURE 41.8 Example of ANSI S3.42-1992 coupler measure for input levels of 50 to 90 dB SPL for the same hearing aid.

Special Tests

Virtually all current hearing aids are delivered incorporating multichannel, DSP. As indicated earlier, there are many significant advantages provided by DSP when compared to previous analog signal processing. One potential disadvantage of DSP in increasing the number of channels of signal processing is group delay. “Processing time” or group delay is defined as the finite time delay created as an input signal passes through a hearing aid from the microphone to the receiver. The group delay in digital hearing aids is considerably longer in comparison to analog hearing aids because of the complex conversion of the input sound signal into discrete quantities for signal processing. Whereas the time required for a single-channel analog hearing aid to process input signals is a few tenths of a millisecond, the time needed for DSP can vary widely depending on the DSP algorithm and number of processing channels. In general, the greater the number of processing channels, the longer the processing time or group delay. One major concern of current open-fit hearing aids is the possibility of an unprocessed signal passing through a vent or leak around the earmold or shell and being heard earlier than the processed signal that is delayed because of the delay created by the hearing aid.

Previous research has demonstrated that long group delay can negatively affect speech production and perception for normal-hearing and hearing impaired patients (Stone and Moore, 2005). Specifically, concerns of auditory confusion and degradation of speech production and perception of participants’ own voices (Stone and Moore, 2005) as a result of delay have been investigated.

Auditory confusion can occur when there is a delay between the hearing aid user observing the movement of the talker’s lips and hearing the sound of the talker’s voice. Summerfield (1992) reported that sound can lag the visual image by up to 80 ms before confusion will occur. Therefore, he recommended that processing for hearing aid users with severe-to-profound hearing loss be as short as possible. A group delay as long as 40 ms was felt to be acceptable.

Stone and Moore (2002) reported on the effect of group delay on normal-hearing participants’ own speech production and own voice perception using a simulation of hearing loss. They reported that delays greater than 20 ms can lead to the perception of an “echo” in the participant’s own voice, whereas delays of less than 10 ms might lead to a perception of a subtle change in the timbre of the sound. In a follow-up study, Stone and Moore (2005) utilized hearing impaired participants to measure the effect of group delay (13 to 40 ms) on perception of the participant’s own voice and speech production. It was concluded that participant disturbance to the sound of his/her voice increased with increasing group delay. Additionally, participants with low-frequency (500, 1,000, and 2,000 Hz) hearing loss greater than 50 dB HL were significantly less disturbed than those

participants with milder low-frequency hearing loss. Specifically, the results showed that delays of greater than 15 ms can be unacceptable to listeners with low-frequency hearing loss at approximately 35 dB HL, but patients with more moderate-to-severe hearing loss in the low frequencies may be able to tolerate longer delays.

Stone and Moore (2002) also analyzed objective and subjective measures of the effects of hearing aid delay on speech production and perception in two different environments with the goal of defining an upper limit to permissible processing delay. They concluded that normal-hearing participants reported that the disturbing effects on perception became significant when delays exceeded 15 ms in an office environment and 20 ms in a test booth. Objective measures of speech production did not show any significant negative effects of delay until the delay reached 30 ms. As a result of these findings, Stone and Moore (2002) proposed that DSP hearing aids should be able to incorporate delays as long as 15 ms with few negative side effects. Additionally, the amount of tolerable processing delay decreased by about 5 ms in reverberant environments as compared to a near-anechoic environment.

Electroacoustic Procedures for Assessing DSP Features

Although not included as part of the ANSI-2003 standard, several tests are now available to verify a number of DSP features. These include measures of group delay, use of modulated “speech-like” signals to assess the compression characteristics of the hearing aid, and the use of a bias signal to assess the effectiveness of the NR algorithm.

GROUP DELAY

Although this may vary between manufacturers, using the Frye Electronics™ hearing aid and real-ear analyzers, the group delay test uses a simple broadband impulse signal and a 20-ms time window. The measured group delay is calculated from the sampling rate (25.6 kHz), internal analyzer delay (approximately 0.5 ms), and the characteristics from the hearing aid. Figure 41.9 illustrates the group delay (curve to the left) for the left (1.5 ms) hearing aid. Ideally, for reasons described above, the audiologist would hope to record a value of ≤ 15 ms. Also, this simple test can inform the audiologist whether the hearing aid is analog or digital. If the group delay is ≤ 1 ms after completing the test, then the hearing aid is probably a single-channel analog device. On the other hand, if the group delay is ≥ 1 ms, then the hearing aid is probably a multichannel DSP device.

MODULATED SPEECH SIGNAL

The NR feature in current DSP hearing aids often reacts to a continuous speech-shaped signal as if it were noise and

FIGURE 41.9 Example of measurement of group delay [1.5 ms] for left and right hearing aids.

reduces gain/output. This can pose problems when trying to verify hearing aid gain/output characteristics. To resolve this problem, manufacturers of hearing aid and real-ear analyzers have developed *modulated* or “live speech” signals so the DSP processes the signal as speech and does not reduce gain/output. With the Frye Electronics™ units, a continuous composite speech signal can also be presented as a randomly amplitude-modulated speech signal in bursts that are 300 ms wide. To verify that the noise suppression (compression) feature of a DSP aid is operating effectively, a simple test is to examine the performance using the continuous composite speech ANSI signal. The audiologist then takes a second measure with the modulated ANSI signal (Figure 41.10). The difference between the two measures (typically the measure for the continuous signal will be lower than the measure for the modulated signal) reflects the amount of overall noise suppression provided by the hearing aid to a broadband noise. If the two curves are superimposed, it is a good indication that the noise suppression feature has been disabled or is not functioning properly, or the hearing aid does not contain noise suppression. It is important to remember that significant differences may be present in the noise suppression feature between hearing aid manufacturers. It is also possible that manipulation of the input level may be required to activate the noise sup-

pression or the audiologist may need to wait a few seconds before the noise suppression becomes active.

In several hearing aid and real-ear analyzers, audiologists also have the option of using several “speech-like” signals. With the Frye Electronics™ units, the audiologist has the option of using an ANSI (ANSI S3.42-1992) or the International Collegium of Rehabilitative Audiology (ICRA) speech signal. The spectra of these two input signals in Frye Electronics™ equipment are quite different (Figure 41.11). The ANSI signal decreases at a rate of 6 dB/octave above 900 Hz, whereas the ICRA signal is flat to about 500 Hz and then decreases more sharply at a rate of 10 dB/octave above 500 Hz. Below 900 Hz, ICRA is 3 dB more intense than ANSI. At frequencies above 900 Hz, ICRA rolls off more steeply than ANSI such that at 2,000 Hz, ICRA is 8 dB less intense than ANSI and by 8,000 Hz ICRA is 16 dB less intense than ANSI. This means it is possible to measure significantly different gain and output values depending on the signal processing of the hearing aid. If the hearing aid has a low compression kneepoint in the high frequencies, it is likely that the measured gain/output using the ICRA signal will be considerably greater than with the use of the ANSI spectra (middle and upper curves in Figure 41.12). The lower curve in Figure 41.12 is the response of the hearing aid to a continuous composite speech signal. This curve

FIGURE 41.10 Example of the differences in measured REAR using a continuous ANSI composite signal [lower curve] and a modulated ANSI signal [upper curve] illustrating the compression of a DSP hearing aid.

shows the least amount of gain, because the hearing aid is processing this signal as noise.

BIAS SIGNAL

To help audiologists verify the effectiveness of NR filters of a DSP hearing aid, Frye Electronics™ introduced a “bias

FIGURE 41.11 Difference in spectrum between the ANSI and ICRA speech signals on the Frye 7000.

signal” test. With this test, a randomly modulated speech spectrum signal (the audiologist can control the overall level of the speech signal) and a randomly modulated puretone signal are presented simultaneously (the audiologist can control the frequency and intensity of the bias signal). With

FIGURE 41.12 Difference in measured REIG for a DSP hearing aid using continuous ANSI composite [lower curve], modulated ANSI [middle curve], and ICRA [upper curve].

FIGURE 41.13 Illustration of the effectiveness of the NR feature of a DSP hearing aid using a 500-, 1,000-, 2,000-, and 4,000-Hz bias signal.

this test, and if the NR filter is functioning properly, the audiologist will see a reduction in gain/output in the frequency region surrounding the bias puretone signal. The remaining portion of the frequency response above and below the bias signal will maintain full amplification. For example, in Figure 41.13, a 500-Hz bias signal is presented with modulated ANSI speech. As can be seen, only the frequency region around 500 Hz reveals attenuation whereas the frequency region above approximately 500 Hz shows full amplification. Also, reported in Figure 41.13 is the same reduction of the output at 1,000, 2,000, and 4,000 Hz using the 1,000-, 2,000-, and 4,000-Hz bias signal. The more channels the DSP aid has, the narrower the frequency region in which the reduction of gain/output occurs with this test. On the other hand, in a hearing aid with fewer channels, the broader bandwidth will reduce the gain/output in a broader frequency region. One must remember that when there is a reduction of gain/output in response to a noise, there is also a reduction of gain/output in the same region of the speech signal (i.e., no change in the signal-to-noise ratio within that channel). It can be assumed that a hearing aid with a greater number of channels may provide greater speech intelligibility/

comfort in noise. This is because a narrower slice of the speech signal is being reduced in response to the NR feature of the hearing aid.

HEARING AID FITTING (THIRD VISIT)

Real-Ear Measures

The most reliable and efficient method for verifying the performance provided by amplification is REM. Research reports that the 95% confidence interval (CI) for repeatability of REM is approximately 3 dB (Valente et al., 1991). By comparison, the 95% CI for functional gain measures (i.e., unaided sound-field puretone or spondee thresholds minus aided sound-field puretone or spondee thresholds) is approximately 15 dB (Hawkins et al., 1987). If the audiologist were to incorporate a modification to a hearing aid (i.e., change in the vent size or tubing diameter, change in the damper in the earhook, or reprogramming of the aid) the difference between the gain measured after the change would have to be at least 3 dB different than the first REM

FIGURE 41.14 Example of measured REUG (lower curve), REAG (middle curve), and REIG (upper curve) for a linear hearing aid to the NAL-NL1 (“A”) prescriptive target for an input level of 65 dB SPL.

for the difference to be considered statistically significant. Because of the greater variability inherent in functional gain measures, the difference between the second and first measures would have to be greater than 15 dB for the results to be statistically significant. One can readily see that REMs are considerably more reliable than functional gain measures. Consequently, it is highly recommended that REMs be used consistently instead of functional gain measures.

Typically, at least three REMs are obtained clinically. The first involves the measurement of the response of the ear canal without the hearing aid in place. This is referred to as the real-ear unaided gain (REUG in gain) or real-ear unaided response (REUR in dB SPL) and is an accurate and reliable measure of the resonance of the ear canal (lower curve in Figure 41.14). To make this measure, the patient is seated in a chair directly facing a loudspeaker (i.e., 0° azimuth) that is placed at ear level at a distance of 12 to 18 inches. The probe-tube from the probe microphone is marked 30 mm from the tip for adult males and 26 mm for

adult females. This mark is placed at the intratragal notch and taped in place. A short burst of a speech-weighted composite noise is presented at a level of 65 dB SPL and stored as the unaided response (lower curve in Figure 41.14). As stated above, this measure represents the ear canal resonance. In the normal adult ear, the REUG has a peak amplitude of approximately 18 dB at 2,800 Hz.

Next, the hearing aid shell, or earmold coupled to a BTE, is placed in the ear canal and the volume control is typically adjusted to the patient’s most comfortable level (MCL). The resulting measure is the real-ear aided gain (REAG in gain) or real-ear aided response (REAR in dB SPL) provided by the hearing aid (middle curve in Figure 41.14). The difference between the REAG and REUG is the REIG (upper curve in Figure 41.14), or the gain provided by the hearing aid. The REIG is compared with the prescribed target (“A” in Figure 41.14) to determine if the measured frequency-gain response is appropriate for the patient’s hearing loss.

To obtain the target REIG, the patient's audiometric data are entered into a real-ear analyzer to generate a "target" REIG ("A" in Figure 41.14) to which the measured REIG is compared. For the hearing loss illustrated in Figure 41.14, most audiologists would agree that the measured REIG closely matches the prescribed NAL-NL2 (Dillon et al., 2011) target.

Verification using a single input level is appropriate if the hearing aid has linear signal processing, because gain remains constant and measuring gain at several input levels would provide little additional information. On the other hand, if the hearing aid has nonlinear signal processing, then verifying gain should be made using several input levels. Figure 41.15A to C illustrates the verification of a hearing aid with nonlinear signal processing where it is easy to see that the measured REIG₅₀ matches NAL-NL1 for a 50-dB SPL input signal (Figure 41.15A), 65-dB SPL input signal (Figure 41.15B), and 80-dB SPL input signal (Figure 41.15C). It can be seen in Figure 41.15A to C

that REIG is greatest for the 50-dB SPL input level and the REIG decreases, as the input level increases from 65 to 80 dB SPL.

Measuring the REAR (dB SPL) to the Dynamic Range (dB SPL)

In a recent survey, Mueller and Picou (2010) reported that of the approximately 70% of audiologists who routinely verify the performance of hearing aids using REM, 78% measure the REAR to a prescriptive target and approximately 22% use the REIG. Since the previous edition of this chapter, there has been a significant increase in the number of audiologists selecting to verify where the amplified output (i.e., REAR in dB SPL) resides within the patient's individually measured dynamic range (DR). Using this method, the "prescriptive target" is the individual DR and the purpose is to verify where the amplified output, in response to a wide range of input levels, falls within the DR.

FIGURE 41.15 Example of REUG [curve 1], REAG₅₀ [curve 2], REAG₆₅ [curve 3], REAG₈₀ [curve 4] in the lower segment of A–C. Also reported is the REIG₅₀ [curve 6], REIG₆₅ [curve 7], and REIG₈₀ [curve 8] for a nonlinear hearing aid to the NAL-NL1 (“A”) prescriptive target for an input level of 50 (A), 65 (B), and 80 dB SPL (C). [continued]

B

C

FIGURE 41.15 (Continued)

FIGURE 41.16 Example of REAR measures for a nonlinear hearing aid. In this case, the “T” represents the predicted threshold in dB SPL and “U” in the *upper part* of the figure represents the predicted LDL in dB SPL. The area between the “T” and “U” is the predicted residual dynamic range for the listener. The “L,” “M,” and “H” represent the NAL-NL1 REAR targets for soft, average, and loud input levels, respectively. The 2, 3, and 4 curves represent the measured REAR for input levels of 50, 65, and 80 dB SPL.

Figure 41.16 illustrates how this is accomplished. In this figure, “T” represents the predicted threshold in dB SPL, “L” is the NAL-NL1 target for an input of 50 dB SPL, “M” is the NAL-NL1 target for an input of 65 dB SPL, “H” is the NAL-NL1 target for 80 dB SPL, and “U” (the most upper curve) represents the LDL. The space between “T” and “U” is the predicted residual DR for the patient. Here, the reader can see the REAR for an input of 50 dB is very close to the “L” target for most of the frequency range. The REAR for the 65-dB input (“3”) is at or near the “M” target. The REAR for the 80-dB input (“4”) is at or near the “H.”

Figure 41.17 illustrates similar information using the MedRx Live Speech Mapping unit. In this figure, the lower “O” line represents threshold and the upper “U” line represents LDL. The lower curve is the REAR to an input of 56 dB SPL using live speech (e.g., spouse talking to the patient using a microphone in combination with the software) and the measured REAR is above the “O” target indicating soft

speech is audible. The middle curve is the REAR in response to an input of 67 dB SPL using the same stimuli and method, whereas the upper curve is the REAR in response to an input of 89 dB SPL. Again, it can be verified that the REAR to the input range of 33 dB (56 to 89 dB) falls within the DR.

Finally, Figure 41.18 illustrates similar information using the Audioscan Verifit system. In this example, the “X” and “O” in the left and right boxes represent threshold for the right and left ears, respectively; the “.” represents the LDL and the “+” represents the REAR target for an input of 65 dB SPL.

Although significant differences exist between these pieces of equipment, their commonality is in allowing the audiologist to measure how the output of the hearing aid lies within the DR range (measured in dB SPL near the tympanic membrane) of the patient. These units allow audiologists to verify that the measured output to an input level of 50 dB SPL is above threshold, the measured output to an input level of 65 dB SPL falls approximately midway between threshold

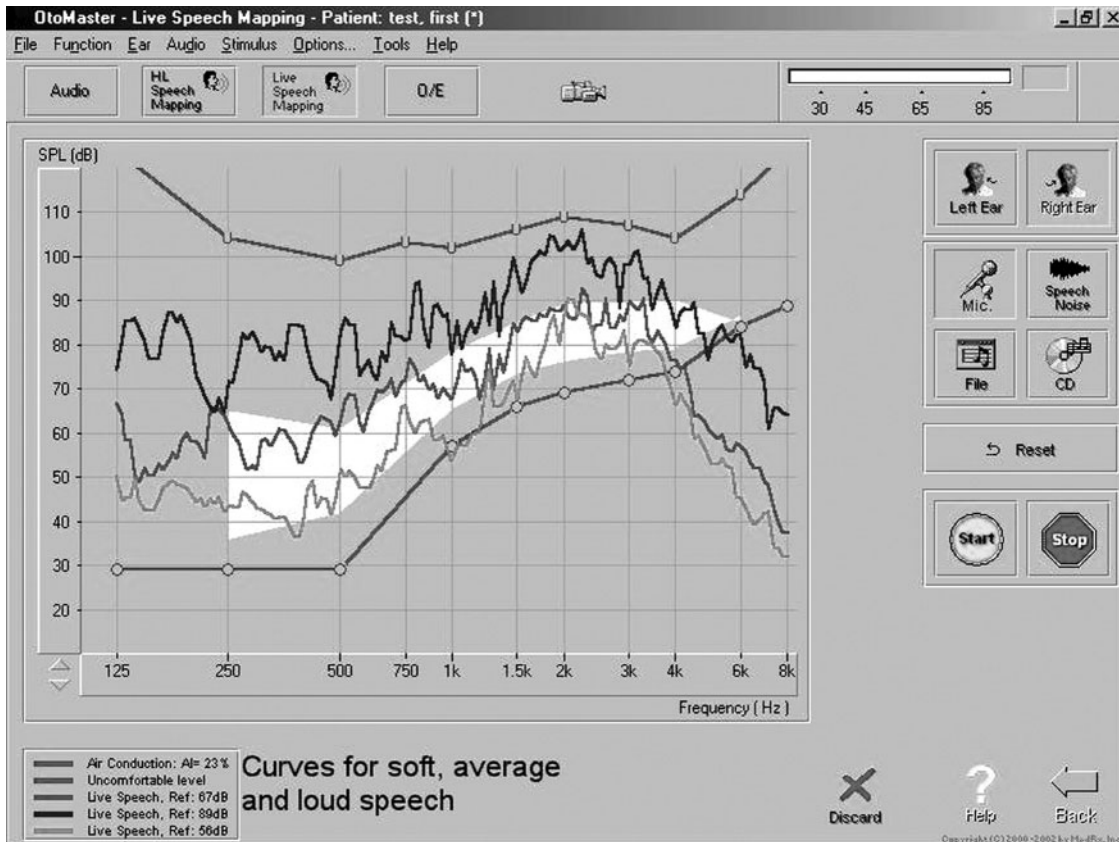

FIGURE 41.17 Example of REAR measures for a nonlinear hearing aid using the MedRx. [Courtesy of MedRx.]

FIGURE 41.19 Measured threshold and LDL (in dB HL) for a patient.

and LDL, and the measured output to a high-input level (85 to 90 dB SPL) is below the LDL.

One problem associated with these devices is the reliance on predicted threshold (dB SPL) and LDL (dB SPL) based on the entered audiogram. After the audiologist enters the audiogram, the respective unit converts the entered thresholds (dB HL) into threshold in dB SPL by using average REDD transformations of dB HL to dB SPL. In addition, the software within these units predict the LDL in dB

HL based on the data published by Pascoe (1988) and then transforms these values into dB SPL using average REDDs. Unfortunately, research has shown that the interparticipant variability of the combined factors of REDD and LDL can be as great as 40 dB wide (Pascoe, 1988; Valente et al., 1997). With such variability, it is difficult to imagine with any degree of confidence that the predicted threshold and LDL in dB SPL would be the same as individually measured thresholds and/or LDLs. If the advantage of these units is that the “target” is the patient’s DR and these units can report how the hearing aid output fits within that DR, then it would seem appropriate that the DR appearing on the monitor of these units reflects the DR of the individual and not the DR of an average individual.

Figures 41.19 and 41.20 illustrate how this could be a potential problem. Figure 41.19 reports the measured hearing thresholds and LDLs in dB HL for the right ear of a patient. The LDLs are the same as those appearing in Figure 41.4 at 500 to 4,000 Hz. These audiometric thresholds were entered into the software of one commercially available real-ear system. From these entered thresholds, the software predicted thresholds in dB SPL by adding the average REDD. The result is the “predicted threshold” illustrated in Figure 41.20. The “measured threshold” is the result of adding the patient’s measured REDD (values in parenthesis in Figure 41.4). As can be seen, in this case there was very little difference between “measured” and “predicted” thresholds (dB SPL). The upper curve in Figure 41.20 is the “predicted LDL” that was calculated by the software of the real-ear system predicting the LDL in dB HL from the entered threshold of the patient based on the results of Pascoe (1988) and adding the average REDD. The

FIGURE 41.20 Measured and predicted threshold and LDL (in dB SPL) for the same patient.

lower upper curve in Figure 41.20 is the “measured LDL” that was measured at the time of the HAE, as described earlier and reported in the table in Figure 41.4. As the reader might recall, the LDL measured by Pascoe (1988) was based on a loudness judgment of “too loud,” whereas the loudness judgment for the measured LDL was “loud, but OK.” In addition, the “measured LDL” uses measured REDD and not predicted REDD. In this case, this is of minimal impact for this patient, as seen in the similarity of predicted and measured thresholds in the lower curves of Figure 41.20.

In this case, the measured and predicted thresholds were quite similar, but the differences between measured and predicted LDLs were quite large. Therefore, the differences in DR between the measured and predicted curves can clearly be seen. In this case, the predicted DR is significantly wider than the measured DR. This can have a significant impact on the selection and programming of the compression and output-limiting characteristics of the hearing aid. If the audiologist used the predicted LDL to determine where to place the RESR₉₀, it can easily be seen how this patient would probably find the output of the hearing aid to be excessively loud and possibly reject amplification.

Selection of Prescriptive Formulae

PRESCRIPTIVE “TARGETS” FOR LINEAR AMPLIFICATION

Although not as commonly used as in the past, for hearing aids providing linear amplification (i.e., constant gain for varying input levels), we verified if the measured REIG “matches” the prescribed REIG by presenting an input signal level of 65 or 70 dB SPL (i.e., REIG65-70). Figure 41.14 illustrates the measured REIG65 (thin curve) in relation to the prescribed NAL-NL1 REIG target (“A” in Figure 41.14). Notice how well the measured REIG65 compares to the prescribed target curve. If this goal is accomplished, we are reasonably assured that adequate amplification has been provided to allow average conversational speech in a “quiet” environment to be audible and comfortably loud. Please note we are not overly concerned if the measured REIG65-70 does not “hit” the prescribed REIG at each frequency, but are more concerned about whether the *shape* of the measured REIG65-70 “matches” the *shape* of the prescribed REIG. This is because the user has the ability to adjust the overall gain with the gain control.

Currently, the most popular prescriptive “target” for linear aids appears to be the NAL-NL2 (Dillon et al., 2011; Keidser et al., 2011) and DSL i/o V5.0 (Scollie et al., 2005).

PRESCRIPTIVE “TARGETS” FOR NONLINEAR AMPLIFICATION

Typically, most hearing aids entering the commercial market use nonlinear signal processing (i.e., greater gain for low-input levels and less gain for high-input levels). Audiologists

can now program crossover frequencies (Cf), compression threshold(s) (CT), compression ratio (CR), and time constants in one or more channels (bands) (see Chapter 35 for in-depth discussion of these parameters). Because of this, prescriptive procedures designed for linear signal processing (i.e., gain remains constant as input level changes) are no longer appropriate. To address this need, several prescriptive procedures for nonlinear signal processing have been introduced.

One approach incorporated into many of the new prescriptive procedures is to re-create the normal loudness patterns of speech and other complex sounds for the hearing impaired listener (i.e., “normalization” approach). This approach is the major fitting goal of hearing aids using wide DR compression (WDRC). Clearly, it may be difficult to normalize loudness patterns for complex sounds (i.e., speech) because abnormal loudness growth functions vary not only as a function of frequency, but also as a function of signal duration. An example of the new procedures using this approach includes DSL i/o V5.0 (Scollie et al., 2005) for variable CR circuit types.

Some professionals argue that the normalization approach may not maximize speech intelligibility when compared to procedures whose fitting goal is to assure that all the frequency bands of speech are amplified to be equally loud at the MCL (i.e., “equalization” approach). Examples of the new procedures using this approach include NAL-NL2 (Keidser et al., 2011) and DSL i/o V5.0 (Scollie et al., 2005) for fixed CR circuit types.

In this section, we provide a brief overview of the two procedures (NAL-NL2 and DSL i/o V5.0) that are the most widely used to verify the performance of nonlinear hearing aids.

NAL-NL2

NAL-NL2 is the most recent attempt to provide a tool to assist audiologists in fitting nonlinear hearing aids more accurately (Keidser et al., 2011). This procedure is reportedly based on the principle of providing a frequency-gain response that maximizes speech intelligibility, while keeping the overall loudness of the input signals at a level that is no greater than that perceived by a listener with normal hearing. In comparison to the previous prescriptive formula (e.g., NAL-NL1) that was described in the previous edition of this chapter, NAL-NL2

- Provides a lower CR when fitted with fast acting compression, but a higher CR can be used in hearing with slow-acting compression for patients with severe-to-profound HL.
- Provides overall gain that is 2 dB lower for female patients than male patients.
- Recommends correction for binaural summation of 2 dB for input levels less than 50 dB SPL and 6 dB for input levels greater than 90 dB SPL. Thus, a bilateral fit has a greater CR than a monaural fit.

- Provides gain adaptation (i.e., increasing gain over time) for new users with moderate-to-severe hearing loss.
- Prescribes less overall gain for an input level of 65 dB SPL than NAL-NL1 for mild-to-moderate hearing loss (i.e., NAL-NL2 provides slightly less gain and a higher CR than was prescribed by NAL-NL1).
- Prescribes a slightly greater low-frequency gain for patients whose primary language is “tonal” (e.g., Chinese, East Asia).
- Prescribes a slightly “flatter” frequency response with greater gain in the low and high frequencies and slightly less gain in the mid frequencies.

To use the NAL-NL2 program, the audiologist performs the following:

- a. The audiologist first clicks the “Client Data” tab to enter the patient’s gender, level of experience with hearing aids (new or experienced), language (tonal or nontonal), and date of birth. Based on these entries, “corrections” are made within the software to generate the prescribed gain (REIG) or output (REAR).
- b. The next step is to click on the “Audiologic Input” tab and proceed to enter the transducer used to assess hearing thresholds (supra-aural earphone, insert earphone, loudspeaker), input value (dB HL, dB SPL in the ear canal or sound field, or nHL), hearing thresholds at 250 to 8,000 Hz for air conduction and bone conduction, predicted or measured real ear to coupler difference (RECD for threshold purposes or hearing aid purposes), REUG (predicted or measured), and REDD (predicted or measured). The RECD is the difference between the output of a hearing aid (or insert earphone) measured in the ear canal versus what is measured in a 2-cm³ coupler. The RECD is affected by individual differences in ear canal volume and tympanic membrane impedance. Finally, the predicted (e.g., average) values for RECD and REUG vary as a function of age and gender.
- c. The third step is to click on the “Section Screen” tab to enter the type of hearing aid (CIC, ITC, ITE, BTE), number of hearing aids being dispensed (unilateral or bilateral to correct for binaural summation), number of compression channels (1 to 18 to correct for channel summation), fitting depth (shallow, standard, or deep to correct for the remaining residual volume between the tympanic membrane and the tip of the hearing aid or earmold), type of tubing (No. 13, Libby 3 mm, Libby 4 mm, thin tube, or RIC), venting (occluded, tight, closed dome, 1, 2, 3 mm, open dome), and compression speed (slow, fast, dual, intermediate, or adaptive). In this section, the software provides suggestions on the “correct” manner to select tubing and venting based on the entered data.
- d. The fourth tab is the “Target” screen. With this screen, the audiologist can “instruct” the software to display target curves for input levels of 50 to 90 dB SPL, type of measure (REIG, REAG, SPL-O-GRAM (e.g., REAR)

real-ear input/output, coupler gain, coupler input/output, audiogram, ear simulator gain or input/output, aided sound-field thresholds, RESR, or coupler OSPL90), and Cf for as many as four channels if the number of compression channels of the dispensed hearing aid was documented in the “compression channel” selection in the “Selection Screen” tab. Finally, for each compression channel, the CT and CR are documented for the selected input levels which are typically 50, 65, and 80 dB SPL. Finally, the audiologist can view how the NAL-NL2 prescription compares to NAL-RP, POGO II (Figure 41.6), and IHAF. There are past prescriptive formulae for linear (NAL-RP and POGO II) and nonlinear signal processing (IHAF).

- e. The final tab is the “Speech Screen” where the audiologist can view the calculated SII (0.00 to 1.0) based on how the aided speech spectrum falls above or below the patient’s thresholds (i.e., audibility) for input levels from 55 (soft) to 75 dB SPL (loud).
- f. Finally, clicking on the “Preferences” under “File” the audiologist can set
 - a. The CT for wide dynamic compression between 0 and 100 dB SPL with the default set @ 52 dB SPL.
 - b. The method of limiting between multichannel, wide-band (default), or none.
 - c. The status of the reference microphone of the real-ear analyzer to head surface/control microphone on (default) or undisturbed field/reference microphone off. Also, the audiologist may set the azimuth of the loudspeaker for REM to 0° (default) or 45°.
 - d. The type of target to REIG (default) or REAG.
 - e. The input levels to 40 to 90 dB SPL or 50 to 90 dB SPL (default).

DSL I/O VERSION 5.0

This is a comprehensive software-based program (Scollie et al., 2005) designed to help audiologists select and verify the performance of linear and nonlinear hearing aids. The primary goal of DSL i/o V5.0 is to place conversational speech in the patient’s most comfortable listening range. The comfortable listening range targets are approximately midway between the participant’s threshold of audibility and the predicted (or measured) upper limit of comfort (one standard deviation below LDLs, as reported by Pascoe, 1988).

To use the DSL i/o V5.0 program the audiologist follows the following procedure:

1. The audiologist accesses the “Assessment” tab to enter the patient’s age (years or months), circuit type (linear or WDRC), patient type (pediatric or adult), style (BTE, ITC, ITE, CIC deep, CIC shallow, body), venting size (none, 1, 2, 3.5 mm, custom, or open), bilateral or unilateral fit, type of transducer (insert earphone using an E-A-R or immittance tip, insert earphone using a personal earmold, conventional TDH, loudspeaker at 0°, 45°,

or 90° or real ear in dB SPL), RECD type (HA-1 coupler tip, HA-2 coupler tip, HA-1 mold, or HA-2 mold), REUG (at 0°, 45°, or 90°), air conduction and bone conduction hearing thresholds (dB HL) at 250 to 6,000 Hz, LDL (dB HL) at 250 to 6,000 Hz, RECD, REDD, and REUG at 250 to 6,000 Hz, number of compression channels (1 to 17), and Cf.

- The next step is to click on the “Target and Output Data” tab to select the input level for Target 1 (usually 50 dB SPL; alternative range is 45 to 59 dB in 1 dB steps), Target 2 (usually, 65 dB SPL; alternative range is 60 to 70 dB SPL), and Target 3 (usually 80 dB SPL; alternative range is 71 to 84 dB SPL), program 1 and 2 type (quiet and noise), verification signal (speech, speech noise, or puretone), and output (REAR, REAG, REIG, or sensation level). At this point the prescribed targets will be generated for the input levels that were selected, as well as the $RESR_{90}$ for a 90-dB input. In the lower section of this screen, targets will be created if the measures were made in a coupler (gain or output) for the same three input levels and for OSPL90 (output saturation level for a 90-dB input).

Once these data are entered, the software illustrates the auditory area between threshold (lower limit) and LDL (upper limit) in dB SPL near the tympanic membrane. In DSL i/o V5.0, the “target” is the auditory area in dB SPL that is measured near the tympanic membrane. The goal is to select hearing aids and then verify that the measured *output* is

- above threshold for a 50-dB SPL input signal,
- below LDL for a 80- to 90-dB SPL input signal, and
- between these two “targets” for a 60- to 70-dB SPL input signal.

“Smoothness” of REAR Measures for Multiple Input Levels

Earlier, we emphasized the need for hearing aid coupler measures to be as smooth for input levels of 80 to 90 dB SPL as for input levels of 50 to 60 dB SPL. The same goals also need to be achieved for hearing aid performance when actually worn by the patient. At this point, our emphasis shifts to observing the “smoothness” of the REAR at 50 to 80 dB SPL (Figure 41.16) for the goal of ensuring that the morphology of the $REAR_{80}$ curve is as smooth as the $REAR_{50}$ curve. If the $REAR_{80}$ curve is “jagged,” then it has been suggested that the hearing aid is generating an excessive amount of intermodulation distortion (Revit, 1994).

$RESR_{90}$ (Real-Ear Saturation Response with a 90-dB Input)

With the hearing aid still in place and the volume control at the same position, we measure the $RESR_{90}$ using a 90-dB puretone sweep (200 to 8,000 Hz) to ascertain the SPL near the tympanic membrane. At the completion of the

sweep, we observe if the measured $RESR_{90}$ is below the LDL measured at the time of the initial evaluation. If it is, this assures the audiologist that intense environmental sounds should not be perceived as uncomfortably loud (Munro and Patel, 1998). As mentioned earlier, Figure 41.5 illustrates the $RESR_{90}$ in relation to the measured LDL (“dots”) at 500 to 4,000 Hz for a patient. Note, at each test frequency, the measured $RESR_{90}$ (thin line) is below the measured LDL. The “dots” with an arrow pointing up indicate that the measured LDL_{spl} was greater than 120 dB SPL at that frequency. According to Munro and Patel (1998), if the results reported in Figure 41.5 are achieved, the audiologist can be reasonably assured that environmental sounds at high input levels will not be judged as uncomfortable by the patient.

Verification of Performance of Directional Microphones

Figure 41.21 illustrates the use of 2-cc coupler measures and Figure 41.22 illustrates the use of REM to verify that the directional microphone is performing correctly. In the first author’s experience, it is not uncommon to receive new hearing aids where either (a) the function of the microphones is reversed so that the rear microphone is amplifying and the front microphone is attenuating or (b) the rear microphone is not working at all, resulting in the hearing aid having only omnidirectional capability. In Figure 41.22, the top curve was measured with the patient facing the real-ear loudspeaker (0°) and the signal (modulated ANSI composite) presented at 65 dB SPL. With the signal remaining on, the patient is slowly rotated so the rear microphone is facing the loudspeaker. As the patient is rotated (making sure the distance between the loudspeaker and the microphone is the same for this measure as it was for the 0° measure), the audiologist views the real-ear system monitor to determine the azimuth where there is the least amount of amplification. In Figure 41.21, this occurred at 135° (hypercardioid polar design) showing a 20- to 25-dB decrease in gain when the rear microphone was facing the loudspeaker in comparison to when the front microphone was facing the loudspeaker. This verifies that the rear microphone is working properly. In cases where the rear microphone is not working, the front and rear measures will superimpose suggesting no reduction in gain caused by the activation of the rear microphone (omnidirectional performance). In the case where the microphone function is reversed, the 0° curve would be an example of a measure for the rear microphone and the 135° would be an example of a measure for the front microphone.

Verification of Feedback

Figure 41.23A to C illustrates how REM can be used to verify the presence of feedback. In Figure 41.23A, the REAR reports that no feedback was present. Figure 41.23B reports the beginning of the presence of feedback at ~4,000 Hz as

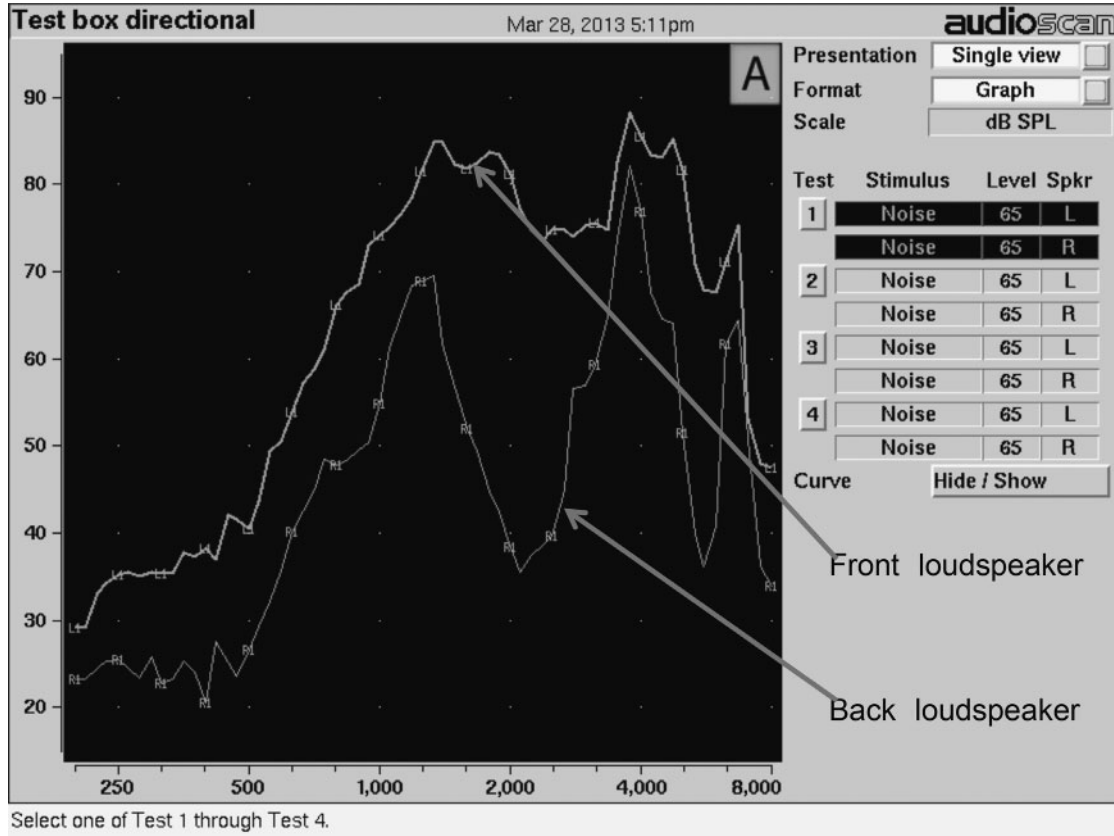

FIGURE 41.21 Using 2-cc coupler measures to verify the performance of a directional microphone.

FIGURE 41.22 Using real-ear measures to verify the performance of a directional microphone.

FIGURE 41.23 Using coupler measures to verify the presence of feedback for a DSP hearing aid. (A) The REAR with no feedback present. (B) The beginning of the presence of feedback at ~4,000 Hz as the volume control was increased. (continued)

FIGURE 41.23 [Continued] (C) The obvious presence of feedback at ~4,000 Hz as the volume control was increased by 1 dB.

the volume control was increased. Figure 41.23C reports the obvious presence of feedback at ~4,000 Hz as the volume control was increased by 1 dB.

Loudness Judgments for Speech

In the previous section, we described a method to validate that a frequency-specific signal (puretone sweep), presented at a high input level (90 dB SPL), was not uncomfortable to the patient. In the “real world” the listener is often exposed to varying levels of speech, which have a much broader bandwidth than frequency-specific stimuli. Therefore, it is important to include in the protocol a method to assess loudness judgments for a “speech-like” signal.

To accomplish this goal in a clinically efficient manner, we present speech composite–noise from a real-ear analyzer at 50, 65, and 85 dB SPL. While wearing both aids for a bilateral fit (or one aid for a monaural fit), we ask the patient to judge the loudness of the speech-weighted noise using the same loudness scaling categories described earlier. If the hearing aids are adjusted properly, the patient should rate the 50-dB SPL input as either “very soft,” “soft,” or “comfortable, but slightly soft.” For an input level of 65 dB SPL, the patient should rate the loudness as “comfortable, but slightly

soft,” “comfortable,” or “comfortable, but slightly loud.” For the input level of 85 dB SPL, the patient should never report a rating of “uncomfortably loud.” If the patient reports the high input level to be “uncomfortably loud,” then the audiologist must consider reducing the output and/or CT. Another alternative would be to provide a more aggressive CR.

Aided Sound-Field Thresholds

One quick and reliable measure is to obtain aided sound-field thresholds using warble tones at 250 to 8,000 Hz presented in a calibrated (ANSI, 2004) sound field. The patient, facing the loudspeaker, is asked to press a button when he/she hears a sound no matter how loud or soft. Research has suggested that if the aided sound-field threshold is 20 dB HL or better, this is indicative that the patient can hear the softest components of speech (Skinner et al., 2002).

Hearing Aid Counseling: Use and Care of the Hearing Aids

Assuming that the fitting goals have been achieved, we then counsel the patient on the use and care of the hearing aids.

Items typically covered include informing the patient about the following crucial areas:

1. The length (1 to 3 years) and terms of the warranty (damage, or loss and damage). The patient is informed that in 1 year a card is sent as a reminder of the need to check his/her hearing and the function of the hearing aids.
2. The audiologist provides the patient with the option of being scheduled to return at 3, 4, or 6 months for a hearing aid check. At this visit, the hearing aid(s) are dehumidified, earmolds cleaned, thin tube replaced, filters replaced, battery compartment cleaned, and 2-cc coupler performance completed. The hearing aid performance is compared to the initial coupler analysis measured at the initial “user” setting.
3. It is important to remind the patient that the hearing aids are purchased on a 30-day trial (varying across different states) period. If the patient should decide to return the hearing aids, then the patient will receive a full refund minus a small “professional fee.”
4. The patient is instructed regarding the operation of the volume control for those hearing aids that have volume controls.
5. The patient is instructed regarding the operation of the remote control (volume control, switching between programs, and other features) if the hearing aids use a remote control.
6. Counseling takes place related to operation of any buttons or switches that may be necessary to operate the hearing aids.
7. The patient is instructed regarding the insertion and removal of the batteries. The patient is counseled to be sure the voltage of the batteries is 1.45 V, because it has been the experience of the authors that batteries with a voltage less than 1.45 may lead to intermittent performance of the hearing aids.
8. The type of battery and expected battery life are explained. We also counsel the patient if the hearing aids have a feature informing when the battery drainage is low.
9. The patient is instructed regarding the insertion and removal of the shells or earmolds.
10. The patient is instructed regarding the problems related to moisture. Each patient is provided a Zephyr® Dry & Store at the time of the fitting. If the patient has been dispensed BTEs, then an air blower is provided, which is used to quickly remove moisture from the tubing.
11. Problems related to cerumen plugging the vent and/or sound channel should be explained. Counseling is also extended to other options for combating cerumen. These may include extended receiver tubing, spring guards, cerumen filters, and tools to remove cerumen from the vent. The patient is also counseled on the correct use of the brush and wax removal device accompanying most custom products.

12. Use of the telecoil is an important area requiring counseling. Whenever possible, the patient is counseled on using the microphone of the hearing aid as an “acoustic” telecoil. Typically, we dial the local weather-line and observe as the patient typically moves the telephone receiver around the entrance to the ear canal and pinna. We counsel the patient on the need to place the receiver of the telephone adjacent to the microphone of the hearing aid. In many cases, this is the position typically preferred by patients for using the telephone with hearing aids. When this is not successful, we then counsel the patient on the operation of the t-coil switch on the hearing aids. Several programmable hearing aids allow the audiologist to program a stronger telecoil response. Recently, several manufacturers have incorporated the EasyPhone feature into their hearing aids. With this technology, the hearing aid automatically switches to telecoil when the circuit detects an electromagnetic signal and back to microphone when it detects that the electromagnetic signal is no longer present (Puttermann and Valente, 2012).
13. Discussion of HAT and aural rehabilitation (our facilities have full-time audiologists providing aural rehabilitation).
14. Finally, we will call the patient in 2 days to determine how the patient is doing; and the patient is scheduled to return within 4 weeks for a hearing aid assessment.

OUTCOME MEASURES (FOURTH VISIT)

Hearing Aid Assessment

At this visit, we are interested in the patient’s overall satisfaction with the hearing aids. For example, we want to know how well the patient performed during the intervening 3 to 4 weeks, as he/she listened to speech in a variety of listening situations. Other questions relate to judgment of sound quality; presence/absence of feedback; ease of communication on the telephone; ability to remove and insert the earmolds, hearing aids, or batteries; the duration of battery life; issues related to the comfort of the hearing aids; and issues related to the presence or absence of the occlusion effect. It is during this interview process that decisions are made relative to the need for readjusting the electroacoustic characteristics or transmission line characteristics of the hearing aids.

At this visit, the patient is also asked to complete the “aided” portion of the COSI or Washington University questionnaires (Figure 41.1).

CONCLUSIONS

In 1998, ASHA published the “Guidelines for Hearing Aid Fitting for Adults.” This chapter’s first author had the honor

of chairing that committee. Recently, the first author had the pleasure of chairing a national Task Force for the American Academy of Audiology (AAA) to develop a national guideline for selecting, fitting, verifying, and validating the hearing aid performance in adults using evidence-based principles based on (Valente, 2006). In all of these guidelines, several important points were made:

1. REM is the preferred method for verifying the performance of hearing aids. Unfortunately, however, approximately 25% to 30% of audiologists do not routinely verify the performance of hearing aids using REM (Mueller and Picou, 2010). This is in spite of the fact that recent research (Abrams et al., 2012) clearly demonstrated that 15 of 22 participants preferred the fitting using REM with the hearing aid programmed to NAL-NL2 when compared to the manufacturer first-fit.
2. Patients need to be counseled on the realistic benefits to be derived from hearing aids.
3. LDLs should be directly measured using frequency-specific stimuli when possible to accurately assess/adjust the output and/or compression characteristics of the hearing aids.
4. Outcome measures need to be included in the hearing aid fitting process.
5. HAT needs to be integrated into the fitting and counseling process.

This chapter has provided a comprehensive overview of procedures to select and fit hearing aids for adults. Many of the requirements of the guidelines suggested by ASHA (1998) and AAA (2006) are included in the procedures outlined in this chapter. We feel that incorporating some or all of these suggestions has a high probability of resulting in a successful hearing aid fitting.

FOOD FOR THOUGHT

1. What is the difference between verification and validation?
2. What is the goal for verifying the increased RESR90?
3. What is the primary purpose of measuring ANSI S3.42-1992?

Building and Growing an Audiologic Practice

Melanie Herzfeld

CHAPTER OVERVIEW

This chapter will describe the skills involved in building and growing an independent audiologic practice and will include the personal experiences of an audiologist who has successfully navigated the business of practice management. The process described here focuses on independent or private practice and also applies to an audiologist charged to create and maintain a practice within an existing setting (e.g., medical group, hospital, foundation). After a short history of the evolution of independent practice, attention is directed to some of the variables involved with establishing and growing a business: Personality types that do well in business, initial decisions (location, financing, taxes, insurance, etc.), marketing, and more. The business of audiology is an important specialty, and all audiologists should have a working understanding of the operational challenges of managing one's own practice.

A BRIEF HISTORY

To be in private practice in audiology seems to be a very coveted goal for many newer graduates. It was not always this way. In fact, for many years, there was no private practice in audiology. There were no hearing aid sales by audiologists, no products being dispensed. Historically, audiology began during World War II to serve the needs of the military (Hosford-Dunn et al., 1995). After the war, the profession moved to the universities, which led to a graduate school curriculum being developed; the first school offering training was Northwestern University in 1946. Even the term *audiologist* is of relatively recent vintage, having been coined in the late 1940s by Hallowell Davis (Galambos, 1998). It is sometimes hard to imagine that this relatively new field is now recognized as one of the most rewarding professions in the United States (CareerCast.com, 2013).

Audiologists in the 1940s, 1950s, and 1960s were involved in research, taught at universities, or delivered clinical services, but had nothing to do with dispensing products. The only professional organization at the time was the American Academy of Speech Correction (which is now the American Speech-Language Hearing Association (ASHA), n.d.). Hearing aids were fit and sold by hearing aid dealers.

Audiologists were the testers, researchers, and rehabilitationists, but were not independent managers of a patient's hearing loss. Their role was less autonomous and, resulting in audiologists being assigned as a provider of ancillary services, which usually infers being under the supervision of a physician. At the time, audiology and speech pathology had much in common, so the two professions were teamed together in one organization.

During these years, audiologists were prohibited from dispensing hearing aids or from making any profit on sales and, interestingly, rehabilitation actually fell by the wayside as the primary focus of audiology became testing. Audiologists who bucked the system and began dispensing aids were stripped of their ASHA membership and considered unethical in practice. However, audiologists began to demand the right to exercise their professional responsibilities associated with dispensing amplification devices, and thus in 1977 the Academy of Dispensing Audiologists was formed (<http://www.audiologist.org/about-ada>). Around that same time period, ASHA agreed to retract its policy of considering the practice of selling hearing aids as a violation of ethics.

Audiologists also began emphasizing the need for further education, which led to the development of the clinical doctorate (American Academy of Audiology, 1991). Private practice grew exponentially from the time dispensing was allowed. However, in the past few years, the number of independent practices has declined as practices are joining big corporate groups. At one point, individually owned practices accounted for about half of the provider locations in the United States; however, as of 2011, this percent had declined to under 25%. Corporate affiliates and corporate-owned locations have become the largest percentage of provider locations (Smirga, 2011). But private practice still remains a goal for many of the students graduating from today's AuD programs. Their perception of private practice, however, has changed from total autonomy to allowing some affiliation with corporate partners.

PRIVATE PRACTICE AND PERSONALITY TYPES

There are presently many work options for audiologists. The advantages of private practice are that the audiologist

has more autonomy and can develop a practice that meets the needs of the independent practitioner. As attractive as this may sound, it is not for everyone.

Who should/should not be in private practice? Private practice requires the audiologist to function independently. This does not mean one must know everything, but instead that one is comfortable with the burdens resting solely on his or her shoulders. A practice demands a great deal of attention, interest, and stamina of the owner. It is the proverbial “the buck stops here” experience. One must be comfortable not only with dealing with patient needs and physician requirements, but also with handling financial services, negotiating leases and contracts, and managing employment issues and staff challenges. It is not for the faint of heart. But it can be a most rewarding job!

Personality testing might help the audiologist decide if private practice is appropriate as a career choice, although most people know how risk averse, how independent, and how comfortable they are with change and with responsibility. The vast majority of audiologists are in the caring field because they want to help others, but can they also accept risk? Can they function independently, deal with business complications, staffing problems, location issues, and supplies, and still manage the patients?

One might begin by taking the online Keirseley Temperament sorter (<http://www.keirseley.com/sorter/instruments2.aspx?partid=0>). This 71-question inventory identifies four temperament types: Artisan, guardian, idealist, and rational. Audiologists tend to be guardians (K. English, personal communication, June 10, 2013) because caring and belonging are trademarks of this personality type; for those who enter this field, these are typical traits. We want to help our patients! These personality types are then further divided into four divergent preferences: Extrovert/introvert, sensing/intuiting, thinking/feeling, and judging/perceiving (see Figure 42.1). Historically, students in health professions such as audiology fell into the intuiting/feeling temperament type but they have transformed, probably with the advent of private practice models, to the sensing/judging (SJ) type. Interestingly this seems to be true of many health professions (Baggs, 2012). The SJs present themselves as being reliable, delivering service well, and being respected. Those who are extroverted, sensing, thinking, and judging are often found in business. Those who are extroverted, sensing, feeling, and judging are often found in health care, dealing with people, but also may be business owners. Those who are introverted, sensing, feeling, and judging are the least likely to want to be leaders, although they enjoy helping make things run smoothly. It becomes clearer which personality type is most likely to succeed in private practice or perhaps even to want to take that step (Keirseley, 1998). In particular, extroversion seems to be a common trait, probably related to the social demands involved with marketing, staff management, attorney and accountant consultations, and landlord and contractor negotiations.

FIGURE 42.1 Personality and temperament: What is the right mix for business?

Like anything else, however, broad generalizations can only begin to help us understand complex issues such as practice ownership. Readers are advised to interview as many practitioners as possible when considering the option of practice management.

Audiologists in private practice have to be able to wear many hats. First and foremost they must be *competent*, that is, must have the requisite job skills to perform the task flawlessly. That is the technician part of their personality. Then they must be an *entrepreneur*, willing to look to the future, to plot and plan. And still they must be a *manager*, making sure that all business details are addressed and that the nature of the business success is defined and achievable (Gerber, 1995). Coming up with goals for the business which are realistic and manageable is key. It is not enough to say, “Business will be solicited,” or “Time will be spent.” It is necessary to consider each and every aspect of the business, to consider not just the test requirements but the patient needs, the referral source, and the community impact. Thus the personality tests may help give an overview of whether or not a particular audiologist has the necessary character traits to be a private practice owner or whether or not this person has the strength of character to deal with transforming his or her self to be able to do what needs to be done to be successful. Personality testing might offer some information of value, even if it is pointing toward skills which need development.

FIRST DECISIONS

Let’s consider an audiologist who demonstrates the temperament to be in private practice or the strong will to try to succeed (which can be just as important). Where does he or she start? See Table 42.1 for a listing of many business considerations.

TABLE 42.1

Business Considerations for the Audiologist Considering Independent Practice

- Location
- Finances
- Space and equipment
- Personnel
- Marketing
- Local, state, and federal regulations

Location

Remember the real estate adage, “Location, location, location!” Location is one of the most important assets in a practice; to a very large extent, where one works determines one’s patient base. The aspiring practice owner will first investigate practices already in the area, for instance, by drawing a circle on a map, conducting an Internet search, and driving around within that circle. How many practices exist, and who owns them? Consider their niches and what is unique about each practice. Find out if any of them are likely to be for sale in the near term. See if there is a missing element. For example, there may be 20 different hearing aid dispensing practices, but none specializing in pediatrics or central auditory testing. Perhaps tinnitus care is not provided in the area or perhaps vestibular testing is not in the mix. It is important to consider one’s own professional interests, professional strengths, and the domains one would most likely want to practice. Once you have done that, look back around that drawn circle and at all of those practices. How close are they to medical offices, to highways? Perhaps it is advantageous to be near other professionals, for instance, a psychology practice or a pediatric office, or near the local otologist or the largest group of internal medicine providers, or to a senior center or senior housing, or even along a bus route. Think about how patients would get to each location and consider the positives and negatives of each; approach each of the existing practices from a patient’s perspective. As an older patient, a younger patient, a driver, a nondriver: How would they get to that practice? Are there too many steps? Two flights up, no elevator? How convenient are they? How clean? How approachable?

Another way to approach this research is to put oneself in the mindset of a job search. Would you want to work here? Who would the patient base be? How would you get referrals? Would the patients you want to see want to come to this practice? What attracts you to want to work in this particular place? What makes you think this is not for you?

Financial Decisions

The audiologist considering independent or private practice will have a steep learning curve while adjusting to the

TABLE 42.2

Important Business Vocabulary for the Private Practitioner

- Noncompete clause
- Practice valuation
- Buying groups
- Business plan
- Personal and professional liability

business world. Table 42.2 lists just a few terms that represent “business vocabulary.” Many decisions need to be made, including “to buy or not to buy.”

TO BUY OR NOT TO BUY?

Once one has seriously considered *where* one would like to practice, the next question is *how to obtain* that practice. Has the aspiring practitioner built up enough equity to start a practice from scratch or to purchase an existing practice? Is there a practice owned by an audiologist who might have an interest in selling sometime in the near future? Talking to the owners of existing practices might help in finding someone interested in selling in the next few years. That practice might be willing to take on an employee with an offer to buy into the practice over time. Just being involved in an ongoing practice one intends to purchase may allow the employee to develop a patient base, which might be helpful when it is time to talk about financing. This of course assumes the employee is becoming the owner of the same practice. At the same time, an employee must be aware of noncompeting clauses in contracts; frequently a condition of employment disallows starting a practice within a certain distance from the one in which the audiologist worked and is equally likely to disallow taking any patient records. However, buying into an existing practice has many advantages. Although it can be more difficult legally, it is certainly less risky to buy an existing practice.

Practice valuation for purchasing an existing practice requires the help of specific professionals. There are many ways to set a value on an existing practice, but this is best left to the experts.

ARRANGING FINANCING

Some practices are part of affiliated groups which will help the new owners finance the arrangements. There are buying groups which offer financing as well as guidance in running a practice. There are also franchise businesses. However, many practitioners need to obtain financing on their own. It is also possible that the current business owner will allow some financing help; again, this requires that the sale arrangement meet the legal requirements regarding interest and payment options.

To approach a bank through the Small Business Association (SBA), due diligence is required. To begin with, one cannot just show up and ask for a loan. In fact, audiologists have reported that they wanted to buy a practice already in existence, only to be told by the bank that they could not use that practice's statistics because they were not the owners and they had no track record with that practice. An audiologist planning to buy an existing practice needs to invest time in the practice in a way that is documented and transparent to financiers. It will be important to show a banker that he or she already has an established base of patients and is familiar with what needs to be done to keep and expand that base.

THE BUSINESS PLAN

The first item a financier will require is a business plan. Samples of business plans can be researched online for additional information on what is specifically needed or how best to present ideas. To get started, see "Helpful Websites" at the end of this chapter.

A business plan begins with a mission statement. The mission statement is a short statement of what one intends to do, why the business should be funded, and what the applicant has done to make sure that any investment in the practice would be a success. An analysis of the business opportunity, financial prediction, niche market approach, and potential referral sources are next. If there are 20 practices near the desired location, the applicant must indicate one's unique approach and the market trends that will support success. This is where research is vital. When buying a practice already in existence, what needs to be done to expand it? How much is the applicant personally investing?

My first foray into requesting money from SBA was for a practice in a shared space with some otolaryngologists. We had recently left a multispecialty medical group and were unable to contact our patient base because of legal requirements. Included in the business plan was a clear and concise description of how we would contact referring physicians, the advertising plan, and a very simple projection of income based on a review of our old data, including a "guesstimate" of the number of existing patients lost to location change, and a projection of new patient growth. Also included were all the costs in the practice analysis, including the amount the audiologist had to invest. Documentation was provided for new equipment and a rationale for the expenses. The banker was happy to discuss the plan, but ultimately indicated the plan was unlikely to be financed unless collateral was offered. However, the banker agreed to send the information along to the banking underwriters without mention of collateral. The banker was pleasantly surprised when the underwriters called her to say the author would receive the funds requested because the business plan was so specific and well written. They had decided the author was a good risk. According to the ADA Practice Model Task Force (2008), audiologists in

private practice seem to have a very low loan failure rate, making audiologists a good loan risk.

When the author then decided 8 years later to venture into a completely independent practice, once again funding was needed, and the request was submitted with the same concise three-page documentation. However, this time the audiologist had a history of financial success and could show a profit and loss sheet for the past 8 years. More money was needed this time because of the need to pay for a complete build out (described in a later section), and once again, the banker was unsure if the loan request would be approved. Doubts arose not because of the track record but because of the current financial climate; money had become tight and he was not sure if the underwriters would fund the loan request without collateral. Once again, to the banker's surprise, the loan was funded and again the underwriters indicated the quality of the statement swayed them. This outcome reinforces the principle that the quality of the writing and the depth of information are vital to one's presentation.

HELP FROM THE SMALL BUSINESS ADMINISTRATION

The Small Business Administration has a tool to help with formulating a business plan. By registering on their site, one can use the SBA Business Plan Tool, which is a step-by-step guide to formulating a successful business plan. Categories or topics on the plan include the executive summary, the company description, market research, information on services and products, marketing plans, financial projections, and a summary statement (<http://www.sba.gov/business-plan/2>).

PROFESSIONAL ADVICE

The journey to independent practice must include help from other professionals. The importance of an experienced attorney, knowledgeable in the ways of starting up a business, and an equally qualified accountant, knowledgeable in projecting and writing a business plan, cannot be understated. These professionals will serve as a lifeline in the quest for private practice and will continue to help the audiologist even after the financing is complete. These professionals will explain why one would want to incorporate or not (discussed in the next section), and the differences within a limited liability company (LLC), a limited liability partnership (LLP), a subchapter S corporation (corporations that pass income, losses, deductions, and credit through to their shareholders for federal tax purposes), and incorporation in general (also detailed in the next section). They help predict tax consequences and plan for financial health. Some audiologists also use a real estate attorney to help them negotiate leases. The takeaway message is that hiring experienced and skilled professionals is invaluable. This is not the time to ask a favor of an uncle who does senior citizen tax returns or a patent attorney because he is a friend. Just as one would hope that

a patient would view the audiologist as the expert in one's area, so the audiologist will need to seek out help in matters of business, law, accounting, and other domains.

TO INCORPORATE OR NOT

Speaking of incorporation, why incorporate? Again, this is a conversation best had with one's attorney because each state has different rules. In New York, for example, a professional wanting to have a corporate identity must apply to the state before becoming a professional corporation or limited liability professional corporation. The name of the corporation is tightly controlled and must be approved; the constitution of the corporate board (president, treasurer, secretary) is also tightly controlled. In a professional corporation in New York State, the shareholders are specified; a corporation can only offer shares to other audiologists or similarly licensed professionals. New York State business law is quite specific in this regard; in the business code section 1508, it states that "no individual may be a director or officer of a professional service corporation unless he/she is authorized to and engaged in the practice of his profession in that corporation." This is not a question of personal decision making but of state law, and thus must be considered in the decision-making process; again, having an expert on the team can make the difference in following laws and making appropriate decisions.

LIMITING LIABILITY AND TAX CONSEQUENCES

The general purpose for incorporating one's practice is to limit liability and tax consequences. Incorporating is intended to protect the owners in case of liability (e.g., malpractice, personal injury, damage to property); however, at this time it appears that liability limitations are limited more to financial obligations and less to personal liability. In a general incorporation, the tax rate is set at a specific level for the corporate entity and then any profit taken personally is taxed again at a personal rate; in essence this is a double taxation. However, if there is a financial loss, it cannot be passed onto the owners. Its advantages are that the business debt responsibility is limited to the business and not the shareholder and also that fringe benefits are deductible by the business. Shares offered in the corporation are always preferred shares.

In an S corporation, the profit is given to the shareholder personally and so taxes are paid only at the personal rate (<http://www.irs.gov/Businesses/Small-Businesses-&Self-Employed/S-Corporations>). Again, there is limited personal liability for business debt unless the bank demands this, which they can do, by asking for a personal bond or guarantee. Fringe benefits are limited by law as to what can be a deductible expense and shares are common. Losses are limited to the extent of personal investment and the amount of income (<http://smallbusiness.chron.com/personal-liabilities-s-corp-3696.html>).

An LLP is a limited liability partnership and has an advantage in that liability is limited generally to the extent of investment in the partnership; in the case of malpractice, it protects the other partners from claims against the practicing partner. For example, if Dr. M is sued for malpractice, his partners in the LLP are not part of the suit; they did not see the patient who is suing and thus have no liability to pay in the case of a lost suit. However, depending on the state in which one practices, this type of corporation or professional arrangement may or may not be used by specific professionals. According to Legalzoom.com, an LLP must have two partners whereas an LLC may have only one overseer or owner. Clearly, obtaining an expert legal opinion on which status is appropriate for a practitioner's circumstances is quite important, since the decision has both financial and liability consequences. Although there are many ways to become incorporated, without professional guidance the wrong corporate identity might be selected.

Sole proprietorship is another option. This label applies to one owner of a business who has not chosen the route of incorporation. The name of the business may be a "DBA" (doing business as) and this might be the owner's name (e.g., Jane Smith, AuD, Audiologist) or a name designated to identify the business (Hearing and Tinnitus Center). The sole proprietor is still responsible for obtaining the appropriate licenses and registrations for both the business and the DBA. It is a simple way to run a business but has risks. Tax returns are simply done as a self-employed individual with all income and expenses listed as personal income/expense. There is no tax return due in the name of the business. The owner is, however, personally responsible for everything related to the business, whether debt or liability, for the problems associated with any employees, or with the business in general. It is also more difficult to obtain funding as a sole proprietor.

Regarding tax consequences, there are differences as well among these entities. Tax differences are not the only reason to select one option over another; it is simply a piece of the puzzle. For corporations which are not S corporations (not having shareholders), profits are taxed at the corporate rate and then taxed again when the profit is taken by the individual. For sole proprietorships and S corporations, the tax rate is the personal rate. What can and cannot be deducted depends on the business type, the number of employees, and state/federal laws. Again, the role of the accountant in helping chart a path through this accounting morass is invaluable.

SPACE REQUIREMENTS

To Share or Not to Share

After meeting with legal and financial advisors, the audiologist must decide where to house the practice. Options include sharing space with a medical practice—not only otology and otolaryngology, but also pediatrics, ophthalmology, optometry, and internist offices. One might open

an independent space or join a group of audiologists. Finding a psychologist or speech pathologist with whom to share space is also a possibility. Depending on the patient base, or projected base, these types of practice decisions might be mutually beneficial. A tinnitus practice with an in-house psychologist can be an advantageous joint venture, for example.

At the present time, several groups operate on a management basis or on a multilevel affiliation basis. There are buying groups, for example, which have a multilevel plan; some practitioners join and give full management rights to the buying group; others pay for the specific services they elect to use; and still others can simply be a user of the buying group services to obtain a discount on products. For some, joining with these groups can be helpful; they not only offer management support but may also offer funding opportunities in exchange for joining their buying group. Location is, however, still the most important decision to be made. As discussed previously, a private practice needs to be accessible, attractive, and appealing.

Size of the Space

The amount of space a private practice requires depends on what is available to some extent, and to some extent it has to be determined by the owner. It is certainly possible to open a small office and then relocate as the practice grows, but this transition can introduce problems, both with the actual relocation and with the risk of losing patients (possibly up to 20%).

Consider the following variables when deciding on space needs. One needs a room to house the sound-treated booth, a lab and storage area, and a waiting area and secretarial space. Closet space is needed for supplies, a server closet, and possible files. Bathrooms might also be necessary. A typical space might require approximately 1,200 square feet. However, often spaces are offered with a minimum greater than planned.

The search for the right space is similar to searching for the right residence: One might find a space in a desirable location but it exceeds one's budget; or the site is priced attractively but has no elevator. Windows are appealing for many businesses but for an audiologist, windows increase noise problems. Some audiologists may desire a small kitchen space. It is recommended to think long term: Would it be possible that eventually the practice might need more space, another booth room, a rentable office?

The audiologist might consider hiring an architect to draw out sample office layouts for consideration. The audiologist will have specs for booth size and the space needed for wheelchair access, as well as the estimated space needed for the waiting room, front desk, lab, and so on. The architect should have expertise in designing restroom facilities with wheelchair access; be aware of local codes and be mindful of the need for sinks where needed. Any sketched architectural

layout is just an idea, but will help guide in computing the space needs of the office.

Lease and Build Out

The new practice owner must also consider the time frame for the lease and the cost of build out (installing walls, doors, cabinetry, plumbing fixtures, lighting, etc.). Again, an attorney is needed to ensure all contracts are fair and in the signee's favor as much as possible. Leases have options, for instance, placing the lessee responsible for paying for the cost of the heating and ventilation system including replacement if needed, or assuming responsibility for the annual service contract but not for replacement costs.

The length of the lease may also be subject to some negotiation. Let's imagine that the audiologist desires a 5-year lease with an option to renew, but the landlord wants a 10-year lease. The audiologist would rightly be concerned that if circumstances did not merit staying open for 10 years, he or she would be personally responsible for the lease payments for the full lease. An attorney may or may not be able to eliminate the personal liability clause, but might be able to negotiate a compromise so that the audiologist is fully responsible for the first 5 years, but after that, if deciding not to remain open, he or she would only be responsible for paying the remaining build out costs that the landlord incurred divided over each year of the remaining 5 years. This is just one example of how attorneys can be a financial benefit even when considering their fees; initially the landlord may not have agreed to that compromise but with skillful negotiations, the middle ground has a chance to be placed into the contract.

The build out on the part of the landlord may include the outside structure, the cost of the carpeting and flooring, the ceiling tiles and a standard number of sprinklers as well as the bathrooms, the office walls, doors, and cabinetry. These details must be confirmed in writing. The architect will then draw up a floor plan, and then submit a quote from a contractor for the costs of the build out. There is always a choice unless the lease prohibits it; one can select one's own contractor or use the landlord's contractor (advantage: One may not have to post a bond for the work done by the landlord's contractor; disadvantage: One has less control over the situation).

Many small details can be missed, but sharing one's plans with a colleague who has gone through this process can help. Having a second set of experienced eyes can result in identifying smaller issues upfront and avoiding an onerous expense later. Something as simple as not seeing that the correct kind of washable paint is being used on the walls can result in increased expense and the need to repaint the office sooner rather than later.

Rent Charges

Calculating an affordable rent is straightforward. A base rent (priced per square foot) for a year is defined in the

contract, as well as annual increases. Rent may or may not include utilities. Some contracts may stipulate that when taxes increase above the base tax at the time of initial contract, that increase is added to the rent. A cap on fees may or may not be negotiable. In some cases, the landlord will not provide build out at all, whereas others may provide an allotment (tenant improvement funds), and any upgrades over the allotted amount are the tenant's responsibility. Parking space agreements should be included in the contract, as well as maintenance. The landlord is typically responsible for maintaining the outside of the building, the common spaces, and the parking area, and those responsibilities should be clearly defined as part of the rental agreement.

EQUIPMENT NEEDS AND SPACE CONSIDERATION

Equipment needs are a critical consideration and must be calculated before designing space or even selecting a space; a practitioner cannot decide on how much space is needed until he or she knows how the space will be occupied. An audiologist setting up a practice will need to decide on videonystagmography (VNG) equipment, double-walled sound booth, using one or two booth rooms, and so on. These decisions are often staggered as short-term and long-term needs. What equipment is necessary at start up, and what can be expanded in the future? One's niche market considerations drive these decisions. For instance, if planning to test the younger population, a larger, double-walled booth is worthy of consideration because space is needed for speakers for sound field testing, as well as accommodating children with a parent or another adult. In addition, since frequently live voice and sound field are used, the more insulated booth is beneficial. If planning to conduct VNG assessments, one will need a room dedicated to those procedures.

Testing Booths

Booths come in different formations: Single-walled booths, single wall with a control booth, single walled with extra quieting panels, double-walled and double-walled with a control booth. The disadvantage of single-walled booths is the compromise to a quiet testing environment; for instance, children tested in sound field can hear the tester through the wall if testing is done via live voice. However, the cost of a double-walled unit is almost double. Control rooms can be added onto the booth to help maintain an acceptable noise level (American National Standard Institute, 1999). Remember that the patient referral system is dependent on satisfied patients who spread the word that your practice is worthy. Consider patient's response to the selection of the booth and what impact that might have on a budding practice.

Audiometers and Impedance Audiometry

Audiometers are available from one and a half channel to two full channel devices. They range in price from a few thousand dollars to almost \$20,000 when fully equipped with sound field, high-frequency testing, and visual reinforcement audiometry. The audiologist will want to consider headphones: Insert headphones, standard circumaural cushions, high-frequency headphones.

For impedance testing, consider whether you will need to include options for Eustachian Tube dysfunction testing or B/G tympanograms. If testing newborns, a 1,000-Hz probe tone would be needed for tympanometry. An option for reflex testing would include manual or automatic control.

Additional Testing Equipment

The audiologist will have considered the cost and reimbursement rates for advanced diagnostic equipment, as well as equipment associated with hearing aid fittings (analyzers, probe mic systems, etc.). Remember that a niche practice will need to invest in equipment specifically for satisfying that population. Thus whereas a practice specializing in tinnitus and hyperacusis will have to invest in high-frequency headphones and in a toolbox full of tinnitus managers, a practice specializing in vestibular testing must include the cost of VNG equipment in the budget and in the space allocation.

Portable Equipment

A portable audiometer would be necessary if testing in nursing homes or assistive living facilities perhaps as well as when testing babies; then a portable audiometer can be brought into the sound booth to work directly with the young child. Some new options include hearing aid analyzers with portable testing equipment; some are networkable and compatible with electronic medical records. If conducting ototoxic monitoring, you will need high-frequency testing capabilities.

Financing Equipment

Equipment can be purchased or obtained with a leasing agreement. There are advantages and disadvantages to both options, so the decision must be carefully considered. In addition, used equipment is frequently available for purchase, and some manufacturers offer leasing or purchase over time. Equipment needs include not only audiometric instrumentation, but also computers, fax machines, telephones, even refrigerators, and coffee pots. When not outright purchasing, frequently the costs increase as payment is made over time; however, for a new practice, it may be

preferable to pay monthly costs rather than borrowing larger sums of money.

CASE STUDY: CALCULATING THE COST OF BUSINESS

Although at this point we have not considered all the variables of starting up a practice, it is never too early to start thinking like a business person and consider the “cost of business.” Following is an example of a basic calculation:

Dr. Mayer, an audiologist, locates an attractive office property which is 1,000 square feet, paying \$20 per foot rent and \$2 per foot for utilities. Dr. Mayer plans on investing \$25,000 in the build out costs, which includes sinking the booth into the floor and putting up cabinets in the lab and in the front desk area. She wants to outfit with an audiometer, a single-walled booth with extra sound paneling, insert phones, and VRA. She selects an impedance bridge with reflex testing and reflex decay as well as 1,000-Hz tympanograms. She plans to purchase an OAE machine and a probe mic speech mapping system, and also plans to obtain office furniture and computers.

Dr. Mayer determines that the overall budget including legal fees will be about \$85,000. But she also needs money for inventory and supplies, so the more reasonable estimate is about \$100,000 in start-up costs. Dr. Mayer has \$20,000, and she will approach a bank for an \$80,000 loan and a possible line of credit.

What is needed to make the monthly payments to the bank and to the landlord? Assume the loan will require \$1,500 a month; rent will be \$2,200; telecommunications (phone and internet) will cost \$200. Utilities are \$300 per month. Without paying herself a salary or hiring front desk personnel, Dr. Mayer’s fixed expenses then are going to be about \$4,200 a month. Also assume that she will be reimbursed for CPT codes 92557 (full audiogram) and 92550 (tympanograms and reflexes both ipsilateral and contralateral), which yields a payment of \$50 per patient. Simple math indicates that she will need to perform 80 audios a month to cover fixed expenses. Proceeds remaining after the first 80 audiograms are applied to salaries and expenses.

If Dr. Mayer purchased less expensive equipment, she may only need \$50,000 in start-up expenses and can manage to cover costs that much sooner, perhaps with only 10 audiograms per week. Dr. Mayer can increase her revenue-after-expenses with OAE and other kinds of testing and, of course, hearing aid fittings. Additionally Dr. Mayer might consider approaching her equipment vendor about a leasing deal; she might consider a lease with the option to buy so that if she found herself doing well sooner than anticipated, she could outright purchase the equipment.

Needless to say, this case study will continue to unfold as the practice develops and as Dr. Mayer evaluates the outcome of each decision. Every audiologist in independent practice must understand what is meant by the cost of busi-

ness, how to calculate it, and how to manage the variables that affect it.

FIRST IMPRESSIONS: THE OFFICE AS A MARKETING TOOL

The general appearance of the practice is important and has been discussed at length elsewhere (e.g., see Carroll, 2012; Irene, 2011). Details to consider include

- Furniture and flooring: Comfortable, durable, easy to keep clean
- Lighting and decorations
- Reading materials (general interest magazines as well as materials on hearing and overall wellness)
- Brochures and demonstration areas (especially handy for various streamers, television remotes, captioned telephones, FM systems, alerting systems, and other assistive technology for patient education and hands-on practice).

Suffice it to say, a patient’s initial impression of an audiologist’s professionalism may depend more on “waiting room appeal” than the framed diploma and license. If not particularly talented in managing visual appearances, hire someone! Perhaps that person can also manage some business details.

PERSONNEL

The audiologist will need to answer several questions about personnel, such as who will run the office? Is it worthwhile to hire a front desk person? A billing person? What can one do independently and where is help needed? Some work can be “outsourced” such as billing, payroll, and making appointments. If sharing space with another professional, perhaps sharing personnel is also an option.

The prospect of hiring support staff can be daunting but help is available. Typical salary requirements for staff can be found through searches of online sites such as www.salary.com, which can provide regionally relevant information. Information such as salary range for years of experience is included in the graphed results. Be advised that salary is not the only consideration; other expenses associated with having an employee include worker’s compensation, state disability, medicare and social security taxes on that income, the cost of sick/vacation days, and possibly health insurance. Conventional wisdom indicates an employer should plan on adding 10% to salary for these benefits. See Table 42.3 for a summary of these contributions.

Small businesses can obtain health insurance through brokers, national organizations, or local organizations. Some groups require that the insureds all be members of that professional group; others allow employees to be insured as long as the owner is a member of said group. Some require at least two to be insured for the small group rates to apply. The healthcare industry is in flux right now as the legislation

TABLE 42.3

The “Salary + 10%” Contributions to Personnel

- Workers compensation
- State disability
- Medicare
- Social Security
- Vacation/sick days
- Health insurance

regarding the new healthcare laws is changing as this is written. There may be state insurance pools or pools across state lines in the future. Additionally, quotations can be obtained online through groups like www.ehealthinsurance.com.

Once the practice is up and running, pensions can be considered. The US Department of Labor has a site defining all the pension options available for small businesses (<http://www.dol.gov/dol/topic/retirement/>). Some are tied to profits and thus in profitable years a set amount will be included but in unprofitable years no deposit may be made. Other options are based on contributions by the employee at a percentage the employee is comfortable making, whether matched or not by the employer. There can also be a stock ownership plan where the employee is given an amount of stock in the corporation. All of these need careful explanation by legal and accounting advisors as well as checking into state requirements and laws.

MARKETING

After the audiologist has found and built up the office space, obtained furniture and equipment, hired a front desk person, and contracted for health insurance, it is time to advertise. Initial steps are to create a brochure, business cards, and a webpage/Internet presence. The audiologist will want to put a personal stamp on the business, but may not have the personal skills to attract patients and referrals with marketing materials. One might want to ask for referrals from trusted colleagues for marketing experts. Different brochures may be needed for different audiences, for instance, a general brochure for internists, pediatricians, or patient groups and a specialized brochure (e.g., tinnitus care) for internists, psychiatrists, and TMJ specialists.

With written materials in hand, and web page functioning, the audiologist will dedicate considerable time delivering these brochures along with business cards to different audiences, including vision specialists, gerontologists, pediatricians, and psychologists (Duldudoa, 2012).

Within the community, marketing opportunities can include visits to senior citizen–assisted living centers, activity centers, nursery schools, and after-school care centers. If interested in providing services to schools, education administrators can be contacted as well. One can offer seminars

in the local libraries, presenting on hearing loss prevention, assistive technologies (captioned phones, relay services, e.g., as well as hearing aids), communication strategies, and so on. Audiologists have a wealth of information to share with the public, and that information raises awareness for audiology in general, and one’s practice in particular.

Advertising

The audiologist will want to consider advertising in local newspapers or on local radio or TV, in weekly disposable papers or local magazines, or via direct mail. Some of these options allow one to advertise his or her practice and also provide an interview for an article about the practice. An “advertorial” is especially valuable as it includes information to raise public awareness of your practice plus information the reader might find helpful and interesting. There is no guarantee of the most effective advertising method for your expertise, interest, and region; trial and error helps one find what works well for that particular practice.

Providing educational seminars or community events open to the public or by reservation is another way to promote one’s practice. This can be done in the office, at a local library or school, or in a nicer setting such as a catering hall or restaurant. In many towns, if the purpose of the seminar is to educate, rather than to sell product, the local libraries allow the use of their community room at little or no cost. Regardless of how advertising is managed, it will be a large part of the budget until the practice becomes established.

PRICING

A key concern for the new business owner is how to set prices for one’s services. In the current era of managed care, the audiologist needs to realize that he or she will most likely be paid the amount the managed care company (insurance) pays for that service. Most patients have some kind of insurance, and rates are typically set by insurers. Sometimes it is in the best interest of a practice to consider which insurances should be accepted and which declined (Brady, 2007). Medicare does not pay for hearing tests for the benefit of purchasing a hearing aid, so in a hearing-aid-only practice, the audiologist can either set a charge for the test or include it in a bundled price.

What is Bundling?

Before the era of managed care, each service or each product had a separate fee. For example, an audiologist might charge a patient \$100 for a full evaluation and \$1,500 for the hearing aid fit on the second visit. The hearing aid fee covered up to three office visits for hearing aid orientation, electroacoustic evaluations, batteries, and supplies (in other words, all services and products were bundled or combined

into one fee). The patient paid the bill in full and left with a statement to submit to the insurance company.

In the 1970s, health maintenance organizations began to come into prominence because of the federal Health Maintenance Organization Act of 1973 which required employers with 25 or more employees to offer options of HMO plans to employees (Hall et al., 2008). More and more, the traditional insurance plans disappeared as Preferred Provider Organizations developed. Because health-care costs were rising, insurance companies began to look closely at fees charged and worked to control the reimbursement process to physicians who functioned as accepting providers (Kongstvedt, 2009). The change from a bundled charge to an unbundled charge came about because of what is and what is not covered by insurers. For instance, instead of charging \$1,500 per aid, one might only charge \$1,000 plus \$250 for orientation, \$100 for probe mic testing, \$50 for batteries and supplies, and \$100 for earmolds. If one decides to “unbundle,” the audiologist will bill the insurance company for each office visit.

“To bundle or not to bundle” is a topic discussed at length on audiology forums and among online patient and patient-advocate groups. For patients who believe they will use fewer services than average, it would appear an unbundled fee schedule will save some money. Whether because of insurance benefit or because patients want to know what they are paying for and what benefit that payment will have, audiologists are now leaning toward the unbundling of their price structures. The largest benefit of unbundling has to do with valuing the services of the audiologist; when bundled, there is no value to the rehabilitation services provided (Coverstone and Miller, 2013).

THE OFFICE IS OPEN AND STILL MORE PAPERWORK!

When the office finally opens and the first patient comes in, the audiologist and/or staff need to ensure that referrals are appropriate, that insurance is valid, that a copy of official identification has been collected, and that HIPAA forms are signed. An up-to-date HIPAA agreement must be prominently displayed and the patient must sign a statement acknowledging that the agreement was seen (US Department of Health and Human Services, n.d.). In addition, with the latest version of HIPAA which was implemented in September 2013, a patient must actively agree to accept any marketing to be sent to that patient. Although one can send an unsolicited birthday card, or an educational newsletter, anything which has marketing intent must have patient permission prior to being sent.

Keeping patient data secure is another mandatory part of a practice. Each practice must have a security policy in writing, a security officer, and a compliance officer. A breach notification policy must be in place. In this age of electronic records, email and faxes, laptops and portable backup drives,

it is vital that there be a record of how to ensure security. Even something as simple as a policy of how to wipe an old computer clean must be documented. Training on privacy issues is a requirement and must be documented.

Business Agreements

Currently under HIPAA, it is mandated that business agreements be kept with every vendor or party who will see protected personal data, including cleaning service, shredding vendors, accountants, hearing aid manufacturers, and equipment representatives. Details of this mandate can be found at <http://www.hhs.gov/ocr/privacy>, as well as a sample business agreement.

Material Data Sheets and Emergency Plans

Material data sheets accompany all cleaning and decontaminating products, as well as products used to modify hearing aids. They list the ingredients which are active and hazardous and how to handle the scene if the product is ingested or splashed into eyes, for example. Check-off sheets are signed to verify that employees have been trained to handle hearing aids and to clean up medical waste. Workers must be provided with training on an annual basis, and vaccines (e.g., for hepatitis) must be offered to all employees at no cost.

Emergency plans are written documentation of how to handle accidents, how to deal with bodily fluids and who has been trained to do so, as well as what to do in cases of physical emergencies. For example, what clean-up procedures are required when a patient has a bathroom accident or a vomiting incident? What plans go into effect if a patient becomes ill during a test procedure? These plans are legal requirements.

In many states, a practice must keep all material data sheets and emergency action plans in a metal file box in a set location, which must be easily found in an emergency. An evacuation plan has to be included in that box as well.

CONCLUSION

From the ADA (2008) document, “Ensuring Audiology’s Future in Healthcare,” it is clear that the students, faculty, and practitioners questioned agree that private practice ownership is where the vast majority see audiologists in the future. Besides the issue of autonomy, the income reported in this document as well as in ASHA’s Audiology Survey 2010 Private Practice is greatest for private practitioners compared to other settings. Although the effort to open and run a private practice might be greater than that of being an employee, the benefit is real. In addition, owners of private practice are more likely to use validation and verification techniques, provide counseling, and demonstrate assistive technology (ASHA, 2010). In other words, the private

practitioner is generally providing much needed and high-quality services. Who can argue that this is an outstanding career choice?

FOOD FOR THOUGHT

1. What is the impact of consolidators (those who are bringing a variety of practices together under one umbrella) and hearing aid manufacturers buying practices?
2. Is there any ethical dilemma in having a hearing aid manufacturer provide funding to a practitioner who wants to purchase a practice?
3. What impact will the retail model or the future of Internet sales have on private practice?

Implantable Hearing Devices

Teresa A. Zwolan

INTRODUCTION

Treatment options for hearing loss now include several implantable devices, including bone-anchored hearing systems, implantable middle-ear devices, cochlear implants (CIs), and auditory brainstem implants (ABIs). This chapter will provide information regarding how such devices work, descriptions of the surgical procedures used to implant these devices, and information regarding contemporary devices, including their Food and Drug Administration (FDA)-approved claims and candidacy statements.

BONE-ANCHORED HEARING DEVICES

Background

Bone-anchored hearing devices successfully transmit sound information to patients with chronic ear disease, external ear canal problems, external ear malformations, and, more recently, patients with single-sided deafness (SSD). They were first introduced by Anders Tjelsstrom in 1977 (Mudry and Tjellstrom, 2011). This early device consisted of a 4-mm titanium screw that was inserted into the bone behind the ear and attached to a bone-conduction hearing device. The screw, also referred to as an abutment, osseointegrates with the skull, meaning that bone grows and fuses with the screw, integrating it into the skull without the involvement of intervening fibrous tissue. A sound processor is then attached to the abutment. The microphone of the sound processor picks up sound from the environment and transmits it to the abutment. Vibration of the abutment results in transmission of sound to the inner ear via direct bone conduction, bypassing both the outer and middle ear. Direct attachment of the abutment to the skull provides several advantages over a traditional bone-conduction hearing aid, including greater comfort, less pain, and improved transmission of sound to the inner ear.

Contemporary Bone-Anchored Hearing Devices

Presently, there are three bone-anchored hearing devices available in the United States (Figure 43.1): the Baha

(produced by Cochlear Americas), the Ponto (produced by Oticon), and the Alpha 1 (produced by Sophono). The Ponto utilizes an implantable abutment while the Sophono is an abutment-free aid that is placed in the bone behind the ear. The Baha has both an implantable (Baha 4 Connect) and an abutment-free (Baha 4 Attract) device that stays coupled via magnetic attraction. The Baha 4 sound processor is compatible with either Baha device. The Ponto has three sound processors available: the Ponto, the Ponto Pro, and the Ponto Pro Power. All three processors may be used with either the Ponto implant system or with specific compatible Baha abutments/implants from Cochlear Bone Anchored Solutions (BAS). Similarly, some of the Baha sound processors can be used with the Ponto implant system. The Alpha 1 and Alpha 2 speech processors are used with the Sophono Alpha Magnetic Implant.

Hard and soft headbands are available for Baha, Ponto, and Sophono processors, making it possible for young children, and occasionally adults, to use the bone-conduction hearing systems without having surgery.

Surgery

The surgically implanted abutment of the Baha and Ponto may be implanted in one or two stages. When done in two

stages, the first procedure involves placement of a fixture into the bone located behind the pinna. The second procedure is performed about 3 to 6 months later, allowing time for osseointegration of the fixture, and involves connecting the abutment to the fixture. With a single-stage procedure, which is primarily used with adults and older children, the fixture and the abutment are implanted at the same time. Surgery for the Sophono and the Baha Attract involves surgical placement of an abutment-free, completely implantable titanium device that is placed in the bone behind the ear. The implanted device houses two magnets that enable the sound processor to attach magnetically to the skull where it sits directly over the implanted device. The sound processor delivers acoustic information across the skin to the implanted device where sounds are then transferred directly to the inner ear via bone conduction. Complications for all three types of bone-conduction hearing systems are rare, but may include infection and inflammation at the implant site or failure of the abutment to osseointegrate with bone (Dun et al., 2011). Additional information about each type of device can be found on each manufacturer's website, as listed in Table 43.1.

Candidacy for Bone Anchored Hearing Devices

All three of these devices received approval in the United States by the FDA for use in patients (1) who have conduc-

tive or mixed hearing loss and can still benefit from sound amplification, (2) with bilaterally symmetric conductive or mixed hearing loss (and both may be implanted bilaterally), (3) with sensory/neural deafness in one ear and normal hearing in the other (i.e., SSD), and (4) who are candidates for an air-conduction contralateral routing of signals (AC CROS) hearing aid but who cannot or will not wear an AC CROS device (<http://www.fda.gov/medicaldevices/productsandmedicalprocedures/homehealthandconsumer/consumerproducts/hearingaids/ucm181482.htm#devices>). Additionally, all three devices are FDA-approved for use in adults and children aged 5 years and older.

CONTEMPORARY IMPLANTABLE MIDDLE-EAR DEVICES

Contemporary implantable hearing devices available in the United States are displayed in Figure 43.2. The Esteem[®] Hearing Implant is an active ossicular prosthesis manufactured by Envoy Medical and is FDA-approved for use in adults 18 years of age or older who have a moderate to severe sensory/neural hearing loss.

Surgery to implant the device typically involves an outpatient procedure that includes a postauricular incision to access the middle-ear space, disarticulation of the ossicular chain, connection of the sensor to the incus, connection of the driver to the stapes, and placement of the sound

FIGURE 43.2 Photos of the Esteem and Vibrant Soundbridge implantable hearing aids.

processor behind the ear (underneath the scalp). The speech processor is connected to the sensor and driver via insulated wires. The sensor converts vibrations from the tympanic membrane and middle-ear ossicles into electrical signals that are sent to the sound processor. The sound processor amplifies and filters the signal based on the patient's hearing needs. The driver receives the signal from the sound processor and converts it back to vibrations that are then transmitted to the inner ear where they are perceived as sound. The Esteem differs from other devices in this chapter because all of its components are implanted, making it waterproof, as well as invisible to others.

The Vibrant Soundbridge is manufactured by MED-EL Hearing Technology GmbH and is FDA-approved for use in adults with moderate to severe sensory/neural, conductive, and mixed hearing losses. It consists of a surgically implanted transducer called the vibrating ossicular prosthesis (VORP) that includes a component known as the floating mass transducer (FMT), which is surgically attached to a vibratory structure of the middle ear. The VORP receiver is placed underneath the skin behind the ear and contains a magnet that helps attach the externally worn Amadé audio processor to the user's head. The microphone of the Amadé picks up sound from the environment and sends a signal across the skin to the implanted VORP for transmission to the inner ear via the FMT.

Nonsurgical Implantable Hearing Aids

A nonsurgical alternative to improved hearing is the Lyric2 produced by Phonak and consists of a hearing aid that is implanted deeply into the ear canal. It is suitable for people

FIGURE 43.3 Photos of the Lyric2 [Phonak] nonsurgical implantable hearing aid.

with mild to moderately severe hearing losses (Figure 43.3). The aid is worn in the canal for a period of up to 3 months and can be worn while performing various activities such as showering, exercising, and sleeping and is removed/replaced every few months when the battery wears out. Additional information about this device can be found on the manufacturer's website: www.lyrichearing.com.

COCHLEAR IMPLANTS

Background

Cochlear Implants (CIs) were originally designed to replace the function of the profoundly impaired inner ear. Candidacy was initially limited to adults and children with bilateral profound sensory/neural hearing losses. Today, adults and children with moderate-to-profound hearing losses receive CIs. Various clinical trials are evaluating the expansion of candidacy to include the use of hybrid devices designed for patients with mild to moderate low-frequency hearing coupled with a severe to profound hearing loss in the high frequencies, to evaluate the use of CIs in patients with greater preoperative speech recognition, and to evaluate the use of CIs as a treatment for SSD. Such expansions in CI candidacy have been fostered by improvements in technology and revision of traditional surgical techniques to allow greater preservation of residual hearing.

There are three manufacturers who provide CI systems in the United States: Advanced Bionics (AB) of Sylmar, CA (Figure 43.4), Cochlear Americas of Centennial, CO (Figure 43.5), and MED-EL of Innsbruck, Austria (Figure 43.6). All of the systems developed by these manufacturers include a surgically implanted device and an externally worn speech processor.

FIGURE 43.4 Photo of the cochlear implant system presently offered by Advanced Bionics [AB].

FIGURE 43.5 Photo of the cochlear implant system presently offered by Cochlear Americas.

Internal Device Components

Contemporary internal devices consist of several common components, including a receiving coil/internal processor, magnet, electronics package, extracochlear electrodes, and an electrode array containing tiny contacts (electrodes) that deliver the electric signal to the inner ear.

The receiving coil is the largest portion of the internal device and is surgically placed in the mastoid bone. It is composed of a magnet (for attachment of the external headset) and an antenna that receives the transmitted signal. All devices use a special plastic casing to house the receiving coil/internal processor.

All of the currently available systems are multichannel and take advantage of the tonotopic organization of the cochlea providing differently processed information to electrodes positioned at different locations within the cochlea. When stimulated, these electrodes provide localized excitation of cochlear nerve fibers, resulting in place pitch information used to understand speech. The number

of stimulating electrodes used in current systems varies from 12 to 22. Several different configurations of electrode arrays are offered by each manufacturer to customize the fit of the electrode into the cochlea. Such arrays vary in several ways, including total length (longer, shorter, and compressed arrays are available) and configuration (i.e., thinner arrays with smaller diameters for improved hearing preservation).

External Components

Currently available CI systems have several common external components that work together to collect, process, and transmit auditory information to the internal components. External components include a microphone, speech processor, connecting cables, and a transmitter coil (Figure 43.7). The microphone captures sound from the environment and sends it to the speech processor, where it is converted into digital information that is coded for transmission to the internal device. The signal is then sent via a wire to the transmitter located on the outside of the implant user's head. The transmitter is aligned with the internal receiving coil and is held in place by external and internal magnets. The integrated circuit within the CI internal processor receives the information, decodes the signal, and delivers electrical stimulation to the implanted electrodes. All of the currently available devices use transcutaneous transmission, which means the signal is delivered across intact skin using a radio frequency link.

Currently available devices offer several options that enable the clinician to provide optimum efficiency and fit of the external equipment for individual patients. Cords come in a variety of lengths, and magnets come in a variety of strengths to accommodate the needs of both adults and children. Additionally, speech processors, cords, and headset components are offered in a variety of colors to maximize cosmetic appearance.

FIGURE 43.6 Photo of the cochlear implant system presently offered by MED-EL.

Processor Features

Early CI systems included large body-worn processors that were powered by AA batteries. Present-day systems continue to include body-worn processors but also include ear-level speech processors. Ear-level processors are modular and include a battery pack that utilizes either rechargeable or disposable batteries and can be attached to the processor and worn behind the ear, or attached to a body-worn battery pack that can be attached to the recipient's clothing. All processors are able to store multiple programs and have special features that decrease their susceptibility to electrostatic discharge (ESD). The number of memories or programs that the processor is able to contain varies from three to nine. Having more than one memory is advantageous as it provides the user with the ability to experiment with

Hearing with a cochlear implant

/01

Microphones on the sound processor pick up sounds and the processor converts them into digital information.

/02

This information is transferred through the coil to the implant just under the skin.

/03

The implant sends electrical signals down the electrode into the cochlea.

/04

The hearing nerve fibers in the cochlea pick up the signals and send them to the brain, giving the sensation of sound.

FIGURE 43.7 Schematic diagram of how a cochlear implant works. [Courtesy of Cochlear Americas.]

different programs and/or different processing strategies outside the clinic setting that helps decrease the number of follow-up appointments needed to adjust the patient's program.

Additional device features include processor dials or remote controls to adjust the settings of the processor, private and public alarms, "lock" features that prevent children from changing the settings on the speech processor or having access to the speech processor batteries, connection to various assistive listening devices and FM units using telecoil, streaming, or Bluetooth technology, and either standard alkaline or rechargeable battery compartments to power the device.

The way the speech processor delivers information to the inner ear is determined by the speech processing strategy. Several different strategies are available with each device and provide clinicians with the ability to customize and maximize patient outcomes. Table 43.2 includes a summary of the various speech processing strategies that are available with contemporary devices. The reader is referred to Wolfe and Schafer (2010) for a detailed description of contemporary speech processing strategies.

Specific features of currently available CI systems will be briefly described below. Additional information can be obtained from each manufacturer's website; see Table 43.1.

Advanced Bionics

The HiResolution Bionic Ear System is manufactured by Advanced Bionics (AB) Corporation of Sylmar, CA. The first commercial device (Clarion) was introduced in 1987

by MiniMed Technologies, which later became Advanced Bionics Corporation in Valencia, CA.

Components of the contemporary AB system are displayed in Figure 43.4. This system includes the HR 90K implant, the Naida CI speech processor, and the recently introduced Neptune—the industry's first waterproof processor. There are three speech processing strategies presently available with the AB device: HiResolution (HiRes-S, HiRes-P, HiRes-S with Fidelity 120, HiRes-P with Fidelity 120), Continuous Interleaved Sampling (CIS) (Wilson, 2000), and Multiple Pulsatile Sampler (MPS).

Cochlear Pty. Ltd.

Cochlear Pty. Ltd. ("proprietary limited") was formed in 1981 in Sydney, Australia. In 1985, the Nucleus CI22 received FDA approval for use in adults and received approval for use in children in 1990.

Components of the contemporary CI system produced by Cochlear Americas are displayed in Figure 43.5. This system includes the Nucleus Freedom (CI24RE) implant and the N6 (CP910) speech processor, a modular device that can be worn on either the body or behind the ear. The speech processing strategies currently available with the Cochlear system include Spectral Peak (SPEAK), Advanced Combined Encoder (ACE), and CIS.

MED-EL

The MED-EL device was first introduced in Europe in the 1970s and was first introduced in the United States in the

TABLE 43.2

Speech Processing Strategies Available with Contemporary Devices

Strategy	Descriptor	Advanced Bionics	Cochlear Americas	MED-EL
NofM	Unlike CIS strategies (described below), which stimulate all active electrodes during each stimulation cycle, NofM strategies evaluate the acoustic energy present in each m channel; stimulation is then only delivered to the n channels with the highest amplitude inputs. The n is typically referred to as maxima and remains constant for each stimulation cycle			X
SPEAK	SPECTRAL PEAK: An NofM-type strategy that typically uses up to 8 maxima. Electrodes are typically stimulated at a rate of 250 pp. Unlike NofM, the number of maxima may change during stimulation cycles depending on the energy of the incoming signal		X	
ACE	ADVANCED COMBINED ENCODER: Also considered an NofM strategy, but utilizes faster stimulation rates and is capable of using more maxima than SPEAK. Similar to SPEAK, the number of maxima during each stimulation cycle may change depending on the energy of the incoming signal		X	
CIS	CONTINUOUS INTERLEAVED SAMPLING: The acoustic signal is digitally filtered and sent through a bank of bandpass filters. Each electrode is stimulated sequentially during each stimulation cycle. Amplitude of stimulation depends on the energy present in each band [greater energy = greater amplitude]	X	X	X
CIS+	A version of CIS that utilizes expanded frequency bands			X
HDCIS	HIGH DEFINITION CIS: A version of CIS that, in addition to sequential stimulation, utilizes sequential stimulation between neighboring stimulation sites to elicit a percept that falls between the percept elicited by the two electrodes			X
FSP	FINE STRUCTURE PROCESSING: A CIS-type strategy that additionally modulates the timing of pulse bursts in the low-frequency channels to provide improved temporal cues and provides information regarding intermediate pitches by using overlapping bandpass filters			X
HIRES	HI RESOLUTION: A version of CIS that utilizes 16 channels, stimulates at higher maximum stimulation rates, and has higher cutoff frequencies for low-pass filters than traditional CIS	X		
HIRES 120	HI RESOLUTION 120: Incorporates current steering to attempt to provide an increase in the number of perceptual channels to 120	X		
HIRES S	HI RESOLUTION-SEQUENTIAL: A HIRES strategy that utilizes sequential stimulation of electrodes	X		
HIRES P	HI RESOLUTION PARTIAL SIMULTANEOUS: A HIRES strategy that provides partial simultaneous stimulation	X		
MPS	MULTIPLE PULSATILE SAMPLER: A partially simultaneous strategy that stimulates two or more nonadjacent electrodes at the same time	X		
SAS	SIMULTANEOUS ANALOG STIMULATION: Stimulates electrodes with continuous analog waveforms. Unlike CIS (which stimulates all electrodes sequentially), SAS stimulates each electrode simultaneously during each cycle of stimulation	X		

1990s. Components of the contemporary MED-EL system are displayed in Figure 43.6 and include the Concert implant, and the Opus 2 and Rondo speech processors. The Rondo is the first CI speech processor that can be worn on the head but off the ear; it was introduced in 2013. Speech processing strategies currently available with MED-EL devices include HDCIS and FSP.

HYBRID COCHLEAR IMPLANT DEVICES

Hybrid devices use both electric and acoustic stimulation in the same ear, by presenting high-frequency information via the surgically implanted electrode array, and low-frequency acoustic information via an ipsilateral hearing aid. These electric acoustic stimulation (EAS) devices are based on the premise that it is possible to preserve low-frequency hearing after CI surgery when one uses careful surgical techniques and certain electrode designs that minimize trauma to inner-ear structures. Previously, it was assumed that patients would experience a total and complete loss of residual hearing following insertion of the electrode array. However, Gstoettner et al. (2006a, 2006b) reported long-term hearing preservation rates of 70% and 83%, respectively, with EAS devices, indicating that hearing preservation is possible following CI surgery.

The Nucleus Hybrid Hearing Implant was FDA approved in 2014 and is suitable for patients with low frequency thresholds no poorer than 60 dB HL up to and including 500 Hz and a PTA (2,3,4 KHz) that is greater than or equal to 75 dB HL in the ear to be implanted. Additionally, the ear to be implanted should demonstrate a CNC word recognition score between 10 and 60% correct while the CNC score for the non-implanted ear should be equal to or less than 80% correct and have a PTA (2,3,4 KHz) greater than or equal to 60 dB HL. Recipients of this device utilize a hybrid sound processor that delivers both acoustic information (via a hearing aid portion connected to the processor) and electric information (via the sound processor). The Nucleus 6 processor, which was recently approved by the FDA, includes a commercially available acoustic component integrated into the processor and is available for use with hybrid patients.

MED-EL's FLEX^{ead} electrode is a 20.9-mm electrode array with a flexible tip designed to reduce the force placed on the cochlea during electrode insertion, increasing the chances for preservation of residual hearing (Hochmair et al., 2006). In 2005, MED-EL introduced the DUET EAS hearing system, which combines the features of the MED-EL TEMPO+ speech processor with digital acoustic amplification circuitry. The MED-EL EAS system is currently undergoing clinical trials in the United States and is not yet FDA approved for widespread use.

DETERMINING CANDIDACY FOR A COCHLEAR IMPLANT

Candidacy requirements for a CI have changed greatly since CIs were first introduced. In the United States, the FDA oversees the selling, distribution, labeling, and marketing of medical devices and determines if the specific wording used in device labeling, including information regarding indications for its use, or candidacy, is appropriate following completion of a clinical trial. They also include wording related to both audiometric and speech recognition criteria. FDA-approved indications differ for adults and children and are often dependent on when the device received FDA approval. Candidacy criteria for contemporary devices are provided in Table 43.3.

When CIs were first introduced, only patients who demonstrated no benefit from amplification (i.e., scored 0% correct on open-set tests of sentence recognition) were considered candidates for a CI. Today, patients may be considered a candidate to receive an FDA-approved CI if they demonstrate various levels of open-set speech recognition. Because of broader candidacy criteria, it is important for clinicians to recommend a CI only if it is believed that the patient will demonstrate improved communication skills with implant use.

Preoperative Testing to Determine Candidacy for a Cochlear Implant

The primary purpose of the preoperative evaluation is to determine if the patient is medically and audiotologically suitable for a CI. Additionally, such information should be compared to postoperative results to evaluate the recipient's progress and device efficacy. The determination of candidacy for a CI is most often made by a group of qualified professionals, including a surgeon, an audiologist, and a speech-language pathologist. The opinions of other professionals, such as that of a psychologist or educator, may also be taken into account.

Test procedures commonly included in the preoperative process for determining implant candidacy are described below.

MEDICAL EVALUATION

During the preoperative medical evaluation, the physician obtains a complete medical history, performs a physical examination, and ensures that the candidate is up to date on all immunizations (see <http://www.cdc.gov/vaccines/vpd-vac/mening/cochlear/dis-cochlear-gen.htm> for information regarding recent Centers for Disease Control and Prevention recommendations). The surgeon attempts to identify the cause of the hearing loss if it is not already known and determines if treatment options other than a CI are more

TABLE 43.3

FDA-approved Candidacy Criteria for Contemporary Cochlear Implant Systems*Adults (18 years of age or older)*

Advanced Bionics HiRes 90K

18 years of age or older with severe to profound, bilateral sensory/neural hearing loss (>70 dB HL) with postlingual onset of severe or profound hearing loss. Limited benefit from appropriately fit hearing aids, defined as scoring 50% or less on a test of open-set sentence recognition (HINT sentences)

Cochlear Americas Nucleus Freedom (CI24RE)

Bilateral pre-, peri-, or postlinguistic, sensory/neural hearing impairment and obtain limited benefit from appropriate binaural hearing aids. These individuals typically have moderate-to-profound hearing loss in the low frequencies and profound (≥ 90 dB HL) hearing loss in the mid to high speech frequencies. Limited benefit from amplification is defined by test scores of 50% correct or less in the ear to be implanted (60% or less in the best-aided listening condition) on tape-recorded tests of open-set sentence recognition

MED-EL Concert

Adults of 18 years of age or older who have bilateral, sensory/neural hearing impairment and obtain limited benefit from appropriately fitted binaural hearing aids. These individuals typically demonstrate bilateral severe to profound sensory/neural hearing loss determined by a puretone average of 70 dB or greater at 500, 1,000, and 2,000 Hz. Limited benefit from amplification is defined by test scores of 40% correct or less in best-aided listening condition on DC-recorded tests of open-set sentence recognition (Hearing in Noise Test [HINT] sentences)

Children

Advanced Bionics HiRes 90K

Age from 12 months through 17 years with profound, bilateral sensory/neural deafness (>90 dB HL). Use of appropriately fitted hearing aids for at least 6 months in children 2–17 years of age, or at least 3 months in children 12–23 months of age. The minimum duration of hearing aid use is waived if X-rays indicate ossification of the cochlea. Little or no benefit from appropriately fit hearing aids. In younger children (<4 years of age), lack of benefit is defined as a failure to reach developmentally appropriate auditory milestones (such as spontaneous response to name in quiet or to environmental sounds) measured using the Infant-Toddler Meaningful Auditory Integration Scale or Meaningful Auditory Integration Scale or <20% correct on a simple open-set word recognition test (Multisyllabic Lexical Neighborhood Test [MLNT]) administered using monitored live voice (70 dB SPL). In older children (>4 years of age), lack of hearing aid benefit is defined as scoring <12% on a difficult open-set word recognition test (Phonetically Balanced Kindergarten Test) or <30% on an open-set sentence test (HINT for Children) administered using recorded materials in the sound field (70 dB SPL)

Cochlear Americas Nucleus Freedom (CI24RE)

Intended for use in children 12–24 months of age who have bilateral profound sensory/neural deafness and demonstrate limited benefit from appropriate binaural hearing aids. Children 2 years of age and older may demonstrate severe to profound hearing loss bilaterally. In younger children, limited benefit is defined as lack of progress in the development of simple auditory skills in conjunction with appropriate amplification and participation in intensive aural habilitation over a 3–6 month period. It is recommended that limited benefit be quantified on a measure such as the Meaningful Auditory Integration Scale or the Early Speech Perception test. In older children, limited aided benefit is defined as $\leq 30\%$ correct on the open-set MLNT or Lexical Neighborhood Test (LNT), depending on the child's cognitive and linguistic skills. A 3–6 month hearing aid trial is recommended for children without previous aided experience

MED-EL Concert

Children aged 12 months to 17 years 11 months must demonstrate a profound, bilateral sensory/neural hearing loss with thresholds of 90 dB or greater at 1,000 Hz. In younger children, little or no benefit is defined by lack of progress in the development of simple auditory skills in conjunction with appropriate amplification and participation in intensive aural habilitation over a 3–6 month period. In older children, lack of aid benefit is defined as <20% correct on the MLNT or LNT, depending on the child's cognitive ability and linguistic skills. A 3–6 month hearing aid trial is required for children without previous experience with hearing aids. Radiologic evidence of cochlear ossification may justify a shorter trial with amplification

suitable, such as performing a stapedectomy in cases of far-advanced otosclerosis. The candidate's general health is also evaluated to determine if he or she is healthy enough to participate in the surgery required for cochlear implantation.

COCHLEAR IMAGING

Computed tomography (CT) or magnetic resonance imaging (MRI) of the temporal bone is routinely performed as part of the preoperative evaluation process to visualize development of the mastoid and inner-ear structures. These procedures identify any inner-ear anomalies, determine if cochlear ossification is present, and help determine the most suitable ear for implant if a unilateral procedure is recommended. Knowledge regarding the presence of cochlear anomalies is important prior to surgery because it may affect the type of electrode array selected for surgery (i.e., compressed, straight, or split array), the surgical approach used to access the cochlea, the insertion depth of the electrode array, selection of the ear for implantation, and final placement of the electrode array. Cochlear malformations rarely preclude placement of a CI (Balkany et al., 1996; Tucci et al., 1995), although severe anomalies may limit the insertion depth of the electrode array to a degree that would compromise the anticipated benefit from the device. Furthermore, associated anomalies of the temporal bone, particularly absence of the eighth nerve, may render cochlear implantation unwise. To avoid unnecessary risks to the patient, disappointment for the family, and delay in the initiation of alternative communication modes, the preoperative assessment of patients with anomalous temporal bones should include MRI and electrically evoked auditory brainstem response (EABR) testing (Kileny and Zwolan, 2004), which will allow the clinician to assess both the structural and functional integrity of the auditory neural pathways.

AUDIOLOGIC EVALUATION

The primary purpose of the preoperative audiologic evaluation is to determine the type and severity of hearing loss. This evaluation typically includes unaided testing of air- and bone-conduction thresholds, speech recognition threshold (SRT), speech detection threshold (SDT), word recognition, otoacoustic emissions (OAEs), and tympanometry and acoustic reflexes. As noted in Table 43.4, FDA guidelines differ across manufacturers with regard to recommended audiometric criteria to receive a CI.

ELECTROPHYSIOLOGICAL TESTING

Auditory brainstem response (ABR) testing is a vital part of the CI candidacy process as it is used to verify behavioral audiometric test results, helps to identify patients with auditory dyssynchrony (ANSD), and helps to rule out the possibility of functional deafness. Additionally, some centers

TABLE 43.4

Tests Commonly Used to Evaluate Speech Perception Skills of Pediatric Cochlear Implant Users

Early Speech Perception Test [ESP] (Moog and Geers, 1990)
Meaningful Auditory Integration Scale [MAIS] (Robbins et al., 1991)
Infant-Toddler Meaningful Auditory Integration Scale [IT-MAIS] (Zimmerman-Phillips et al., 1998)
Word Intelligibility by Picture Identification [WIPI] Test (Ross and Lerman, 1979)
Northwestern University-Children's Perception of Speech [NU-CHIPS] Test (Elliott and Katz, 1980)
Phonetically Balanced Kindergarten [PBK]-50 Word List (Haskins, 1949)
Bamford-Kowal-Bench [BKB] Sentences (Bench et al., 1979)
Glendonald Auditory Screening Procedure [GASP] (Erber, 1982)
Lexical Neighborhood Test [LNT] (Kirk et al., 1995)
Multisyllabic Lexical Neighborhood Test [MLNT] (Kirk et al., 1995)

perform EABR (Kileny and Zwolan, 2004; Kileny et al., 1994) testing prior to implantation to verify electric stimulability of an ear. Such testing is usually performed in the operating room immediately prior to CI surgery and involves the presentation of current pulses via a transtympanically placed promontory needle electrode (Stypulkowski et al., 1986). The EABR is particularly useful when questions arise regarding the presence or stimulability of the eighth nerve in the ear to be implanted (e.g., when a patient presents with a history of cochlear anomaly coupled with no responses to audiometric testing).

HEARING AID EVALUATION AND SPEECH PERCEPTION TESTING

The preoperative hearing aid evaluation (HAE) is necessary to verify that the candidate's device is appropriate for his/her level of hearing loss. Although recommended hearing aid settings vary among clinicians, the amount of gain a candidate receives from amplification should be verified using a probe microphone approach that is referenced to ear canal SPL (Valente et al., 2006). Once an appropriate hearing aid has been selected for the evaluation, testing to evaluate speech recognition skills when using the appropriately fit hearing aids may begin.

When evaluating candidacy for a CI, it is important to consider the amount of time the candidate has used appropriate amplification. This is particularly true with children, prelingually deafened adults, and adults and children who

demonstrate some open-set speech recognition as experience with amplification may influence auditory detection and speech recognition skills. In most cases, a 1- to 3-month trial with appropriate amplification is recommended to ascertain the potential for aided benefit. With children, feedback provided by a speech-language pathologist who works with the patient during the trial period can be valuable. A shorter trial with amplification is justified if there is radiologic evidence of cochlear ossification or if the patient clearly receives no benefit from amplification. A longer trial or extended speech and language therapy may be needed if the clinician observes good improvement in auditory skills during the trial period.

Speech perception testing should be performed in a sound field using recorded test materials whenever possible (this is often not feasible, however, when testing small children). Most clinics and most clinical trials presently use a presentation level of 60-dB sound pressure level (SPL) for test stimuli (Firszt et al., 2004).

When administering speech perception tests, patients should be seated in a sound-treated room that contains minimal visual and auditory distractions. The presentation level should be calculated using a calibration microphone placed at the center of the listener's head. Test materials should be presented a single time only, and feedback should not be provided.

There are several different speech perception materials available for use with children and adults. When testing adults, most clinics follow recommendations provided in the manual of the Minimum Speech Test Battery (MSTB) (<http://www.auditorypotential.com/MSTBfiles/MSTB-Manual2011-06-20%20.pdf>), which was revised in 2011 and includes a recommendation to administer the following tests preoperatively and 3, 6, and 12 months postoperatively: One 20-sentence list of AzBio sentences (Peterson and Lehiste, 1962) presented in quiet, one 20-sentence list of AzBio sentences presented in noise, one 50-word list of CNC words, one 16-sentence list-pair (8 sentences per list) of the BKB-SIN test (Bench, 1979) preoperatively, and one 20-sentence list-pair (10 sentences per list) of the BKB-SIN postoperatively. A portion of the testing should be performed with each ear aided separately as well as in a binaurally aided condition to compare pre- versus postoperative performance. Testing ears individually also helps with other decisions, such as the selection of which ear to implant in cases of unilateral CI and determination of binaural advantage received from using two devices.

It is important to keep in mind that speech recognition scores provided in Table 43.3 are guidelines approved by the FDA for particular products, and that specific wording of each product is influenced by several factors, including the timeframe of FDA approval and design of the clinical trial. Thus, some patients have received devices “off label,” meaning that they demonstrated preoperative speech recognition scores that are better than current FDA-approved

recommendations for that device. Factors that may contribute to a decision to recommend an implant to someone outside FDA recommendations include the effect that reduced speech recognition has on the patient's ability to function in educational, occupational, and social settings. In some instances, insurers will only preauthorize payment for the device if the patient meets FDA indications, limiting any flexibility the clinic may have regarding candidacy.

It is also important to note that Medicare, the national health insurance program that provides health insurance to US citizens aged 65 and above, has specific criteria that clinics need to follow if a patient is enrolled in Medicare. Presently, these criteria differ from those of the FDA. On its website (www.cms.hhs.gov), the Centers for Medicare and Medicaid Services (CMS), which administers the Medicare program, presently indicates that implantation is for treating bilateral pre- or postlinguistic, sensory/neural, moderate-to-profound hearing loss in those who get limited benefit from amplification (i.e., $\leq 40\%$ correct for the best-aided listening condition using recorded tests of open-set sentence recognition). CMS also states that individuals with hearing test scores of 40% to 60% can receive a CI if both the provider and patient are enrolled in an FDA-approved category B IDE (Investigational Device Exemption) clinical trial, a trial under the CMS Clinical Trial Policy, or an upcoming, controlled comparative trial that is approved by CMS as meeting the requirements for National Coverage Analyses and also meets their specific quality standards. Additional information regarding this matter can be obtained from the CMS website (<http://www.cms.hhs.gov/>).

Selection criteria for children have also been expanded to include candidates with minimal open-set speech perception skills. Like adults, the specific wording used in FDA-approved guidelines differs for currently approved devices. FDA-approved indications for use of all devices state that, in younger children, limited benefit is defined as lack of progress in the development of simple auditory skills in conjunction with appropriate amplification and participation in intensive aural rehabilitation over a 3- to 6-month period, and all recommend that hearing aid benefit be quantified in young children using measures such as the Meaningful Auditory Integration Scale (MAIS) (Robbins et al., 1991) or the Early Speech Perception (ESP) test (Moog and Geers, 1990). With older children, all three manufacturers recommend use of the open-set Multisyllabic Lexical Neighborhood Test (MLNT) or Lexical Neighborhood Test (LNT) (Kirk et al., 1995), depending on the child's cognitive and linguistic skills. Like adults, the particular score used to define lack of benefit varies. For the Nucleus Freedom, lack of aided benefit is presently defined as a score $\leq 30\%$ correct, whereas the Advanced Bionics HiResolution and the MED-EL Pulsar systems define this as a score $\leq 20\%$ correct on such measures. With both children and adults, preoperative

speech perception testing should include tests that measure a variety of speech perception skills.

Pediatric speech perception tests can be broken down into three general areas: (1) Closed-set tests that measure prosodic cue, speech feature, or word perception; (2) open-set word and sentence tests that provide an estimate of the child's ability to communicate in the "real world"; and (3) auditory development scales, such as the MAIS (Robbins et al., 1991), that use parental report to evaluate the child's listening skills in his or her daily environment. Speech perception tests commonly used with children in pre- and postoperative CI evaluations are listed in Table 43.4. For a comprehensive review of these test procedures, the reader is referred to Gifford (2013).

SPEECH AND LANGUAGE EVALUATION

Speech-language evaluations are performed at most centers as part of the pediatric pre- and postoperative evaluations. This evaluation is essential because it provides information regarding the child's development of speech and language skills—a critical factor when considering pediatric candidacy for a CI. During this evaluation, the speech-language pathologist may evaluate the child's developmental expressive and receptive language skills, articulation skills, and speech intelligibility. Importantly, the child's communicative status is evaluated with respect to normative models of language development, and this provides information regarding expectations for speech and language improvements that may or may not be seen following intervention with a CI. Occasionally, the speech-language pathologist may recommend participation in structured therapy before making a recommendation regarding the patient's candidacy for a CI. Such therapy may be particularly helpful in borderline cases, in cases where the child has received little therapeutic intervention or has been inappropriately fit with amplification, and also in cases of auditory neuropathy spectrum disorder (ANSD).

Similar to speech perception materials, the specific tests used in the speech and language evaluation are dependent on the child's age and language level. Postoperatively, children with CIs should continue to participate in regularly scheduled speech and language therapy and evaluations. These evaluations help determine which speech cues are or are not being perceived by the child, help identify lack of progress that may be because of internal device failure, provide information that may aid in programming the child's device, and help determine auditory training goals that can be focused on during speech and language therapy sessions.

PSYCHOLOGIC EVALUATION

The psychologic evaluation is primarily performed with pediatric patients but may also be necessary with adults who present with concerns regarding cognitive status or

mental function. With children, a preoperative evaluation should include nonverbal assessment of cognitive, social, emotional, and adaptive abilities to determine if factors other than hearing impairment are hindering the child's auditory development. Depending on the patient's age and the presenting concerns, the ability of the child to attend to and remember information may also be assessed, and recommendations may be made regarding educational services. The presence of a cognitive impairment may impact the child's ability to develop spoken language skills and will influence the counseling provided to parents regarding expected outcomes. Parents of very young children should be informed that some psychologic deficits (e.g., autism) are not typically identified until the child is 2 years of age or older and that performance with the device may be hindered if additional disabilities are identified.

In recent years, greater numbers of children presenting with a disability in addition to their hearing loss have received CIs (Donaldson et al., 2004; Waltzman et al., 2000; Wiley et al., 2005). This change has increased the need for preoperative psychologic evaluations that will help determine how effectively the child will be able to utilize the auditory signal. The input of the psychologist is essential when determining if referrals to other professionals are necessary prior to and after the child receives a CI.

PATIENT EDUCATION

Patient education is an ongoing part of the pre- and postoperative evaluation process. When the patient is first seen, information should be provided regarding device options, CI technology, candidacy requirements, expectations of performance, appointments involved in the evaluation process, and financial obligations. Many centers make arrangements for patients to meet with a CI recipient or with the parents of a pediatric CI recipient to discuss the implant evaluation process.

COORDINATION OF SERVICES WITH THE CHILD'S EDUCATIONAL SETTING

Ideally, parents should inform the child's school about the plans for the child to receive a CI as it is important for educators to understand how to use and troubleshoot the device. An in-person visit from the implant audiologist or speech-language pathologist is ideal as it allows the clinician to observe the child in his/her classroom setting and may foster recommendations being made regarding management of the child's auditory needs in the classroom.

DETERMINATION OF IMPLANT EAR

Over the past few years, bilateral CIs have become increasingly common for both children and adults. Numerous insurers and various professional organizations recognize

bilateral CIs as the standard-of-care treatment for individuals with bilateral severe to profound hearing loss. When it is determined that a patient is a candidate for a CI, one of the decisions that needs to be made is determination of which ear to implant (if it is determined the patient will receive a unilateral implant), which ear to implant first (if the patient is receiving sequential bilateral implants), or if the patient should receive simultaneous bilateral CIs. If being provided with a unilateral implant, the determination of which ear to implant can be influenced by several factors. Many clinics routinely implant the ear with the least amount of residual hearing, whereas other clinics routinely implant the patient's "better" hearing ear. Some clinics determine the ear of implant on a case-by-case basis, whereas others leave this decision up to the patient and/or the parents.

Recent studies indicate numerous benefits of bilateral implantation, including benefits for speech perception resulting from overcoming the head shadow effect, improved speech understanding in noise, improved sound localization (Patrick et al., 2006), binaural squelch (Buss et al., 2008), and binaural summation (Dorman et al., 2011). Similar findings have been reported for bilateral implants in the pediatric population (Litovsky et al., 2006), along with more rapid language acquisition (Wie, 2010) and improved speech recognition skills (Wolfe et al., 2007).

Summary of Preoperative Testing

In summary, preoperative testing is used to determine if a patient is a suitable candidate for a CI. Three primary questions that should be addressed in the preoperative evaluation include the following: (1) Can we increase the patient's auditory detection skills? (2) Can we improve the patient's speech understanding when compared to that obtained with a hearing aid? (3) In the pediatric population, is there a good chance that implant use will facilitate or improve spoken language more than would be expected with continued hearing aid use?

It is important for clinicians to remain current regarding candidacy guidelines as the specific criteria used to determine candidacy frequently change and will continue to evolve as technologic advancements are made and patient outcomes continue to improve. Updates regarding current CI candidacy can be obtained by contacting local CI programs or by accessing CI manufacturer websites.

SURGICAL PROCEDURE

Surgery begins with administration of general anesthesia. Hair is shaved above and behind the ear, the skin is prepared with an antiseptic solution, and sterile drapes are placed around the ear. A postauricular incision is made, and a well is created in the skull behind the mastoid bone to accommodate the receiver-stimulator portion of the internal device. The surgeon drills through the mastoid air cells and removes

bone between the tympanic membrane and the facial nerve until the round window and the cochlear promontory are visualized. An opening (called a cochleostomy) is made into the basal turn of the scala tympani just anterior to or through the round window, and the electrode array is inserted into the scala tympani. If a ground electrode is attached to the receiver, it is then placed under the temporalis muscle. The receiver-stimulator is placed and secured into the well behind the mastoid, the incision is closed, and a pressure dressing is placed over the ear for 24 hours. Some surgeons may forego the use of the well and instead place the implant receiver in a tight pocket of skin behind the mastoid.

Some special considerations are needed when implanting young children because surgical intervention with this age group requires specific knowledge of temporal bone anatomy and the impact of skull growth on the implanted device. Although temporal bone growth has been shown to continue through adolescence, anatomy of the facial recess is fully developed at birth (Eby, 1996). The most significant developmental changes are in the size and configuration of the mastoid cavity. Eby and Nadol (1986) recommend that the surgeon leave approximately 2.5 cm of additional electrode lead in the mastoid area to accommodate for head growth. Additionally, modifications to the surgical technique or the use of specialized electrode arrays may be necessary when the patient presents with anatomic anomalies, such as cochlear ossification or malformation.

CI surgery typically lasts between 2 and 5 hours depending on the surgeon's experience, the device selected, and the complexity of the anatomy encountered in each patient. Most clinics perform this as an outpatient procedure, enabling patients to return home in less than 24 hours. Children and adults return to their normal routines when they feel well enough to do so, often within 1 week of surgery.

Cochlear implantation has the same risks as other procedures conducted under general anesthesia and those of other surgeries of the middle or inner ear. In centers with considerable experience performing CI surgery, such risks are quite limited and are greatly outweighed by the advantages that the properly selected patient will obtain from the implant. Risks include a remote possibility of infection, temporary or permanent facial paralysis on the operated side, mild temporary taste disturbances, tinnitus, and vertigo. In traditional CI surgery, one may expect loss of any residual hearing in the implanted ear, as well as mild pain and numbness at the site of the incision following the surgery. Removal of the CI may become necessary if the internal device suffers electrical or mechanical damage, if an infection at the site cannot be successfully treated with medication, or if the device or the electrode array becomes displaced. Such surgical intervention is similar in scope to initial placement of the device, although generally less risky because of the drilling having been completed at the original operation.

CI recipients must avoid various medical/surgical procedures that could damage the implanted device or the

functioning auditory nerve fibers that transmit the electrical signal to the brain. The use of monopolar electrosurgical instruments in the region of the head or neck, diathermy, neurostimulation, ionizing radiation therapy involving the area of the implant, electroconvulsive therapy, and MRI must all be avoided because they can cause excessive magnetic and electromagnetic interference, which may result in demagnetization of the internal magnet, displacement of the device, and/or disruption of the device electronics. Two commercial CI devices, the Nucleus Freedom and Advanced Bionics HR 90K, are manufactured with a removable internal magnet and may be preferable for patients who are expected to need MRI in the future, such as those who suffer from multiple intracranial tumors related to neurofibromatosis type II. The MED-EL Cochlear Implant System, which does not have a removable magnet, is FDA-approved for use with MRI at a maximum strength of 1.5 Tesla.

POSTOPERATIVE MANAGEMENT: PROGRAMMING THE DEVICE

After surgery, patients return to their implant center for initial programming of their device. The recommended amount of time between surgery and device programming varies; some centers activate the device within days, whereas others may wait several weeks. Waiting for device activation allows for healing and reduction of swelling around the incision, which will enable the headset magnet to adhere properly. The particular procedures followed for the activation will vary depending on the patient's age as well as on the device that was implanted.

For all devices, initial programming begins with connection of the patient's speech processor to the audiologist's computer. This interface of hardware to the internally implanted device enables the clinician to perform objective and subjective measurements needed to appropriately set the device. For all devices, telemetry is performed at the beginning of the appointment and provides valuable information regarding the status of the internal device. Telemetry systems work by sampling, digitizing, and reporting back to the clinician information about the voltage generated on the internal electrodes during stimulation. Telemetry measurements provide information about electrode impedances, short-circuited electrodes, and voltage compliance for each of the electrodes in the array (Abbas et al., 2006). Such measurements guide clinicians in their determination of which electrodes to include or exclude from the recipient's program.

Next, the clinician works with the patient to determine the softest level of sound that results in hearing for each of the electrodes. This level is referred to as "threshold" and is recorded on a computer using programming software. Additionally, the upper level of stimulation is determined for each active electrode. Depending on the type of device used, the level of stimulation is increased until the patient

reports the sound is "most comfortable" (M level) or is loud but comfortable (C level). This process results in creation of a speech processor program tailored to the hearing of the individual being tested.

Programming of the electrodes and creation of the speech processor program can be particularly challenging with young children and with patients who are unable to provide feedback regarding the perceptibility and loudness of the electrical signal. With young children, traditional behavioral test techniques, such as behavioral observation audiometry (BOA), visual reinforcement audiometry (VRA), and conditioned play audiometry (CPA) (see Chapter 24), are used to determine threshold and comfort-level measurements. Additionally, objective measures, such as neural response telemetry (NRT), neural response imaging (NRI), auditory nerve response telemetry (ART), and measurement of electrically evoked stapodial reflexes (ESRT), may aid in determination of programming levels. The reader is referred to Hughes (2013) for additional information regarding the use of objective measures to develop speech processor programs for CI recipients.

Various programming techniques are used to refine the patient's psychophysical measures, such as loudness balancing, pitch scaling, and sweeping of the active electrodes. The finalized psychophysical data are applied to a particular speech processing strategy using programming software. Once it is determined that the program is appropriate, it is transferred to the patient's speech processor, and the patient takes it home to use following completion of the initial programming session.

The total number of electrodes used by a patient may be less than the number of electrodes available on the array. Determination of which electrodes to use may be influenced by factors such as telemetry test results, mode of stimulation, the patient's response to electrical stimulation, encoding strategy, and surgical placement of the electrode array. For example, the patient may experience discomfort, dizziness, or facial nerve stimulation when one or more of the electrodes are stimulated. When this occurs, the electrode is simply deactivated, which means it will not be used in the patient's program and will not cause discomfort. Additionally, the optimal number of electrodes differs for the various speech processing strategies. Thus, several of the electrodes along the array may be deactivated to use only the optimal number needed for a particular speech processing strategy. Lastly, an incomplete insertion of the electrode array may limit the number of electrodes that can be stimulated. Such incomplete insertions may occur with cochlear malformations or cochlear ossification.

The number of times patients return to their implant center for continued programming varies greatly and can be affected by factors such as the patient's psychophysical/programming needs, distance traveled to reach the implant facility, implant center protocols, and occupational demands. In many clinics, children are seen twice a month for the first

3 months, monthly for the next 3 months, and then every 6 to 12 months to program their speech processor. During such visits, warble tone thresholds should be obtained in a sound field while the patient utilizes the speech processor to verify the appropriateness of the patient's program. At many centers, speech perception testing is performed every 6 to 12 months.

Adult patients are typically seen twice a month the first month, and then 3, 6, and 12 months postactivation. Most patients are then seen annually for programming and speech perception testing. Such testing is valuable because it can be compared to previous speech perception test results to determine if performance has improved or declined. Decreases in scores are unusual and may indicate that the current program is not optimal for the patient or that there is a problem with the external equipment or the internal device.

(RE)HABILITATION

The goal of postoperative rehabilitation and training is to maximize oral communication (OC) skills with the device. The amount of rehabilitation provided to recipients varies greatly and will depend on several factors, including performance with the device, length of deafness prior to implantation, primary communication mode, and availability of services offered at school and by the implant program. With children, speech and language therapy is essential to maximize spoken language outcomes received with a CI.

Postlingually Deafened Adults

Most postlingually deafened adults have only mild rehabilitative needs following adequate adjustment of their device. Such rehabilitation primarily focuses on training in the proper care and use of the device, utilization of assistive listening devices with the CI, and training to maximize communication ability in difficult listening situations, such as listening in the presence of background noise and using the device on the telephone. Some adults enroll in classes to improve their speech-reading skills. Additionally, there are many computer-assisted programs and online aural rehabilitation resources that adults may use to improve their outcomes with the device.

Prelingually Deafened Adults

Prelingually deafened adults demonstrate greater rehabilitative needs than postlingually deafened adults. Because they tend to demonstrate a higher nonuse rate than postlingually deafened adults, it is recommended they receive preoperative counseling to ensure they have realistic expectations regarding performance and that they be seen more often than postlingually deafened adults for the first year following activation. Such visits provide an opportunity for

ongoing counseling regarding issues related to dissatisfaction with the device. Additionally, adjustments can be made to patients' programs to maximize the clarity of the signal they are receiving. This is often needed because prelingually deafened adults may demonstrate more frequent changes in their hearing ability than postlingually deafened adults. These changes often include increased consistency in their ability to detect sound, gradual increase in the upper level of the dynamic range (increased comfort or most comfortable levels), and an improved ability to do loudness balance scaling. Many prelingually deafened adults report that initial stimulation of their device results in a sensation of feeling, rather than hearing. This feeling may occur in the forehead, sternum, throat, or the area around the ear. Increased experience with sound, however, often facilitates a transformation from feeling to hearing.

There are several rehabilitative programs designed for use by both pre- and postlingually deafened adults. All three implant manufacturers offer computer programs for purchase that are aimed at improving the speech perception skills of adults and children. Thomas and Zwolan (2006) found that use of the Rosetta Stone language learning software (Fairfield Language Technologies, Harrisonburg, VA) fostered statistically significant improvements for speech intelligibility, auditory comprehension, and reading level for prelingually deafened adults when the program was used consistently at home for a period of 3 months. Home-based computer programs appear to be particularly beneficial for prelingually deafened adults because they are self-paced and provide the implant recipient with a nonthreatening learning partner.

Children

The (re)habilitative needs of children with CIs are great. This is an important part of the implant process that must be provided if the child is to receive maximum benefit from the device. Such (re)habilitation should include parent training and parental involvement; speech perception training and assessment; speech and language assessment and training that includes speech production and receptive and expressive language; and involvement of the child's teachers. In many instances, the child's school is the primary provider of (re)habilitative services. The audiologist and/or speech-language pathologist on the CI team may additionally work with the child on rehabilitative tasks and make recommendations to the child's school regarding (re)habilitative needs. In some cases, children attend private therapy in addition to that provided by their school system. For specific information regarding rehabilitation therapy techniques commonly used with children with CIs, the reader is referred to Allum (1996) and Estabrooks and Birkenshaw-Fleming (2006). Additionally, each CI manufacturer provides excellent resources for parents, educators, and hearing professionals regarding pediatric aural (re)habilitation and device troubleshooting.

Use of a Hearing Aid in the Contralateral Ear

CI recipients receive a variety of recommendations regarding use of a contralateral hearing aid with a CI. Such recommendations should be made on a case-by-case basis and take into consideration the amount of hearing in the non-implanted ear, appropriateness of the hearing aid for the patient's loss, the willingness of the recipient to continue using the contralateral aid, and the patient's early level of performance with the CI. Continued use of the aid following CI activation may be recommended by some clinicians, whereas others may recommend removal of the contralateral hearing aid as they feel it may increase the amount of time it takes to adjust to the sound quality of the implant. Some clinicians may recommend reintroduction of the aid once the recipient has accepted the sound quality of the CI. It is important to note that continued use of the device on the contralateral ear may foster bimodal benefit and may also positively impact the performance of that ear if it receives a sequential CI later on.

AN OVERVIEW OF CURRENT SPEECH PERCEPTION AND SPEECH AND LANGUAGE PERFORMANCE

Adults

Performance of adults with CIs is greatly affected by several factors, including age at onset of deafness, length of deafness, and primary communication method. Patients who lost their hearing prior to the development of speech and language skills (prelingually deafened adults) typically demonstrate poorer speech perception skills with an implant than postlingually deafened adults (Skinner et al., 1992; Waltzman and Cohen, 1999; Zwolan et al., 1996). Postimplant changes in speech recognition scores vary greatly for prelingually deafened adults. Some demonstrate progress, whereas others demonstrate little or no change in scores over time, even when combined with intensive rehabilitation (Yang et al., 2011). Because of these factors, prelingually deafened adults demonstrate a higher device nonuse rate than postlingually deafened adults. However, many prelingually deafened adults use their device regularly, report that they are satisfied with their device, and report that using the CI improves both their expressive and receptive communication skills (Zwolan et al., 1996).

The speech recognition performance currently obtained by postlingually deafened adults far exceeds that envisioned when CIs were first introduced as well as the results obtained by prelingually deafened adults. At minimum, most postlingually deafened adults demonstrate greatly enhanced lipreading skills when using their CI, and most hear so well that they

are able to converse interactively over the telephone. Results of the most recent multichannel clinical trial for the Nucleus Freedom device in adults indicate a mean group score of 57% correct for CNC words, a mean score of 78% correct for HINT sentences in quiet, and a mean score of 64% correct for HINT sentences in noise (Balkany et al., 2007).

Children

Several factors are known to impact children's performance with a CI, including age at onset of profound deafness, age at which the child receives the implant, status of the cochlea, amount of residual hearing prior to implantation, presence of additional disabilities, and the child's educational environment, to name a few. Recent publications indicate that many children who receive CIs at a young age approach levels of speech perception and speech–language performance similar to those attained by children with normal hearing (Eisenberg et al., 2006; Geers et al., 2003; Taitelbaum-Swead et al., 2005). Such outcomes far exceed those anticipated when CIs were first introduced.

AGE AT IMPLANT

Current FDA guidelines for the three commercially available devices indicate that it is appropriate to implant children as young as 12 months of age. There appear to be several arguments that support such an early age for implantation. First, providing an implant at an early age maximizes the amount of auditory information available to the child during the critical period for learning language (Cairns, 1986; Dale, 1976) and providing the child with sound decreases the length of auditory deprivation, which has a positive effect on the outcome (Young, 1994). Numerous investigators report that patients implanted at younger ages attain better speech perception scores and oral language capabilities than children implanted at older ages (Miyamoto et al., 2003; Waltzman et al., 2002). Recent research suggests that the optimal age for children to receive an implant is prior to their second birthday as children implanted prior to 2 years demonstrate significantly better expressive and receptive language skills than children who receive the device after their second birthday (Markman et al., 2011; Niparko et al., 2010). Even earlier implantation is supported by Houston et al. (2012), who found that after about 2 to 6 months of CI use, infants who received a CI at earlier ages (7 to 15 months of age) performed similar to infants with normal hearing on a preword learning task, whereas infants who received their implants at later ages (16 to 25 months of age) demonstrated poorer performance than their same-aged peers with normal hearing.

STATUS OF THE COCHLEA

Preoperative CT or MRI provides important information regarding the status of the cochlea and is used when

providing preoperative counseling to families regarding anticipated outcomes with a CI. Recipients who present with abnormal cochleae, such as those with congenital malformations or cochlear ossification, may experience reduced performance because of incomplete insertion of the electrode array, insufficient loudness growth, or deactivation of electrodes because of electrical stimulation of the facial nerve. However, patients who present with such anomalies are often considered to be candidates for a CI (Balkany et al., 1996; Tucci et al., 1995). El-Kashlan et al. (2003) found that, although prelingually deafened children with postmeningitic hearing loss and ossified cochleae received significant benefit from CIs, their mean overall performance was poorer than that of children with CIs and nonossified cochleae. Eisenman et al. (2001) found that some children with radiographic cochlear malformations performed as well as their matched counterparts with normal cochleae, although their improvements occurred more slowly over time and that children with more severe malformations demonstrated poorer performance than children with mild abnormalities or normal cochleae. CIs are contraindicated for patients with an absent auditory nerve whereas patients with a hypoplastic nerve may develop an ability to detect sound with a CI but often demonstrate reduced outcomes. Buchman et al. (2011) advocate for considering alternative forms of intervention, such as ABIs, when patients with severe anomalies fail to receive benefit from a CI.

ADDITIONAL DISABILITIES/DIAGNOSES

Some children may demonstrate disabilities secondary to their deafness that may affect performance with a CI. Non-cognitive disabilities, such as blindness and cerebral palsy, are not likely to impact the decision to implant or to impact the child's eventual performance with a CI. Cognitive disabilities, on the other hand, are likely to impact performance (Waltzman et al., 2000) and may affect the decision regarding candidacy. These conditions include children diagnosed with learning disabilities secondary to meningitis and children diagnosed with mental impairments such as autism (Donaldson et al., 2004). If a child with cognitive disabilities receives a CI, appropriate expectations must be set at home and at school regarding expected performance with the device.

Recently, there has been a large increase in the number of children with ANSD who receive CIs. Auditory neuropathy spectrum disorder (ANSD) is a term used to describe an auditory disorder characterized by recordable OAEs and/or cochlear microphonics, absent or atypical ABRs, and speech recognition skills that are poorer than would be expected based on the audiogram (Rapin and Gravel, 2003). Determination of candidacy for a CI in patients with AD can be difficult because such patients may meet candidacy criteria based on their poor speech recognition skills but may fail to

meet criteria based on their audiometric thresholds being better than current criteria indicate. Determination of CI candidacy for patients with AD is additionally complicated by the finding that some patients demonstrate improvement of detection and speech recognition skills over time without a CI (Neault, 2003) and that many children who present with AD also present with additional medical diagnoses that may affect expected performance outcomes (Rance et al., 1999).

Several investigators have reported that CI recipients with ANSD demonstrate postoperative outcomes that are similar to those obtained by more traditional CI recipients (Budenz et al., 2013; Slinger and Trautwein, 2002) and hypothesize that cochlear implantation is successful in such recipients because it provides a suprathreshold electrical stimulation to the auditory nerve, with the hope of reintroducing synchronous neural activity that cannot be achieved with acoustic stimulation (Mason et al., 2003). Because of the potential loss of residual hearing, determination of implant candidacy for a child with AD should be made carefully and should be determined on a case-by-case basis. One factor that should receive strong consideration is the child's spoken language skills, as the presence of a severe language delay demonstrates a need for intervention.

COMMUNICATION METHODOLOGY

When a child is identified with a hearing loss, parents must select a treatment plan that determines the child's primary method for communicating with others. These communication options include American Sign Language (ASL), simultaneous (total) communication (TC), oral communication (OC), and the auditory-verbal (AV) approach (see Chapter 44). Such options vary greatly in the amount of emphasis they place on the child's use of spoken language, and therefore, can affect outcomes with a CI.

Several investigators have compared the speech perception and speech and language skills of children with CIs who use these various methods of communication. Many recent studies report that children trained to use either AV or OC demonstrate more rapid gains in spoken communication abilities than children who use TC (Tobey et al., 2004). Geers et al. (2003) compared speech and language and speech perception measures of children who received a CI prior to the age of 2 and found that most children with average learning ability who used OC produced and understood the English language at a level comparable to that of their peers with normal hearing.

With regard to educational placement, there is good agreement that children will perform optimally with a CI if their school supports the child in his or her use of the device, offers aggressive auditory management and treatment, and provides an optimal auditory environment that promotes and encourages auditory development.

SURGICAL COMPLICATIONS AND DEVICE FAILURES

Occasionally, patients will experience failure of the internal device or surgical complications will occur that will necessitate surgical revision or replacement of the internal device. Possible reasons for such intervention include mechanical device failure, less than optimal electrode placement, skin flap complications, need for technologic upgrade, or intratemporal pathologic conditions (Donatelli et al., 2005). Mechanical failures of the internal device are often referred to as either “hard failures,” which are unequivocal device failures identified or verified by integrity testing performed by the device manufacturer, or “soft failures,” which occur when the implant recipient experiences discomfort or an unexplained decrease in clinical benefit, even though manufacturer-conducted integrity testing indicates the device is functioning within normal limits. The “hard” failure rates reported by clinics vary and range from a low of about 3% (Donatelli et al., 2005) to a high of 11% of all patients, and 15% of pediatric patients (Parisier et al., 1991). Fortunately, many studies have found that reimplantation following device failure is a viable option and that many CI recipients show improved or stable benefit following reimplantation (Buchman et al., 2011; Donatelli et al., 2005; Ray et al., 2004).

FUTURE DIRECTIONS

Future advances in the field of CIs are highly anticipated and expected. Some implant manufacturers are evaluating techniques for drug delivery to the cochlea via the electrode array. Such drugs could prevent further degeneration of the auditory system or may help keep electrode impedances and power requirements low by preventing tissue growth within the cochlea following implantation (Hochmair et al., 2006). Internal and external components of CI systems will continue to decrease in size whereas their design, flexibility, and function will continue to improve. Additionally, it is likely that completely implantable CI systems will be available in the future. Implant recipients will continue to demonstrate even greater speech recognition skills, enhanced music perception, and improved hearing enjoyment in quiet and in noise as new and improved speech processing strategies are developed.

FOOD FOR THOUGHT

1. Implant candidates are scanned to examine the integrity of the cochlea and to identify any structural abnormalities, including the presence or absence of ossification. What would cause ossification, and to what degree would it impact the decision to implant?
2. As mentioned earlier, cochlear implantation is conducted under general anesthesia. What concerns would the surgeon consider regarding the use of general anesthesia?

3. The FDA has approved CIs for children as young as 12 months of age. Many centers provide CIs to children who are younger than 12 months. What are the possible reasons for implanting sooner, and also, what are some advantages of implanting sooner than 12 months of age? What types of concerns might an audiologist have regarding provision of an implant to a child who is less than 12 months?

Intervention, Education, and Therapy for Children with Hearing Loss

Christine Yoshinaga-Itano and Kristin M. Uhler

INTRODUCTION

The role of the audiologist in the management of families of children who are deaf or hard of hearing (D/HH) has evolved markedly since the beginnings of newborn hearing screenings. The audiologist is often the first point of contact for families whose child does not pass a newborn hearing screening and is in a unique position to ensure their child's hearing health and also overall well-being. Audiologists counsel the family regarding the impact of hearing loss (HL*) on the child's development and, where appropriate, may raise the question of an additional disability from their observations, developmental screenings, or concerns voiced by parents. As children grow, audiologists continue to play a vital role in their patients' academic, social, and emotional development.

This chapter will begin with a review of the federal laws that define and support services to children with HL and their families. We will then consider current evidence-based practices in intervention, education, and therapy, some fundamental guidelines and principles and best practices for family-centered care, and quality indicators of educational services to school-aged students.

SPECIAL EDUCATION LAWS

Individuals with Disabilities Education Act

As described in Chapter 26, children with disabilities are protected by the Individuals with Disabilities Education Act (IDEA) (US Department of Education, 2006). "Hearing impairment" and "deafness" are categorized as disabilities under this law. The IDEA is divided into sections; for our purposes we will consider Parts B and C.

Part C provides early intervention for children with disabilities from birth to age 3. The following services are included under this section: (1) Home visits, family training,

and counseling; (2) special instruction; (3) audiology and speech pathology services; (4) sign language and cued language services; (5) vision services; (6) assistive technology, including hearing aids, and other services.

The law also requires the assignment of a **service coordinator**, who in most situations is the first contact. If the coordinator has limited background in HL, the audiologist can play a major role in educating him/her and the entire Part C system about the child's needs and development, including the urgency of aggressive intervention (Yoshinaga-Itano et al., 1998).

Part C requires that all services be described and monitored with an individualized family service plan (IFSP), which must be completed within 45 days after the referral of the child to EI services. The IFSP involves a comprehensive multidisciplinary evaluation (with at least two different disciplinary areas of expertise) as well as an identification of services needed. The IFSP is evaluated annually in the first 3 years of life and reviewed every 6 months if needed.

The evaluation must include the assessment of (1) cognitive development, (2) physical development (including vision and hearing), (3) communication development, (4) social-emotional development, and (5) adaptive development. It also includes a family-directed assessment of the family's resources, priorities, and concerns and identification of the supports needed by the family to meet their child's needs. Children with permanent bilateral HL are eligible for Part C services; however, each state determines specific eligibility criteria, so children with unilateral HL, children with minimal HL (mild, high frequency, low frequency, borderline), auditory neuropathy/dyssynchrony, and children with medically manageable HL may be excluded from eligibility. Audiologists should play a major role in defining eligibility for services if their state's Part C system does not include all children who are D/HH.

TRANSITION TO PART B SERVICES

When children reach age 3, they are re-evaluated to determine their eligibility for support in a preschool program. To

*In this chapter HL refers to hearing loss and not hearing level.

help plan ahead, families are notified of a transition planning conference no less than 90 days before the child's third birthday. Every state has different criteria for inclusion in Part B services for children who are D/HH (Johnson and Seaton, 2012).

Part B is applicable to children aged 3 to 21 and addresses the academic, developmental, and functional needs of the child. As described in Chapter 26, schools are required to provide an eligible child with a free appropriate public education in the least restrictive environment as described in the child's individualized education plan (IEP). The IEP is a document that describes learning goals and responsible service providers.

An important refinement of Part B includes several "special factors" provisions, including one tailored to D/HH students: "[i]n the case of a child who is deaf or hard of hearing, consider the child's language and communication needs, opportunities for direct communications with peers and professional personnel in the child's language and communication mode, academic level, and full range of needs, including opportunities for direct instruction in the child's language and communication mode." This requirement helps the IEP team address the unique communication and learning challenges experienced by children who are D/HH.

Section 504 of the Rehabilitation Act of 1973

Children who do not qualify for special education services under Part B of IDEA may qualify for services guaranteed by Section 504 of the Rehabilitation Act of 1973 (Johnson and Seaton, 2012). A 504 plan will provide the student with accommodations so that the child may access the information and content in the educational setting. The 504 plan may indicate that the child is in need of assistive technology such as FM devices, real-time captioning, sign language interpreters, and/or note-takers. Section 504 can be considered the educational equivalent of the Americans with Disabilities Act, and as such assures that the child who is D/HH has access to communication. However, because they are functioning at grade level, children under 504 plans do not receive any specialized educational instruction or special education direct services. See Chapter 26 for more discussion on 504 plans.

GUIDELINES AND BEST PRACTICES

In addition to federal laws, pediatric audiologic practices are informed by guidelines and descriptions of evidence-based best practice. The following section will review several materials developed to guide families and children through the educational "maze."

The Joint Commission on Infant Hearing (JCIH) Position Statement (2013)

Unlike other disabilities, EI services provided to infants/children who are D/HH and their families are designed to prevent delay in most of the children identified through universal newborn hearing screening (UNHS) programs. This distinction, which places children who are D/HH in a "risk prevention" category, is unique and in contrast to special education services that are initiated only when a significant delay is demonstrated. Therefore, it was necessary to delineate the characteristics of quality early intervention for infants/children who are D/HH and their families. The JCIH responded to this need. The JCIH has representatives from the fields of audiology, pediatrics, education, otolaryngology, and speech-language development. In 2013, the JCIH updated its 2007 position statement with the following 12 goals:

- Goal 1. All children who are deaf or hard of hearing (D/HH) and their families have access to timely and coordinated entry into EI programs supported by a data management system capable of tracking families and children from confirmation of HL to enrollment into EI services.
- Goal 2. All children who are D/HH and their families experience timely access to service coordinators who have specialized knowledge and skills related to working with individuals who are D/HH.
- Goal 3. All children who are D/HH from birth to 3 years of age and their families have EI providers who have the professional qualifications and core knowledge and skills to optimize the child's development and child/family well-being.
 - Goal 3a. Intervention services to teach American Sign Language (ASL) will be provided by professionals who have native or fluent skills and are trained to teach parents/families and young children.
 - Goal 3b. Intervention services to develop listening and spoken language will be provided by professionals who have specialized skills and knowledge.
- Goal 4. All children who are D/HH with additional disabilities and their families have access to specialists who have the professional qualifications and specialized knowledge and skills to support and promote optimal developmental outcomes.
- Goal 5. All children who are D/HH and their families from culturally diverse backgrounds and/or from non-English-speaking homes have access to culturally competent services with provision of the same quality and quantity of information given to families from the majority culture.
- Goal 6. All children who are D/HH should have their progress monitored every 6 months from birth to 36 months of age, through a protocol that includes the use of standardized, norm-referenced developmental evaluations,

for language (spoken and/or signed); the modality of communication (auditory, visual, and/or augmentative); social-emotional and cognitive issues; and fine and gross motor skills.

- Goal 7. All children who are identified with HL of any degree, including those with unilateral or slight HL, those with auditory neural HL (auditory neuropathy), and those with progressive or fluctuating HL, receive appropriate monitoring and immediate follow-up intervention services where appropriate.
- Goal 8. Families will be active participants in the development and implementation of EHDI systems at the state/territory and local levels.
- Goal 9. All families will have access to other families who have children who are D/HH and who are appropriately trained to provide culturally and linguistically sensitive support, mentorship, and guidance.
- Goal 10. Individuals who are D/HH will be active participants in the development and implementation of EHDI systems at the national, state/territory, and local levels. Their participation will be an expected and integral component of the EHDI systems.
- Goal 11. All children who are D/HH and their families have access to support, mentorship, and guidance from individuals who are D/HH.
- Goal 12. As best practices are increasingly identified and implemented, all children who are D/HH and their families will be assured of fidelity in the implementation of the intervention they receive.

These goals will serve as foundations for discussions on “continuous improvement” among pediatric practitioners for years to come.

Best Practices for Family-Centered Early Intervention

A second document identifies a set of best practices in the area of early intervention for families and their children (Moeller et al., 2013). This document was developed by EI providers and parents from a number of countries at an international conference. Readers are encouraged to obtain this article, which includes topics not addressed in the JCIH document, including informed choice and decision-making, family/provider partnerships, family social and emotional support, family/infant interaction, use of assistive technology and supporting means of communication, and collaborative teamwork.

Quality Standards for Educational Services for School-Aged Children Who Are D/HH

An example of quality standards for provision of educational services for children who are D/HH is the *Colorado*

Quality Standards for Programs and Services for Children who are Deaf or Hard of Hearing document. Examples of programmatic quality standards include these:

- programs will provide a clear statement of purpose, including outcomes for expected learning, communication competency, and social/emotional well-being, and
- programs will provide training to general education personnel regarding accommodations, modifications of the curriculum, and understanding of the impact of HL on development and learning.

Predeveloped standards such as these help programs know what “quality” looks like.

Deaf Child’s Bill of Rights

The Deaf Child’s Bill of Rights has been adopted by a growing number of states and includes some additional IEP considerations for children who are D/HH. The Deaf Child’s Bill of Rights includes using a communication plan for children who are in general education. Rights include the following:

1. The IEP team cannot deny instructional opportunity based on the amount of the child’s residual hearing, the ability of the parent(s) to communicate, or the child’s experience with other communication modes. When discussing these issues, the following questions may be helpful to clarify the child’s needs: When considering the child’s primary communication mode, is there just one? Does the child use a combination of modes? What mode do the parents use with their child? What mode does the child use to communicate with his/her friends?
2. The plan must include a statement documenting that an explanation was given of all educational options provided by the school district and available to the child. When considering all educational options, are the options available in the school district?
3. The plan must include a statement documenting that the IEP team, in addressing the child’s needs, considered the availability of D/HH role models and a D/HH peer group of the child’s communication mode or language. Because of the low incidence of a hearing disability, many students who are D/HH find themselves without contact with other children with HL. Additionally, 95% of these children are born into families with normal hearing (NH), which can further increase isolation. Questions to ask: Is there an opportunity to hold weekly “chats” online with other D/HH kids? Does the family know about regional activities designed for D/HH children? Explore all known opportunities.
4. The plan must include a statement that the teachers, interpreters, and other specialists delivering the communication plan to the student must have demonstrated proficiency in, and be able to accommodate for, the child’s primary communication mode or language. Discuss the

communication proficiency of the child/student's service providers and write a statement of the needs of the staff. Is training/in-service/mentoring a possibility? Is there an accommodation not being utilized?

5. The Plan must include a statement of the communication-accessible academic instruction, school services, and extracurricular activities that the student will receive. These questions may help to clarify the student's needs: Is the student enjoying full access to academic instruction and services? To extracurricular activities? Audiologists should pay special attention to the IEP checklist for Recommended Accommodations and Modifications. Are TTY's, captioned television, interpreters for field trips, and so on being utilized?

More information on the Deaf Child's Bill of Rights can be found at this website: <http://www.nad.org/issues/education/k-12/bill-of-rights>.

Colorado Individual Performance Profile

The Colorado Individual Performance Profile (CIPP) was developed as a tool for the IEP placement process. Use of the CIPP assures that there is uniform decision-making across the state for placement decisions into a specific type of educational setting. Without a placement tool such as the CIPP, there is no guarantee that decisions for placement are evidence based or that children who are D/HH will receive appropriate services (Yoshinaga and Ruberry, 1992).

The CIPP sets child performance criteria for placement in one of six possible educational settings:

1. Indirect services via monitoring only (typically 504 plans);
2. Indirect services via consultation with the teacher of the mainstream classroom requiring an IEP;
3. Direct services: More than 60% of the time in the mainstream classroom with 1 to 4 hours per week of specialized instruction from a teacher of the deaf or other special education provider;
4. Direct services: 21% to 60% of the time in the mainstream classroom with 1 to 2 hours of daily specialized instruction;
5. Direct services: Less than 20% of the time in the mainstream classroom with 3 to 4 hours of daily specialized instruction; and
6. Direct services in a separate facility.

Students are assessed in Reading, Language, Math, Social Skills, and Cognitive Skills on assessments that are norm referenced so that children who are D/HH can be compared to their peers with NH. Further information about the CIPP can be found on the Colorado Department of Education website: <http://cospl.coalition.org/fedora/repository/co:2157/ed14408d342002internet.pdf>

Placement and Readiness Checklists

Audiologists who participate in IEP meetings may also find the Placement and Readiness Checklists (PARC) helpful (http://www.handsandvoices.org/pdf/PARC_2011.pdf). The PARC are designed to assist in the IEP process.

There are two parts to the PARC. Part 1 addresses essential skills needed by the student to actively and meaningfully participate in the general education classroom. It includes four checklists: General Education Inclusion Readiness, Interpreted/Transliterated Education Readiness, Captioning/Transcribing Readiness, and Instructional Communication Access. These checklists can be used in combination or independently, depending on the student and the purpose of the review.

Inclusion in the general education classroom is evaluated through the General Education Inclusion Readiness Checklist. Identification of skills needed to benefit from services in the general education classroom is evaluated through the Interpreted/Transliterated Education and the Captioning/Transcribing Readiness checklists. Analysis of how a student accesses instruction is evaluated through the Instructional Communication Access Checklist. The Readiness checklists can also be used to identify IEP goals that will assist a student with acquisition of the necessary skills as well as a tool to monitor the acquisition of the desired skills.

Part 2 is the Placement Checklist, which evaluates the accessibility and appropriateness of the general education setting, including the physical environment, the general learning environment, the instructional style of the teacher, the school culture, and how well the learning environment is matched to the student's communication, language, and social needs. The Placement Checklist can be used as often as the classroom environment changes or other needs suggest monitoring.

SUPPORTING FAMILIES

Of course, we must always keep in mind that audiologic services are provided to each child within the context of the family. A child's learning success is strongly correlated to family support, and family support is enhanced when the audiologist takes every opportunity to "stay in step" with the family during its journey. Following are important considerations to include in the audiologic care.

Setting the Stage for Healthy Development

Counseling strategies are critically important for diagnostic audiologists. As bearers of difficult news, our skill in delivering the information and supporting parents through their emotional adjustment to the confirmation that their infant/child is D/HH is of utmost importance (English et al.,

2007). Emotional anxiety can be reduced if the family receives information in a timely manner and when the early intervention support provided is immediate, skilled, and knowledgeable about early childhood deafness (JCIH, 2013). A multilayered system of support should include the audiologist, educators, speech-pathologists, pediatricians, other parents, and D/HH professionals.

BONDING AND CELEBRATION OF THE NEW FAMILY MEMBER

The most important job of the first contact is to refocus families on the special time of getting to know their newborn. Bonding of mothers to babies is an important factor in the rate of language development (Pressman et al., 1999), and audiologists should actively inquire about the child's overall development. For example, what is the baby's personality? What seems to calm or upset the baby? Has the baby had his/her first smile? Does the baby smile back when the mother/father smiles at him/her? Does the baby seem to be visually alert? What have they learned about this new member of their family? Are they recording important developmental progress through diaries and pictures? Does the baby initiate interaction with parents, siblings, or pets? How does the baby react if someone is sad or angry? Does the baby react to facial expressions and to tone of voice?

We do not want families to miss the amazing development that takes place in the first year of life. It is important for parents to be emotionally available to their child and to observe whether their babies are emotionally available to them. We are trying to teach parents to observe and know their babies. This will help when we begin to ask them to observe responses to auditory stimuli, especially their voices.

Immediately after the birth, some mothers suffer from postpartum depression (Hoffman and Drotar, 1991). Audiologists and EI providers need to know the boundary between grieving as a direct result of the diagnosis of deafness or HL and more severe clinical depression that requires referral to mental health professionals.

REDUCING AND PREVENTING STRESS

Parental stress levels are strongly associated with language development of children who are D/HH (Hintermair, 2007; Pipp-Siegel et al., 2001). Parents report lower stress levels when they are provided with immediate support after the confirmation of HL and have the opportunity to explore their opportunities and options. The important message for the parents is that babies react to their emotions. The more they take care of themselves, the happier their baby will be, and the less parental stress, the faster the language development (Pipp-Siegel et al., 2001). With appropriate EI services, parents are usually able to deal with stress without requiring

support from mental health professionals, and in fact tend to cope as well as parents with typically developing children do, even as they contend with multiple appointments, hearing aids, new information, and weekly EI services. It is also important to remember that stress does not disappear as a child grows up—it just changes. Each new stage of a child's life (first day of school, first sport try-out, first driving lesson, first summer job) can bring a new type of stress to the family. Audiologists will want to heed warning signs and have a referral process at hand if it appears parents are struggling more than expected.

Counseling Strategies

Audiologists need to learn a variety of counseling strategies. Delivering information in a manner that is the most effective for diverse populations is an important skill. Hersey and Blanchard's (1993) model can be adapted to provide a framework for an audiologist's understanding of the family's skill/resources and readiness/motivation to participate in audiology or intervention services. The model identifies four different styles of counseling: (1) Telling, (2) selling, (3) collaborating/participating, and (4) delegating.

TELLING

Families with the lowest levels of involvement and readiness may respond best to directive counseling approaches. In this approach, the professional provides the family with information about "what to do next." The goal of this type of counseling is to assist and support the families' development from one style of counseling to one that provides the family with more responsibility for decision-making. Cultural differences may also impact the choice of counseling techniques. In cultures where families have the expectation that professionals know best about what to do, they may expect to be told what to do next. In fact, they may interpret the presentation of a number of options as indication that the professional is not knowledgeable or skilled (Jezewski and Sotnik, 2001). As families become more acculturated, learn and adapt to the culture of the country in which they now live, they may respond very differently to other types of counseling styles.

SELLING

For families with higher levels of knowledge/involvement but lower levels of readiness/motivation, the counseling approach that may be most beneficial is one that provides the family with the motivation to pursue a specific plan of action, such as keeping hearing aids on the child or learning sign language. If the parents feel convinced that the child is more responsive when wearing the hearing aids or by learning sign language, their motivation to follow-through may be significantly enhanced.

COLLABORATING/PARTICIPATING

For families with higher levels of readiness and lower levels of knowledge/involvement, the family may respond best to collaborative counseling. In these situations, the family does not need encouragement for motivation, but it does need more information and support from the audiologist.

DELEGATING

For families that are at the highest levels of knowledge/involvement and readiness/motivation, the counseling strategy that may be most effective is one that provides the families with the information about resources and delegates them to proceed, checking back when they need additional information or direction.

The same model can also be useful for counseling children as they grow. They too have different levels of knowledge/involvement and readiness/motivation and these levels can change with age. For example, the counseling approach that worked best when the child was younger, highly motivated, and very knowledgeable may cease to be the approach of choice when the child is older, for example, social situations change, and the child is no longer convinced that wearing the hearing aid is beneficial/necessary or is important enough to overcome perceived social judgment and negative social circumstances. Arming the child with the information necessary may require a “selling” or “collaborating” technique.

When Families Choose a Goal for Visual Communication

Because an audiologist is a specialist in hearing, when a family chooses a goal for communicating through visual and/or tactile-kinesthetic communication, the audiologist should refer the family to the appropriate specialist with expertise in early childhood deafness and HL. These professionals may include educators of the deaf, speech-language pathologists (with training in both visual communication and auditory spoken language), and/or professionals who are fluent in sign language. Today, families may choose combinations of different communication modes and methods and the audiologist should work in partnership with these professionals.

A significant proportion of children who are D/HH rely on visual communication support even when their primary language access is through auditory spoken language. Auditory access to spoken language can be compromised by suboptimal auditory learning environments (e.g., noisy classrooms, noisy public environments such as supermarkets or parks), breakdowns in technology (e.g., batteries, cords), distance and low intensity of the speech of the conversational partner, structural abnormalities in the sensory system, and/or auditory perceptual disorders. Visual com-

munication support may include adequate lighting, speech reading, natural body language and facial expressions, avoidance of visual noise/clutter, real-time captioning for older children, sign language, and cued speech.

American Sign Language (ASL) is an indigenous sign language of the United States. ASL, like all other languages has its own syntax, grammar, phonology, semantics, and pragmatics. ASL is not a communication approach; it is a language like English, Spanish, Mandarin, or Arabic.

There are two communication approaches that involve ASL. One is the **Bi-Bi (Bilingual-Bicultural)** approach, which refers to communication between people with ASL and written English. A related approach is called **bimodal-bilingualism**. This communication approach involves the use of spoken English and ASL.

Simultaneous communication is a communication approach often mistakenly referred to as total communication. Total communication uses many methods (ASL, spoken English, audition, gestures, fingerspelling, writing) separately or in combinations, in no particular order but as needed to communicate successfully. Simultaneous communication is an approach in which parents and teachers consistently speak and sign simultaneously.

Manually coded English is similar to simultaneous communication. It employs spoken English accompanied by sign language in English word order and often with the use of signs that designate English morphology, such as word endings like /s/, /ed/, /ing/. *Signed English*, *Seeing Exact English (SEE 1)*, *Seeing Essential English (SEE 2)*, or *Linguistics of Visual English (LOVE)* are specific sign systems used in a simultaneous communication approach. They were developed in the 1970s when the use of sign language was first used in public programs for educating children who were D/HH. Signed English is the closest to ASL because it consists of ASL vocabulary and signs in English word order.

Cued Speech is a cueing system that can be used simultaneously with spoken English. The cues have the advantage of being learned rapidly, often in a few days, and are designed to provide visual hand cues to receiver that facilitate the use of speechreading cues. Since only 40% of the phonemes of English are visible on the lips/face, these hand cues assist the listener in separating “visemes” (sounds that look similar on the lips from one another, for example, /b/ and /p/). The hand cues are only related to specific speech sounds; they are not signs having linguistic intent and do not use gestural representations of the meanings of words in the way that a true sign system does.

Today’s choices for parents who are hearing include learning strategies for listening and spoken language development, learning one or more visual communication approaches, or learning “all of the above.” In some rare cases, it is possible that a child who is D/HH cannot access spoken language, such as a child who is born without an auditory nerve or cochlea, or a child with a severe auditory processing disorder. In these cases, the children may communicate

solely through visual communication, although children with severe auditory processing difficulties may benefit from wearing amplification. However, services are typically initiated before professionals know that a child who is D/HH cannot access spoken language effectively.

Parents who are D/HH and use ASL as their primary communication must consider whether or not they would like their child to also access spoken language through the use of amplification technology and educational services that focus on listening and spoken language.

When Families Choose a Goal for Spoken Language

Most parents who are hearing choose a goal of developing listening and spoken language skills for their child. There are two approaches toward this goal:

Auditory verbal communication uses a unisensory (auditory only) approach. To promote listening, therapists and families often use their hand or a screen to cover their mouths and eliminate visual cues while children focus on the input and their own speech production. In normal conversation, however, infants and toddlers tend to learn listening and spoken language naturally, with creative efforts to highlight sounds and auditory attention (e.g., “I Hear with My Little Ear”).

With later-identified children, the auditory verbal approach usually involves a significant amount of drill and practice for the child to master auditory skills. With appropriate learning objectives, children who are D/HH have been able to rapidly develop skills, often with very few examples. When children become dominant auditory spoken language users, they do not rely on speechreading skills and, just as with children who have NH, they do not stare at their communication partner’s face to access and understand the spoken language communication. However, this attention to the face may naturally occur in noisy environments, just as it would for children with NH.

In contrast, the **auditory oral** communication approach uses a dual-sensory access to spoken English through both auditory spoken language and speechreading cues. Historically, children and parents learned both auditory stimulation and speechreading skills. However, speechreading lessons are not common today in the instruction of children who are D/HH.

ASSURING OPTIMAL AMPLIFICATION

When families chose spoken language, the audiologist becomes responsible for timely and appropriate fitting of amplification. Additionally, children must not only have technology capable of accessing spoken language, but must also have access to abundant verbal input in their environment. Children learn language by being exposed to language, and families can be shown how to increase that exposure.

The American Academy of Audiology (2013) has developed evidence-based guidelines with prescriptive formulae to fit children with hearing aids. The guidelines recommend using either National Acoustics Laboratory (NAL) or Desired Sensation Level (DSL) prescriptions for infants. Each of these formulae calculates the speech intelligibility index (SII) for varying input levels (soft, medium, and loud), taking into account the child’s specific HL and stimulus chosen by the audiologist. The SII is a measure used to quantify audibility of the speech signal (ANSI, 2012) and is described in depth in Chapter 40.

HELPING PARENTS AND TEACHERS WITH HEARING AID MANAGEMENT

Parents and teachers have much to learn about maintaining their child’s hearing aids and cochlear implants. They need to know how to conduct a daily listening check of their child’s hearing aids and be able to determine if the device is providing the desired input. Parents should be given a kit with materials such as a hearing aid air blower, listening stethoscope, battery tester, retention devices (clips and cords), dehumidifier kits, stickers, and information on loss prevention, moisture protection, and “child proofing.” Hearing instrumentation orientation should include care of hearing aids and troubleshooting (see Chapter 39). There is much to remember about batteries, including battery life, storage, disposal, insertion, removal, and overnight storage. Information on coupling to assistive devices and telephones is needed. The website Equal Voice for Deaf Children Lesson 104 has a demonstration of troubleshooting instructions for hearing aids and cochlear implants (<http://evdcweb.org/level100/lesson104/lesson104.html>). For instructions related to specific implants, see Chapter 43.

All children using amplification technology should have their technology checked on a daily basis. The IFSP/IEP team should designate the professional most knowledgeable and available to conduct the daily amplification checks. Children should be taught as early as the preschool years to manage their own amplification and to report when their devices are not working. Without routine monitoring, up to 50% of the amplification used by children today in educational settings are likely to function inappropriately (Burkhalter et al., 2011).

ASSESSING THE CHILD’S USE OF TECHNOLOGY

No matter how appropriately the child’s amplification is fit, unless the child wears the amplification, the benefit of the amplification will be compromised. Two coordinated tools have been designed to capture parent and teacher input regarding use of amplification. The Parents’ Evaluation of Aural/Oral Performance of Children (PEACH) and the Teachers’ Evaluation of Aural/Oral Performance of Children (TEACH) are designed for children 3 to 7 years of age

(Ching et al., 2000). The PEACH and TEACH tools consist of an interview with parent or teacher with 15 questions targeting the child's everyday environment. The PEACH/TEACH include scoring for five subscales (Use, Quiet, Noise, Telephone, Environment).

Additionally, a data tracking feature is often available on pediatric hearing aids. Parents should be informed that the hearing aids have a data tracking system and that the audiologist can monitor amplification use. Parents can also be asked how many hours per day that the child wears his/her amplification. If the child is not using amplification often, the first question we should ask is if parents perceived little or no difference in the child when wearing or not wearing the amplification. Could the amplification be "underfit" and result in plugging the child's ears? Is there a way that the audiologist can demonstrate to the family what the child can do with amplification as compared to limitations when they do not wear the amplification?

ASSESSING CHILDREN'S PROGRESS

Auditory Skill Development

In addition to knowledge about the technical aspects of amplification, the audiologist is the expert about auditory skill development. The audiologist assesses auditory skills for several purposes: (1) To assure appropriateness of the amplification for detection and discrimination, (2) to monitor the child's progress in auditory skill development, and (3) to design appropriate habilitative techniques for the development of auditory skills sufficient for the acquisition of listening and spoken language. Auditory skills assessments that can determine the child's development in Detection, Discrimination, Identification, and Comprehension can provide valuable information for the audiologist (Erber, 1982):

Detection: Can the child detect that a stimulus is present?

Discrimination: Can the child detect differences or similarities between stimuli?

Identification: Can the child apply labels to the auditory stimuli that he/she discriminates?

Comprehension: Can the child understand the meaning of spoken stimuli?

A more complex hierarchy of auditory skills development is delineated in the Functional Auditory Performance Indicators (FAPI) discussed later in this chapter.

As soon as amplification is fit, parents should be taught how to be watchful observers of their child's responses to sound. Parents should be encouraged to observe how their child/student responds to the Ling speech sounds (ah, ee, oo, s, sh, m) (Yoshinaga-Itano and Sedey, 2000) and to report back to the audiologists if their child does not respond to these speech sounds (indicating specific frequencies). This

informal listening check should be done frequently so if a change in response is noted, adjustments/repairs to amplification can be made quickly. If the amplification is still functional, the listening check might indicate a change in the child's hearing—an important consideration because the percentage of children with progressive HL increases with age (Berrittini et al., 1999). Teachers should also be taught how to do Ling sound checks on a daily basis whether or not the child is educated predominantly in special education services or in the regular classroom.

The measurement of auditory skill development in early childhood is a challenge. A number of observational checklists have been developed for the young child who is D/HH; unfortunately, almost all of these checklists lack any normative data on children with NH. However, since the goal of audiologic intervention is to keep children who are D/HH as comparable to their peers with NH as possible, it is very important to evaluate the children's auditory skills as compared to children with NH.

LITTLEREARS

One parent questionnaire with normative data is the LittleEars Parent Interview (Kühn-Inacker et al., 2003), which is intended for children birth through 24 months. LittleEars consists of 35 questions. The first 18 items deal with auditory awareness, auditory attention, auditory localization, simple discrimination such as recognizing speech on the telephone, and recognizing emotion. The remaining 17 items address speech imitation and language comprehension, such as following commands, understanding simple and complex commands, and knowing family member names, such as Mommy and Daddy. The questionnaire was standardized on 218 NH children aged 0 to 24 months. LittleEars is designed for children with profound HL who are candidates for cochlear implants and for monitoring auditory skill development after implantation.

THE CINCINNATI AUDITORY SKILLS CHECKLIST

This checklist (Meinzen-Derr et al., 2007) includes a number of items on a hierarchy of auditory skills. It provides a more comprehensive overview of the child's auditory skill development and can be used to document progress. The Cincinnati Auditory Skills Checklist (ASC) has 35 items divided into four auditory levels: (1) Detection, (2) Discrimination, (3) Identification, and (4) Comprehension. This checklist was designed for monitoring the auditory skill development of children with all degrees of HL.

FUNCTIONAL AUDITORY PERFORMANCE INVENTORY (FAPI)

The FAPI is a criterion reference checklist and does not have norms for children with NH or children who are

D/HH. It is intended to monitor progress throughout intervention (Johnson and Brown, 2004). The FAPI can provide assistance to parents as they observe their child's auditory skill development on a regular basis. It addresses functional auditory skills in seven categories: (1) Awareness & Meaning of Sound, (2) Auditory Feedback and Integration, (3) Localizing Sound Source, (4) Auditory Discrimination, (5) Auditory Comprehension, (6) Short-Term Auditory Memory, and (7) Linguistic Auditory Processing. It provides a hierarchy of developmental skills and addresses differences in distance and listening conditions and uses a formula to help the therapist or educator define each skill as "not present," "emerging," "in process," or "acquired."

EARLY LISTENING FUNCTION (ELF)

The ELF (Anderson, 2000), for children age 5 months to 3 years, is not an assessment per se, but rather a validation and "discovery" tool, designed to help parents learn what their child can and cannot hear, with and without hearing aids, when speech and environmental sounds are affected by distance and noise. The ELF helps parents understand the impact of a disability they cannot see and helps them understand the conditions that yield consistent auditory responses from their child. The ELF has 12 listening situations in which the parent observes the child and records the distance the child responds to the auditory stimuli. The 12 activities are conducted in quiet and noisy situations, near the child and also farther away (6 inches, 3, 6, 10, and 15+ feet). Loudness calibration is not essential, but parent participation in typical environments is critical. Parents administer the ELF at home and then share their observations with the audiologist, who can monitor development over time. Anderson (2000) hypothesizes that the ELF may be beneficial to family engagement and empowerment. During ELF listening activities, parents are encouraged to envision the size of the child's "listening bubble," meaning the space around the child where audibility is optimal.

Beyond the early childhood period, audiologists may use standard pediatric speech discrimination tests to monitor a child's auditory discrimination ability in quiet and in noise, as described in Chapter 24.

ANALYZING THE AUDITORY SPOKEN LANGUAGE ENVIRONMENT

Even if technology is fit correctly, children cannot learn to listen and use spoken language at age-appropriate levels unless they are exposed to spoken language. Research indicates this exposure should far exceed the usual input available to children with NH (Aragon and Yoshinaga-Itano, 2012). Technology is now available that is capable of characterizing the auditory/language environments of children who are D/HH. The LENA (Language Environment Analysis) is a small digital language processing recorder, about the size of a credit card carried in a pocket that can capture 10 to

16 hours of the daily auditory environment of the child (see www.lenababy.com). With this technology, parents/families are able to count the number of words spoken to their child in an average day, the number of conversational turns, and the number of child vocalizations. When the recordings are analyzed, the family and therapists receive specific information about the amount of adult spoken language available to the child, the frequency and quality of the child's vocalizations, the amount of silence in a day, and the percentage of the day spent in general noise, TV/radio, meaningful speech (within an audible range), and distant and overlapping speech. Audiologists and parents may be surprised to find that some children spend more than 60% of their day in silence, or 40% of their day amidst TV and radio noise, or that the home environment includes noise that is not under the control of the parent (appliances or outside noise). With this information, families become aware that their goal for their children to learn spoken language will be compromised unless the auditory characteristics of the learning and listening environment are modified.

The LENA instrument provides a mechanism for quantifying the daily spoken language environment or the daily "auditory diet" of the child. Aragon and Yoshinaga-Itano (2012) provided information about the language environment of children who had NH and children who were D/HH in both English- and Spanish-speaking homes. Results indicated that some children who are D/HH spend a high percentage of the day in silence (66% as compared to a mean of 28% for children with NH), in noise (20% as compared to a mean of 3% for children with NH), and with TV/radio playing (33% as compared to a mean of 10% for children with NH). These results prompted the early interventionists and audiologists to investigate the causes of these high percentages. In some cases, the noise levels were not under the control of the family; for example, noise from an old refrigerator or from a nearby river could not be reduced. In some cases, the amount of distant/overlapping language was high and the amount of meaningful language low. Parents were encouraged to read to their child several times a day as a natural way to increase their "word count."

As depicted in Figures 44.1, 44.2 and 44.3, the typical child with NH (in English- and Spanish-speaking homes) has access to an average of approximately 12,000 words a day, has approximately 474 conversational turns, and makes about 2,000 vocalizations. To elicit child vocalizations and conversational turns comparable to hearing children, the child who is D/HH needed to be exposed to an average of 17,000 to 18,000 words per day (Aragon and Yoshinaga-Itano, 2012). Many factors may contribute to this difference, as children who are D/HH are not always wearing their amplification, their amplification is not functioning properly, or the signal to noise ratio may adversely affect the quantity of their vocalizations and their conversational turn-taking.

To date, studies using the LENA system have primarily focused on infants, toddlers, and preschool children.

FIGURE 44.1 Adult word count for four groups: D/HH Spanish, typically developing Spanish, D/HH English, and typically developing English [Aragon and Yoshinago-Itano, 2012]. [Reprinted with permission from Thieme Publishers.]

Additionally, older children’s auditory spoken language environment can be measured with the Functional Listening Evaluation (FLE) (Johnson and Seaton, 2012), which assesses children’s auditory abilities within the classroom environment. With the FLE, students are presented words and sentences at close and far distances, in quiet and in noise, to determine their abilities in each condition, as described in Chapter 26.

Vocal/Speech Development

Audiologists typically do not monitor vocal development, but they may be trained to monitor the relationship

FIGURE 44.2 Conversational turns of four groups: Spanish D/HH, typically developing Spanish, typically developing English, and English D/HH [Aragon and Yoshinago-Itano, 2012]. [Reprinted with permission from Thieme Publishers.]

FIGURE 44.3 Percentage of items on Pragmatics Checklist mastered by age and hearing status [Goberis et al., 2012]. [Reprinted with permission from Thieme Publishers.]

between auditory skill development and vocal production. Following are some tools used by other professionals for this purpose.

ASSESSING SPEECH PRODUCTION

Speech-language pathologists often use the Conditioned Assessment of Speech Production (CASP) (Ertmer and Stoel-Gammon, 2008) to assess the speech production of a child who is D/HH. The CASP has three levels of assessment: (1) Pre-canonical Vocalizations (vowels with no consonants); (2) Basic Canonical Syllables (consonant–vowel productions); and (3) Advanced Forms (multisyllabic utterances with multiple consonants). The CASP is a clinically practical and developmentally appropriate tool for auditory-guided speech development in very young children who are D/HH. It provides a quick measure of progress over time of the vocal development for an infant population, an age group for whom vocal production assessment has been absent, and for assessments post-cochlear implantation from 6 to 24 months. The CASP is empirically tested and an objective measure of prelinguistic gains in speech perception and production.

ASSESSING VOCAL PRODUCTION

The Infant Monitor of Vocal Production (IMP) (Moore, 2010) is a parent interview designed for use in the first year of life. This assessment examines three important transitions in vocal production: (1) Reflexive vocal production that does not require an auditory feedback loop (4 to 6 months of age), (2) vocal production that mimics the suprasegmental and some segmental elements of the native spoken language at about 6 to 7 months of age, and (3) the transition from vocalizations to word production (from 10 to 12 months of age). The IMP has been especially useful

in cochlear implant candidacy considerations for children with auditory neuropathy/dyssynchrony. Collection of normative data is in process at the time of this writing.

ASSESSING PHONEME DEVELOPMENT

Recently, Wiggin et al. (2013) described the emergence of correct production of English phonemes by degree of HL and age and found that, in general, the phoneme development of early-identified children who are D/HH followed the order of development of children with NH with some delays. Children with mild HL produce approximately 20 different consonant types by age 2.5 years, comparable to children with NH. However, as the degree of HL increases, so does the delay in development: Children with moderate HL reach this level by 3 years of age, and children with severe HL reach this level of consonant production by 5 years of age. Children with profound HL who do not have a cochlear implant do not typically develop intelligible speech by 5 years.

MEASURING SPEECH INTELLIGIBILITY

When children have NH, their parents and others report being able to understand about 25% to 50% of their speech at 15 months of age (Yoshinaga-Itano and Sedey, 2000). By 21 months, parents usually understand almost all of what children say with careful listening, and by 27 months almost all of children are rated as intelligible with little or no effort. Not surprisingly, HL impacts articulation development, and speech intelligibility is affected by the degree of HL. Even children with mild bilateral HL, identified early and receiving weekly EI services have delays in their speech intelligibility to 5 years of age.

A frequently used tool is the Speech Intelligibility Rating Scale (SIRS) (Semar and Metz, 1988), which rates intelligibility on a 6-point scale:

- 1 = I always or almost always understand the child's speech with little or no effort.
- 2 = I always or almost always understand the child's speech; however, I need to listen carefully.
- 3 = I typically understand about half of the child's speech.
- 4 = I typically understand 25% of the child's speech.
- 5 = The child's speech is very hard to understand. I typically understand only occasional, isolated words and/or phrases.
- 6 = I never or almost never understand the child's speech.

Yoshinaga-Itano and Sedey (2000) found that when parents, early interventionists, and independent coders used the SIRS to rate speech intelligibility, their ratings were quite consistent. They also reported learning from using the SIRS over time that children with mild and moderate HL had a more rapid growth rate in intelligibility than children with moderate, moderate-severe, severe, or profound HL.

ASSESSING ARTICULATION

The *Goldman Fristoe Test of Articulation-2 (GFTA-2)* (Goldman and Fristoe, 2000) is a standardized test of articulation that uses picture cards to elicit words. It is commonly used to assess children who are D/HH. Early-identified children have made significant gains in their speech development, but still have some lingering articulation errors. Because many of these children have very intelligible speech, many of them do not receive intervention services in articulation. However, even at 7 years of age, children who are D/HH have articulation errors that may not interfere with intelligibility but are not a correct production of the phoneme in all positions in words. On the GFTA-2, 42% of children who are D/HH have demonstrated articulation scores below the 10th percentile (Sedey, 2009).

Tomblin et al. (2008) studied the longitudinal speech development of children with cochlear implants with a minimum of 8 years of cochlear implant experience. The development of speech sound production seems to stabilize after 6 years of cochlear implant use and typically approaches a plateau after 8 years of CI use. In this study, mean speech sound production accuracy was 15% pre-implantation, 63% after 4 years of CI use, and 81% after 8 years. The researchers concluded that a positive prognosis for speech production can be made at the 4-year point of cochlear implant use.

Children with HL greater than a puretone average of 50 dB HL have been found to have significant differences in their speech production in the first year of life even when early identified. McGowen et al. (2008) found that children with HL had fewer multisyllable utterances with consonants, fewer fricatives and fewer stops with alveolar-velar stop place, and more restricted front-back tongue positions for vowels than did the children with NH. When children's HL is not identified early, they tend to experience persistent difficulties in speech intelligibility in conversation and production of fricatives from 28 to 84 months of age (Moeller et al., 2010).

Language Development

The assessment of language development begins in infancy. Several assessments have been used, including the following.

MACARTHUR BATES COMMUNICATIVE DEVELOPMENT INVENTORIES

MacArthur Bates Communicative Development Inventories (CDI) (Fenson et al., 1993) is a parent questionnaire assessment of the child's lexicon size, gesture development, vocabulary comprehension, and syntax. The CDI has been used to monitor progress of children who are D/HH in the state of Colorado since the 1980s and is currently being used in 14 other states through the National Early Childhood Assessment Project (Sedey and Yoshinaga-Itano, 2012).

Using the CDI, Mayne et al. (2000) found that children who are D/HH in their region (Colorado) had expressive vocabulary delays even when they had been identified early and had normal cognitive development. By 2.5 years, the typically developing child has approximately 600 words in his/her expressive vocabulary, compared to 400 words among children who are D/HH, one more piece of evidence supporting aggressive intervention.

EXPRESSIVE ONE WORD PICTURE VOCABULARY TEST (EOWPVT-3)

The EOWPVT-3 is a standardized test of expressive vocabulary commonly used in the diagnostic evaluations of children with NH for language disorders and also for children who are D/HH (Brownell, 2000). The expressive vocabulary task requires a child to describe a picture with a single word. Children who are D/HH who are early-identified with appropriate early intervention follow-through have demonstrated vocabulary levels about 6 months delayed from the norms for children with NH from 4 to 7 years of age (Yoshinaga-Itano et al., 2009).

TEST OF AUDITORY COMPREHENSION OF LANGUAGE (TACL-3)

The TACL-3 is a picture-pointing task that assesses the development of vocabulary, grammar, and sentence construction (Carrow-Woolfolk, 1999). It has been used to evaluate children who are D/HH and to compare their language development to children with NH. Research in this area indicates that children with and without HL develop similar receptive syntax skills (Yoshinaga-Itano et al., 2010). However, when examining languages samples of children interacting with their parents, delays in expressive syntax were found (Sedey, 2009). Children with NH tended to produce more utterances, words, and morphemes than children who were D/HH. In addition, children who are D/HH had significantly fewer negatives, conjunctions, and personal pronouns than children with NH.

Pragmatics

Pragmatics is the use of language in social situations, involving interpersonal skills such as taking conversational turns, adjusting one's language to the age or status of a communication partner, or rephrasing when one is misunderstood. Pragmatic language development of children who are D/HH in their early years has been neglected in the research literature. To address this concern, Goberis et al. (2012) developed the *Pragmatics Checklist* for parents and teachers to monitor the development of pragmatic language skills. The checklist includes 45 items across 7 pragmatic language categories: (1) Instrumental (request for action/object), (2) Regulatory-Command, (3) Interactional-Social rules/poise/politeness, (4) Per-

sonal Expression of Feelings, (5) Heuristic—Questions to obtain information, (6) Imaginative-Pretending, and (7) Informative—Cause and Effect.

Children with no HL usually master all the skills on this checklist by the age of 6. However, in a recent study, children with HL were found to have mastered only three of these skills at this age. This is an important finding relative to long-term child success. Establishing strong pragmatic language skills is important for the development of social skills and literacy. Focus should begin in early childhood but should continue throughout the education of the child. Partnerships between professionals and parents will assist in the development of age-appropriate pragmatic language skills.

Social-Emotional Development

Children who are early identified tend to have personal–social skills within the range of normal development, whereas children who are later identified have demonstrated significant delays in personal–social skill development commensurate with their expressive language skills (Yoshinaga-Itano and Abdala de Uzcatogui, 2001). To evaluate these skills, professionals and parents often use the *Child Behavior Checklist* (Achenbach and Rescorla, 2000), designed for children aged 1.5 to 16. Age-appropriate checklists take about 10 minutes to complete and inquire about sleep problems, attention and anxiety, mood swings and different expressions of stress, as well as language development. Results can help determine the need for a referral to a professional counselor.

Another tool designed to help audiologists understand a child's social development is called *My World* (www.idainstitute.com). This counseling tool depicts classrooms and other spaces on a flat board and provides movable avatar figures that a child can use to represent him/her and other people. Children are asked about social situations at school, at home, on the playground, and other settings. The tool provides a vehicle for the child to convey information about his/her ease in listening, learning, communicating in real-world situations, and friendships and other social concerns. It has been successfully used on children who are D/HH as young as 3 years of age.

Barker et al. (2009) in a study of 116 children with severe to profound HL aged 1.5 to 5 years found significant relationships between language, attention, and behavior problems. Children with sensory/neural HL have been found to have higher rates of behavior problems (e.g., aggression, delinquency, and hyperactivity), rates being around 30% to 38%, compared to 3% to 18% for children with NH (van Eldik et al., 2004; Vostanis et al., 1997).

SUMMARY

This chapter examined the impact of HL on learning, from infancy through the school years. We examined the legal mandates, guidelines, and best practices available to families

and their children and the kinds of decisions families face, especially regarding communication. We briefly examined how children's learning challenges are measured and also reviewed some of the evidence-based practices currently being used to support learning success. Needless to say, the audiologist is crucial to this success.

FOOD FOR THOUGHT

1. Two documents (JCIH, 2013; Moeller et al., 2013) are currently being used to define early intervention practices for children who are D/HH and their families. How might these be applicable to the educational needs of older children?
2. Pediatric audiologists need to be careful observers of more than a child's hearing abilities. What other developmental issues should an audiologist monitor?
3. Audiologists need to be experts of the normal development of auditory skills. Observe young children at different age levels and try different auditory tasks with them to familiarize yourselves with what should be expected at each age level.

Audiologic Rehabilitation

Joseph Montano

AUDIOLOGIC REHABILITATION

Many consider audiologic/aural rehabilitation (AR) to be the heart and soul of the profession of Audiology. Certainly it was the impetus for the military origins of the field and continues to be the way we define our profession. However, in practice, AR takes a back seat to diagnostic procedures and, in fact, may not be a reimbursed service through third-party insurers in the United States. Why the discrepancy then between practice and perception?

When audiologists are asked about their role in the AR process, opinions vary greatly. Some may feel it defines everything we do in our profession, whereas others consider it to be specialized treatments, such as speechreading and auditory training (AT). Audiologists even disagree on what to call this area of expertise: Aural, audiologic, or auditory rehabilitation. Few, however, would argue that audiologists play a pivotal role in the management of hearing loss in children and adults, regardless of what it is called or how it is defined.

Hearing health care continues to evolve and professional roles and boundaries have begun to blur. It is important that we have an understanding about the provision of audiology services, in this ever-changing healthcare landscape, and that we adapt the philosophies, skills, and knowledge that define our profession to the current state of service provision. With that in mind, this chapter will provide the reader with a foundation in AR that reflects the changes occurring in the provision of health services and infuse the process into a framework reflecting our practice environment.

The Changing Healthcare Arena

Audiology has, for the most part, been practiced within a medical/biomedical model of service delivery (Erdman, 2014; Erdman et al., 1994): A top-down system whereby patients are seen for assessment procedures resulting in traditional diagnoses and treatments. In this model, care is directed by the audiologist and the patients are, for the most part, passive in the process. They are expected to comply with the recommendations put forth by the audiologist that, more often than not, result in the acquisition of hearing aids for remediation of hearing loss. This method of service

delivery can be particularly limiting when seen within the context of the ever-evolving world of patient-centered care.

Global healthcare initiatives are investing heavily in the move toward improved quality of health care through patient-centered practice. The Institute of Medicine (2001) emphasizes the importance of health provision that is patient driven and mindful of individuals' beliefs, wishes, and values. Medical decisions are guided by the inclusion of the person in the development of treatment goals and activities. The recent passage of the Patient Protection and Affordable Care Act (2010) is an example of legislation that encompasses the ideals of patient-centered care and the current shift in beliefs that influence health provision.

For the field of Audiology to embrace this patient-centered care philosophy, there needs to be a rethinking of the model used in practice, a shift from the biomedical to the biopsychosocial or rehabilitative methods of service delivery. This model would embrace the inclusion of the patient in the assessment and treatment decisions, a horizontal approach where the audiologist works together with the patient and family to agree on a method of treatment. The decisions are collaborative rather than prescriptive. For example, hearing aid recommendations should be made on the basis of the psychosocial and behavioral impact of the hearing loss rather than just the audiometric results. We need to listen to what the patient needs rather than tell them what they should have.

Consider for a moment the treatments historically associated with the provision of AR service: Hearing aid orientation, AT, speechreading, and communication groups. One can easily see how they can fit within a biomedical model of service provision. Once a hearing loss is identified, these options can be recommended as part of a treatment plan. Early definitions of AR tended to focus their attention on these procedural specific elements without consideration of the underlying characteristics of hearing loss and the impact it has on function.

Publications through the World Health Organization (WHO), most notably the International Classification of Impairment, Disability and Handicap (WHO, 1980) and the International Classification of Function, Disability and Health (2001), greatly influenced the development of more recent AR definitions and contributed to the move

toward patient-centered care-related content. ASHA (2001) described AR as an “ecological, interactive process that facilitates one’s ability to minimize or prevent the limitations and restrictions that auditory dysfunctions can impose on well-being and communication, including interpersonal, psychosocial, educational and vocational functions” (p 2). Multiple factors are identified in this definition aligning themselves with the principles associated with patient-centered care. The emphasis on the “interactive process,” function, and environmental influences highlight the importance of collaboration in the AR process.

Recently, Montano (2014) defined AR as “... a person-centered approach to assessment and management of hearing loss that encourages the creation of a therapeutic environment conducive to a shared decision process which is necessary to explore and reduce the impact of hearing loss on communication, activities, and participations ...” (p 27). Key elements within this statement embrace the concepts closely aligned with changes occurring within the health-care arena. Use of terminology such as “a patient-centered approach” and “shared decision process” reflects the para-

digim shift currently underway. In addition, terms such as “activities” and “participations” are associated with the concepts presented in the WHO ICF (2001). Thus, I believe that the incorporation of AR into practice should include a biopsychosocial model of service delivery and not be restricted to the biomedical standard.

The provision of AR services is frequently focused on the results obtained from an audiogram with the emphasis largely on the dispensing of some kind of amplification device(s). This has been classified as a technocentric approach and follows the biomedical model of service delivery (Montano, 2011). AR practiced within the biopsychosocial model would stress the importance of counseling thereby considered a patient-centered approach, but not to the exclusion of amplification devices.

Table 45.1 compares and contrasts components of both the technocentric and patient-centered models. Although many of the services described may be similar, philosophically they differ. For example, although assessment of hearing is certainly important in both models, standard audiometric evaluation is more relevant in the technocentric

TABLE 45.1

Comparison of the Technocentric and Patient-Centered Models of Service Provision in Audiologic Rehabilitation

Technocentric Model	Patient-Centered Model
History—obtaining a detailed history contributes to differential diagnosis. Traditional methods typically involve the use of closed-set questionnaires	A patient narrative fosters a dialogue between clinician and patient through the use of open-set inquiry
Audiometry—precise evaluation of hearing is essential to the development of all specific AR goals	Self-assessment is a valuable tool to measure the impact of hearing loss on a person’s function. This, along with the audiometric information, presents a more complete picture for the audiologist and can be insightful for the patient
Hearing assistive technology systems are critical to achieving improved communication in the presence of hearing loss. The use of hearing aids and assistive devices becomes the emphasis of treatment	Hearing assistive technology systems are certainly important but need not be the sole basis for intervention. They should be incorporated into a process of adjustment to hearing loss
Hearing aid orientation tends to become the emphasis of the therapeutic aspect of treatment	Interventions are decided through shared decision making and may include procedural therapies such as auditory/visual training and individual and group treatment
Verification is critical when amplification is part of the treatment plan	Verification is critical when amplification is part of the treatment plan and results need to be interpreted with regard to patient input and preference
Accessories are plentiful and add another layer of technology to an often complex adjustment patients are experiencing	Regardless of the technology devices or accessories, the emphasis is placed on person’s needs and abilities
Follow-up consists primarily of acoustic modifications to amplification	Counseling-based follow-up, support, and encouragement are emphasized with referrals to outside sources, as necessary, such as consumer groups

TABLE 45.2

Examples of Auditory and Nonauditory Consequences of Hearing Loss

Auditory Consequences	Nonauditory Consequences
Patient is unable to follow conversations even in quiet environments	Increased social isolation, depression, may appear confused, anger
Patient is unable to hear effectively at office meetings	Nervous that job may be at risk, anxious that he/she may have missed information that was pertinent to his/her work responsibilities
Patient cannot hear whispers	Loss of intimacy, no longer enjoys quiet times at home with spouse, misses sounds of nature
Patient is unable to hear conversations in restaurants	Avoids going out with friends, is disengaged during conversations, feels left out
Patient is unable to hear the television unless the volume is very loud	Spouse watches same program in another room, arguments about the television volume
Patient struggles to hear conversation when there is even the slightest noise in the room	Works hard trying to focus on visual cues, exhaustion, irritability
Patient is unable to hear on the telephone or even the telephone ring	Anxious that he/she may miss an important call, refuses to answer the phone

example and self-assessment is a critical component of the patient-centered approach. Even basic procedures like obtaining patient history are fundamentally approached in different ways with one method using standard history intake forms and the other engaging in a dialogue or patient narrative. Therefore, combining these two approaches is likely to provide the best outcome.

The goal of AR is to help the person adjust to issues related to living with hearing loss, including both auditory and nonauditory aspects (Erdman, 2000). Thus, the audiologist should keep in mind that he/she is not only trying to obtain the best audiometric result, in general, but concerned about the specific psychosocial implications for the person. These may include issues related to depression, anxiety, increased isolation, and lack of intimacy, to name a few. Table 45.2 describes some examples of auditory and nonauditory consequences of hearing loss.

For every auditory characteristic of hearing loss, there are potential nonauditory ramifications. For example, a man who is unable to communicate effectively at an office meeting may feel anxious that his job could be in jeopardy or perhaps insecure that he will be able to understand important details presented. The impact of hearing loss is rarely just auditory and the audiologist must be perceptive to the possible related issues. As such, for him/her to build a relationship and help patients adjust to hearing loss, counseling needs to be a component of all aspects of AR, both assessment and treatment. Counseling then is the backdrop to the management of patients with hearing loss.

COUNSELING

Counseling is at the heart of the patient-centered approach described by Montano (2011). Although audi-

ologists are aware of the importance of counseling their patients about hearing loss and hearing aids, many believe that it is a process that may be independent from their normal clinic responsibilities. I believe that counseling is critical for the person with a hearing loss. Clark and English (2014) reported that counseling is infused into all aspects of audiology practice and is the basis for developing a “common ground” with patients throughout each phase of assessment and treatment.

Counseling, within the audiologist’s scope of practice, is considered by many to consist of two components: Information/education and personal adjustment/support (Clark and English, 2014; Luterman, 2001). That is, counseling tends to focus on providing patients and their families with education to help them self-manage their hearing loss and monitor their reaction to the information they are receiving. This is accomplished by a combination of careful observation and good listening skills. Telling a person that they need hearing aids may be upsetting to some resulting in an emotional response, thus the audiologist must be prepared for different reactions to such recommendations.

The audiologists’ counseling role is not restricted to being purely educational, but rather is a critical partner in the journey toward patient acceptance of hearing loss. As such, counseling provides the support necessary for patients to better understand the impact of hearing loss in their lives. It requires the audiologist to be aware of the emotional adjustment one may undertake when dealing with a communication loss such as hearing impairment and be able to recognize the feelings expressed both verbally and nonverbally through their interactions.

A misconception is that the process is the same as therapeutic interventions performed by psychologists, social

workers, and other mental health professionals, when in reality it is the foundation for relationship building that will enhance the AR process. Although the audiologist is the professional who is most knowledgeable about hearing loss and the impact it may have on psychosocial functioning, should he/she encounter a patient presenting with clinical signs beyond those related to adjustment to hearing loss, an appropriate referral should be made. With the vast majority of patients, however, the audiologist is there to support them as they learn to live with hearing loss.

When counseling is included in a patient-centered care approach to AR, it can lead the audiologist in many directions. Counseling can provide the audiologist an understanding of the patient's journey and perspective on the hearing loss. Gregory (2012) described a possible patient journey tool developed by affiliates of the Ida Institute. The tool was designed to highlight the potential phases and directions one may go through on their way to seeking hearing health care. For example, early on in the journey, a patient may identify difficulty hearing in a certain situation such as a family gathering; or perhaps, a spouse might ask that the television volume be lowered. These early indications of hearing loss continue until the person acknowledges the possibility of hearing loss and begins to seek treatment. The use of patient journey narratives also illustrates the intricate nature and psychosocial manifestations of hearing loss (Manchaiah and Stephens, 2011).

Readiness for Change

An understanding of the person's journey can provide the audiologist with valuable information on the readiness of the patient to begin the AR process. This concept has been well researched in areas related to behavior change such as addictions, weight loss, and diabetes management. Similarly, Goldstein and Stephens (1981) identified four categories

of "aural rehabilitation types" (see Table 45.3). Classifications range from those who are highly motivated to seek out AR services to those who are extremely negative about dealing with issues related to hearing loss. Judgments as to which category a patient may be classified can be made with knowledge obtained through a narrative history, responses to self-assessment questionnaires, or even the referral source for audiologic evaluation.

The stages of change model was developed with the notion that behavioral adjustment occurs in increments and that people move intentionally toward decision making (Prochaska and DiClemente, 1983). This model has recently been adapted by the Ida Institute (2011) to illustrate the stages of change faced by patients as they move toward AR treatment. As seen in Figure 45.1, a circle represents patient evolution from a stage of pre-contemplation/contemplation to preparation and action moving toward both successful maintenance and permanent exit or, in some cases, relapse, only to return to the circle of change at a later time. To progress through the cycle, patients seek out education, information, advice, encouragement, and support with the audiologist as the professional capable of meeting all these needs. By understanding the patient journey, knowing each story, and acknowledging his/her position within the stages of change, the audiologist has the foundation to provide a comprehensive AR program.

The audiologist and patient work together to determine which components of an AR program are necessary to help develop improved communication skills and ultimately establish successful management of hearing loss. Although amplification may be a vital element of this process, alone it will likely fall short from meeting this primary objective. The AR components, whether they consist of supportive counseling, information on communication strategies, or therapeutic intervention, are necessary to achieve favorable outcomes. For the audiologist to offer comprehensive solutions for patients with hearing loss, they must

TABLE 45.3

Audiologic Rehabilitation Candidacy Types

Type	Description	Example Characteristics
Type I	Very positive, motivated to improve	Self-referred, positive outlook, looking forward to improving communication skills
Type II	Positive with some complications	Concerned about stigma, acknowledges need for help, but nervous about hearing aids
Type III	Mostly negative, but agreeable to attempt trial with amplification	Referred by family member, significant concerns about hearing aids, may look to restrict use of amplification
Type IV	Negative, rejects possibility of hearing aids and AR	Forced by family member to seek treatment, agrees to hearing test but not AR consult

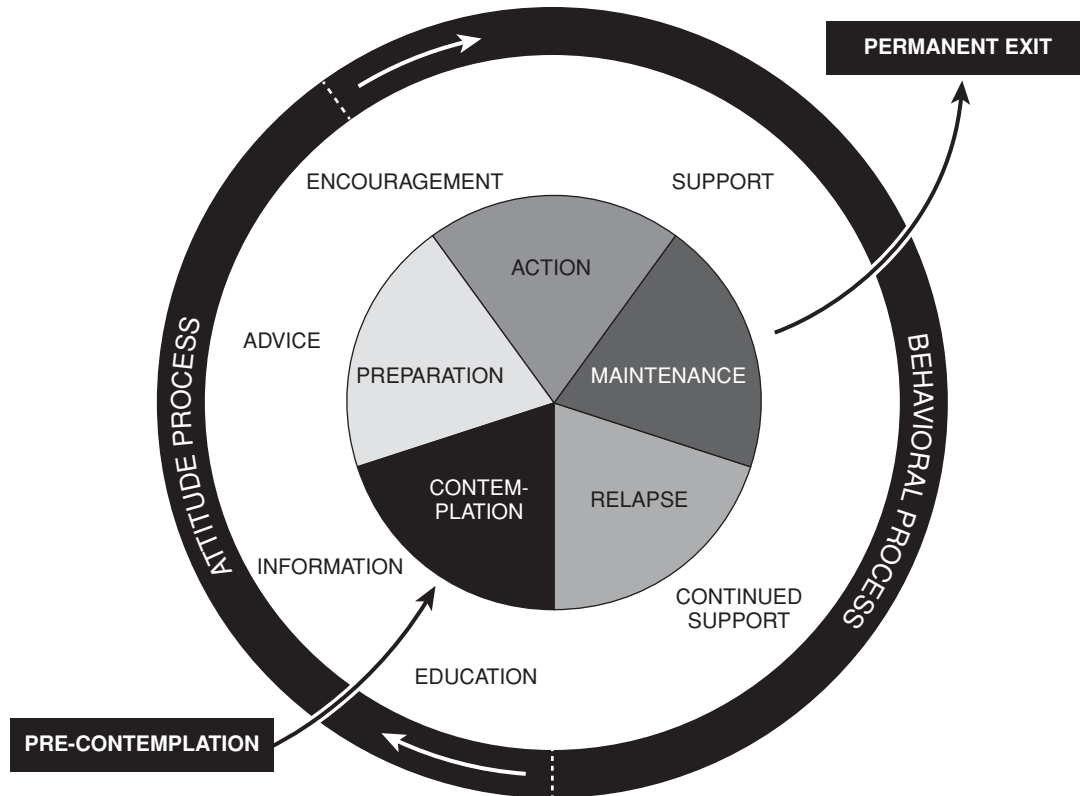

FIGURE 45.1 Ida Institute Circle Tool: Readiness for change.

be aware of not only the technology available to meet the amplification needs, but the existing procedural therapeutic interventions.

OPTIONS FOR THERAPEUTIC AR INTERVENTION

Although it would be wonderful if the use of hearing assistive technologies would resolve all the communication difficulties faced by individuals with hearing loss, this is not the case. Even the most skilled hearing aid user will report difficulties communicating in certain listening environments. Often, hearing aid dispensing takes place in optimal settings, quiet offices, and clinics and does not reflect the real-world conditions patients face on a daily basis. Although noise simulation programs are available from most hearing aid manufacturers, they only approximate the patient environments. Not only must they approach communicating with a sensory deficit, but this process must take place in locations where noise may be present, lighting may be insufficient, speakers may have accents or poor conversational skills, and discussion topics can change rapidly. To maximize communication performance, the person with hearing loss must learn to take advantage of all the sources of information available to assist with the interpretation of auditory cues. To best accomplish this, they must use visual and auditory information and communication strategies

and be prepared for communication failures. As such, these concepts become the focus of communication therapy, most commonly referred to as auditory/visual training (AT and speechreading).

Auditory Training

In their historical perspective of AT, Kricos and McCarthy (2007) traced the roots of AT back to the 19th century. Although AT practice has been a component of AR since the evolution of Audiology after World War II (Ross, 1997), in recent years there has been a surge in popularity among audiologists because of the availability of interactive computer-based training programs. The ability to provide a therapeutic AT option that could be offered either in the clinical setting or in a home-based setting has spurred the growth of this intervention. Sweetow and Palmer (2005) performed a systematic review of research of individual AT in adults and although the results were mixed, they found no deleterious results of the training. As part of their discussion, they believed AT might be best accomplished through interactive computer-based programs as it was believed that individual adult intervention was time consuming and not cost efficient. More recently, Chisolm and Arnold (2012) performed an additional systematic review of research on individual AT and determined that evidence exists that AT results in at least short-term improvement of speech understanding.

WHAT IS AT?

Interpretation of auditory input requires the use of multiple processes beyond hearing. Cognitive functions, pragmatics, language mastery, and visual perception are only a few of the components of auditory processing of information. Degradation of auditory input from hearing loss significantly impacts many of the processes used. With this in mind, AT is meant to help persons with hearing loss improve their ability to interpret, process, and assimilate auditory input. Sweetow and Sabes (2014) described AT as “a process designed to enhance the ability to interpret auditory experiences by maximally utilizing residual hearing” (p 277). Therefore, AT therapeutic intervention is intended to foster awareness of sound cues available to the listener (Carhart, 1960).

Intervention can be provided either individually or in group settings. Although group settings are valuable and desired to foster socialization and improved communication strategies and behaviors, it can sometimes be difficult to meet the individual AT needs of the group members. For this reason, AT intervention is best served on a one-to-one basis with programs designed with individual requirements considered. Speech perception testing (see Chapter 5 for information) can be performed to determine a baseline level of functioning and the training programs can be designed from the results obtained.

TRAINING CONSIDERATIONS

Traditional approaches to AT are described as either analytic or synthetic. The use of analytic training requires the clinician to focus therapy on the fundamental aspects of speech, breaking it down to its component parts. This intervention focuses on vowel and consonant recognition through the use of phonemes or phoneme clusters.

Synthetic training, on the other hand, emphasizes listening skills through the use of sentence materials that incorporate the inclusion of auditory and linguistic skills for interpretation of the message (Sweetow and Sabes, 2014).

Erber (1982) described a framework for AT that included four levels of speech skills that are essential elements of communication: Detection, discrimination, identification, and comprehension. Speech detection or awareness simply refers to the ability to recognize that sound is either present or absent and is the basis for more advanced levels of speech understanding. Discrimination is the ability to distinguish one sound or groups of sounds from another. It implies that the person is able to detect differences in acoustic characteristics such as intensity, duration, and rate. The next level of speech understanding is identification. Here, the listener is capable of applying labels to the sounds heard. That is, the ability to correctly identify the acoustic input. Finally, once the speech has been identified, the final level is comprehension. Here, the listener understands and assigns meaning to the perceived speech signal.

Comprehension is, of course, the necessary requirement for communication. It is the result of detection, discrimination, and identification.

AT traditionally progresses from easy speech perception tasks to more complex stimuli. Treatment follows a hierarchy of the levels of speech perception, progressing from gross to fine sound discrimination, and both analytic and synthetic approaches are used to achieve this progression. In analytic training, differences between voicing characteristics, place, and manner of articulation may be the focus. These same concepts can then be reinforced through the use of sentence material.

TECHNOLOGY AND AT

Computer-based AT programs have flourished in recent years. As a result, audiologists have increasingly begun recommending AT to their patients. Sweetow and Sabes (2007) likened the need for AT to physical or occupational therapy when an individual suffers a leg or arm injury. These therapies are widely accepted and expected as part of the treatment for these conditions. The availability of home-based training programs makes it more accessible for many.

There are a number of computer-based programs available. Sweetow and Sabes (2014) describe these programs as typically automated and adaptive. They are able to monitor use and skill level, and the programs tend to increase in difficulty as the user progresses. Scores are maintained and in some cases can be monitored from the audiologist's office. The exercises contained in many of these programs consist of auditory/visual and cognitive training, as well as repair and communication strategies.

Two programs in particular have generated a great deal of interest, Listening and Communication Enhancement (LACE) (Sweetow and Sabes, 2006) and Read My Quips (Levitt et al., 2011). LACE, in particular, is responsible for stimulating a resurging interest in AT and is the most widely used computer-based program.

LACE is designed to offer adults with hearing loss exercises meant to enhance listening skills and improve communication. The program provides activities to address listening in adverse conditions and some of the cognitive changes that impact aging adults. Training is offered in 20, half-hour sessions and a record of skill is recorded and plotted for easy interpretation. LACE is divided into three main sections: Degraded speech, cognitive training, and communication strategies.

Degraded speech exercises consist of situations where an adult with hearing loss would experience listening difficulties such as speech in noise, rapid speech, and competing speakers. Cognitive training includes processing speed and auditory memory. Finally, communication strategies are provided in areas such as environmental modifications, expectations, and effective communication behaviors.

Read My Quips (Levitt et al., 2011; Sensesynergy, 2011) is designed as an entertaining adaptive speech in noise program. The authors believed that for training to be effective it should be fun. With that in mind, the program presents a series of crossword puzzles consisting of amusing quips (i.e., “Can an atheist get insurance against acts of god?”). It uses an auditory/visual format with cues offered under varying signal to noise ratios.

Many of the available AT computer-based programs combine both auditory and visual stimuli in their exercises. The use of both modalities in communication enhances the perception of auditory input and is consistent with the natural methods used to process speech.

Visual Speech Perception/ Speechreading

There are numerous influences that impact our ability to perceive spoken language. Most communication interactions include both auditory and nonauditory information used concomitantly to receive and decipher verbal input. For a message to be perceived, the listener uses expertise garnered from audition and vision, environmental perception, contextual and facial cues, nonverbal communication, gestures, and language competency. Often, interpretation of the spoken signal is degraded because of factors such as environmental conditions (noise, competing speech, reverberation, lighting, and distance from the source), speaker characteristics (foreign accent, facial hair, rate of speech, loudness of speech, and vocal characteristics), and hearing loss. To maximize the ability to perceive spoken language, the listener uses information received from a variety of input channels with speechreading becoming a compliment to hearing.

The terms speechreading and lipreading are frequently used interchangeably to describe visual speech perception. Although similar, they imply different aspects of this pro-

cess with lipreading referring to the perception of more specific articulatory movements and speechreading being more inclusive accounting for information provided through lipreading along with gestures, facial expression, and environmental influences (Lansing, 2014).

Visual speech perception, although an important component of the multisensory process we call communication, is threatened by various factors when it is the sole source of spoken language. See Table 45.4 for some of the limitations associated with visual speech perception and the understanding of spoken language including issues related to the visual signal itself, language, environmental factors, and communication styles.

Visual signal refers to the specific characteristics of speech including visibility, place, and manner of articulation. Much of what is spoken cannot be interpreted by vision alone. Many sounds are produced within the mouth with no external visual characteristics. In addition, many sounds that are visible appear identical to the receiver. For instance, place of articulation produces confusions when presented in the visual condition alone. The allophones /p, b, m/ appear the same on the lips and would only be distinguishable through sentence or word content. Consider the sentence “He will hit the ball with the bat.” Although the word “bat” may have the same appearance on the lips as “mat” and “pat,” the context of the sentence provides the necessary information for interpretation. Sounds and words that look alike are referred to as homophenes and said to be homophenous (Jeffers and Barley, 1971). The use of /p, b, m/ is an example of homophenous sounds and “pat, mat, and bat” are homophenous words. The category when viewed together as a group of sounds is a viseme referring to the units of speech that are indistinguishable from each other (Fisher, 1968).

Visemes are classified by the visibility of speech characteristics. Binnie et al. (1974) classified visemes into five distinct homophenous categories: Bilabials (/p, b, m/),

TABLE 45.4

Limitations of Visual Speech Perception on Understanding Spoken Language

The visual signal	Much of speech cannot be visually observed, many phonemes have identical physical appearances, and perception is dependent on voicing, place, and manner of articulation
Language competency	Spoken language is impacted by pragmatics, syntax, semantics, and phonological processes. Interpretation of the input signal is related to language potential
Environmental conditions	The setting for communication impacts perception: Lighting, distance from the speaker, room decor, auditory and visual distractions
Communication styles	Characteristics of the speaker and proficiency of the listener influence perception: Patterns of articulation, presence of facial hair, cultural influences, speechreading ability

Adapted from Lansing C. [2014] Visual speech perception in spoken language understanding. In: Montano J, Spitzer J, eds. *Adult Audiologic Rehabilitation*. 2nd ed. San Diego, CA: Plural Publishing; pp 253–276.

labiodentals (/f, v/), interdental (/θ, ð/), rounded labials (/Σ, ʒ/), and linguals (/t, d, n, s, z, k, g/). Given that the high percentage of sounds do not possess externally visible characteristics along with the redundancy of those that do have visibility, it is understandable why visual information alone may not suffice to provide adequate communication.

In addition to limitations imposed by the speech stimuli themselves, visual perception is also impacted by linguistic or language processes. As shown in Table 45.4, the listener's ability to process and interpret language has an impact on their ability to perceive the spoken message. There are many linguistic constraints that can occur in the communication of a message that have their bases in the listener's language proficiency. Areas such as pragmatics, lexicon, syntax, and phonologic processes are relevant to speech perception and will influence a listener's ability to interpret auditory input.

Environmental influences impact visual speech perception in a number of ways. Conditions such as lighting, distance from the speaker, angles, room clutter, and auditory distractions all can impact the transmission and reception of a speech signal. Sanders (1993) reported that a 5-foot distance between the speaker and listener is optimal for speech perception and Johnson and Snell (1986) identified a minimum visual acuity of 20/30 in at least one eye necessary for successful speechreading ability.

VISUAL PERCEPTION TRAINING

Speechreading assessment and training has been the focus of much research throughout the decades with very little consensus on standardized procedures. There are a limited number of available speechreading tests that have gone through the appropriate standardization procedures, many of which were developed decades ago. There is a need in AR, to develop normative data on speechreading abilities and create standardized tests to allow accurate skill measurement. Although systematic reviews for AR have been performed with specific areas covered such as AT and group intervention, there is no current publication available to look specifically at speechreading. Binnie (1977) measured attitudes about communication following speechreading training. He reported that although pre- and postmeasurements of speechreading ability did not yield any statistically significant improvements, there was a measurable positive improvement with subjects' confidence in communication.

A consideration faced by clinicians when they are deciding on speechreading activities is whether materials used should be presented in the vision alone or vision and audition condition. Certainly, vision alone would be most challenging and may actually be a source of frustration for many patients. Alpiner and Schow (2000) recommended a bisensory approach to speechreading assessment and training. The combination of both vision and audition more accurately represents the patient's true mode of communication

and would be useful for planning treatment and monitoring progress. The use of a bisensory approach implies that materials can be presented using both modalities in quiet and in simulated conditions of background noise.

As was the case with AT, speechreading therapy can be provided using either an analytic, synthetic, or a combination of approaches. Analytic speechreading would focus on identifying the visual components of viseme speech groups starting with very visible phonemes like the bilabials and progressing to the more difficult to identify such as the linguals. The training would focus exclusively on the visual characteristics of the phonemes. Synthetic training would use this same strategy, more visible to less visible, but present material in sentences or continuous discourse looking to encourage an understanding of meaning and not perhaps every sound segment.

DeFilippo and Scott (1978) first introduced the idea of continuous discourse tracking as a method to evaluate and train speech perception. The method rapidly gained wide acceptance largely as it appeared at a time when cochlear implant technology was being introduced for clinical use. Tracking became the preferred method of training for cochlear implant recipients and was quickly assimilated into AR programs throughout the world. According to the authors, "A talker and receiver engage in a dialogue for a designated period of time in which the receiver reports his perception of successive segments of read text and is corrected by the talker until the text is verbatim. Performance is measured in number of words or text repeated correctly per unit of time" (p 1186).

The method is particularly useful as it can be used in a variety of presentation conditions: Visual alone, vision and audition, amplification alone, cochlear implant alone, and so on. Typically, the presenter chooses the discourse material based on the interests and language skill levels of the patient. A series of strategies are reviewed and the discourse is read in short segments frequently for a period of 10 minutes. At the end of the time period, the total number of words, correctly identified, is divided by the number of minutes of the exercise yielding a word per minute score. This score is then plotted on a graph providing the patient with a visual representation of the progress he/she is making in treatment with a comparison between performance with and without amplification. Figure 45.2 represents the outcome of tracking for a patient wearing binaural amplification. Note the steady increase in the word per minute scores across treatment sessions with performance being the best in the aided visual condition.

COMPUTER-BASED SPEECHREADING TRAINING

The use of computer-based training programs has become increasingly popular in recent years. As was the case with the programs described in the AT section of this chapter, most available programs combine audition and vision in their

Patient Name: John L. MRN: _____
 Device: _____
 Date: _____

Total Score: _____
 Audiologist: _____

FIGURE 45.2 Speech tracking progress chart.

training. A popular program, Seeing and Hearing Speech (Sensimetrics Corporation, 2008) is an interactive program that allows users to proceed at their own pace with exercises focused on areas such as word stress, hearing in noise, and consonant confusions. Users have the option of practice in either visual alone or vision/audition conditions. Materials can be presented at varying rates and results are plotted along a continuum for easy interpretation. Included in the program are tips for successful communication.

Conversation Made Easy (Tye-Murray, 2002) is another interactive speechreading program available through the Central Institute for the Deaf. It consists of three modules for training adults and teenagers focusing on communication repair strategies. As with Seeing and Hearing Speech users can decide on the modality for presentation: Vision, audition, or vision/audition. These programs along with the ones described in the AT section provide opportunities for self-study of speechreading and AT. Although these programs can be effective, they are somewhat isolating as they

are performed alone in one's home environment. To foster improved communication, group intervention may allow for increased socialization and reinforcement of the skills that were developed through either individual therapy or at-home computer-based intervention.

Group Treatment

There is an abundance of research on the value of group aural/audiologic rehabilitation (GAR), with results suggesting positive outcomes. Certainly, the idea that treatment be provided for people with hearing loss in a group setting makes sense. GAR, for individuals with communication challenges and their communication partners, can be valuable for exchanging information and ideas about living with hearing loss. One of the benefits of GAR is the ability for the audiologist to actively address the psychosocial effects of hearing loss (Preminger and Nesbitt, 2014). Trychin (2009) refers to hearing loss as a communication loss that

has an impact not only on the patients but also on the people around them. The group setting creates a safe haven for communication with partners who possess similar traits. It provides the participants an opportunity to not only share experiences, and learn from others, but also provide support and counsel, and know they are not alone in their experiences.

Systematic reviews of the literature seem to support the inclusion of group treatment in AR programs. Findings reported by Hawkins (2005) supported GAR highlighting achieved benefits that included reduction in participation restrictions, that is interactions on the social level, improvement in the use of amplification, improved communication strategies, and improvements in personal adjustment. Chisolm and Arnold (2012) identified a series of studies that demonstrated consistent short-term and some long-term benefits of GAR interventions (Chisolm et al., 2004; Hickson et al., 2007; Preminger and Yoo, 2010).

Although evidence exists that GAR can be an effective component of AR, few audiologists offer such services. This may be because they are unsure of how to proceed or uncomfortable with the notion of running a group. To address this deficiency, faculty and staff of the Ida Institute (2012) developed a web-based tool designed to encourage the inclusion of GAR in hearing healthcare settings including hospitals, speech and hearing centers, community centers, and private practice (Montano et al., 2013). The tool, referred to as the Group Rehabilitation on-Line Utility Pack (GROUP), is available at their website (www.idainstitute.com) following the link to the “Tool Room.” Once accessed, the audiologist is provided with an online guide that can assist him/her in developing, marketing, and implementing GAR programs in their work facility. The GROUP is broken into several specific areas, including a thorough bibliography and resource materials for the participant. The resource library provides information on marketing, establishing groups, activities that can be used in the session, and information on reimbursement for services. Perhaps one of the most informative aspects in this section is the ability for the participant to view actual videos with the authors demonstrating GAR in action. Trychin (2014) provides specific suggestions for developing and implementing GAR programs with suggestions on specific activities that can be used in treatment, and they are demonstrated and available in the resource library of the program.

GAR programs can be developed and run in many different ways. They might be therapeutic and provide the opportunity for the audiologist to provide information on treatment options, hearing aid troubleshooting, speechreading, and so on. The groups can be primarily for socialization, giving people the opportunity to practice the skills they have developed to enhance communication with hearing loss. Referral to consumer support organizations, such as the Hearing Loss Association of America, can meet some of the socialization and information needs of patients.

This is especially true when GAR programs are not offered in the community. Regardless, the opportunity to meet and socialize with others with similar conditions is rationale enough for referral to local support groups.

SUMMARY AND FUTURE CONSIDERATIONS

The purpose of this chapter was to provide the reader with a basic foundation on services available for the provision of treatment to help patients manage their hearing loss. It was presented in the context of patient-centered care, that is, the recommendations and treatment plans are developed using a shared decision process that includes the cooperative efforts of both the patient and the audiologist. In this way the AR programs can be unique to the people they are established for. The audiologist acts as a guide and jointly helps patients explore the options available to them. In some cases it might be the need for and use of hearing aids and assistive listening devices, and for others perhaps instruction on communications strategy techniques. Other patients might need individualized treatment including AT and speechreading.

Regardless of the direction the AR program takes, the audiologist accompanies the patient on his/her continuing journey of learning to live with hearing loss and developing the skills necessary to maximize abilities. The foundation of such a program is counseling. The audiologists need to embrace the concept that they are indeed the most qualified to assist patients with hearing loss and explore the options available to them. The provision of information and support is the basis for this counseling relationship. The partnership that develops between the audiologist and the patient with hearing loss will be at the core of successful AR programming. Embracing the concept of the biopsychosocial model of service delivery will ensure that AR remains a vital part of the audiologist's identity in the new and ever-changing healthcare arena.

Understanding the need and importance of providing AR does not ensure the availability of these services for people with hearing loss. There have been obstacles to AR implementation that impede its inclusion in many programs. One in particular in the United States is the lack of reimbursement for these services. At the time of this writing, ASHA has spearheaded efforts to introduce legislation that would support audiologist reimbursement for comprehensive audiology care. This would change its position from a specific diagnostic professional classification to one that is inclusive, with rehabilitative services.

Future trends in health care will demand a more patient-centered provision of service. The sale of hearing aids is quickly being engulfed by outside entities such as insurers, big box stores, and physicians. If audiology is to thrive it should return to its roots and embrace the rehabilitative foundations of our profession. There is nothing I

can think of that would align itself better with a patient-centered philosophy and the future trend in health care than the inclusion of rehabilitation services by audiologists. AR should be the centerpiece of services provided for adults with hearing loss.

Infection Control

A.U. Bankaitis

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) and subsequent discovery of the human immunodeficiency virus (HIV) during the 1980s moved infection control to the forefront in the healthcare community. The concern for cross-contamination associated with HIV resulted in the issuance of federally mandated infection control requirements, providing the healthcare industry with specific guidelines on how to minimize the risk of exposure to potentially infectious agents. Since that time, the scope of infection control has expanded well beyond blood-borne diseases to include all microorganisms associated with potential degree of disease transmission. Although implementing an infection control plan is a relatively straightforward endeavor, appreciating its relevance to audiology along with understanding general principles and required components is necessary to ensure proper application and execution of such principles.

INFECTION CONTROL

Infection control refers to the conscious management of the environment for the purposes of minimizing or eliminating the potential spread of disease (Bankaitis and Kemp, 2003, 2005). Although the discovery of HIV impacted infection control in all areas of health care, it is not limited to minimizing the spread of HIV; rather, infection control programs are designed to minimize the spread of disease from any number of ubiquitous microorganisms readily found throughout the clinical environment (e.g., *Staphylococcus*, *Pseudomonas*) regardless of how remote the possibility of disease transmission may be perceived. The mindset of an effective infection control program is based on the universal assumption that every patient, bodily fluid, substance, or agent is potentially infectious. As such, diagnostic and rehabilitative services provided by audiologists must be delivered in a manner consistent with infection control guideline requirements and applied uniformly across each and every patient.

RELEVANCE OF INFECTION CONTROL TO AUDIOLOGY

As primary healthcare providers for hearing and vestibular disorders, audiologists have always been expected to practice basic hygiene procedures in the form of hand washing and general housekeeping; however, infection control must extend well beyond these general practices for several reasons. Table 46.1 provides a list of reasons why infection control is relevant to audiology. First, a number of governing bodies have issued federal mandates related to infection control making it a legal responsibility for audiologists to implement required infection control elements as specifically outlined throughout established guidelines within the clinical environment. The Occupational Safety and Health Administration (OSHA) is the federal agency governed by the United States Department of Labor that is responsible for regulating the workplace to ensure safety and healthful working environments. OSHA oversees and enforces infection control programs throughout environments where patient care services are provided to ensure compliance with federal standards as well as those guidelines outlined in the Universal (Standard) Precautions issued by the Centers for Disease Control and Prevention (CDC). In other words,

TABLE 46.1

Relevance of Infection Control to Audiology

Federal mandates issued by OSHA applicable to and required of all healthcare providers
Nature of audiologic practice inherently increases potential for disease transmission
Scope of audiology practices increases chances of exposure to bodily fluids including cerumen, ear drainage, pus, mucous, and/or blood
Audiologic services sought by wide range of immunocompromised individuals susceptible to opportunistic infections
Microbial contamination of hearing instruments

infection control is the law; failure of compliance results in citations and fines.

Beyond legal requirements, managing patients with hearing and/or vestibular disorders involves a notable degree of patient contact, including the use of various reusable objects that come in direct and indirect contact with multiple patients. From this perspective, the very nature in which audiologic services are delivered inherently increases the potential for disease transmission, and appropriate measures must be taken to eliminate cross-contamination. For example, contact transmission represents the most common means of disease transmission in clinical environments where these types of services are provided (Bankaitis and Kemp, 2003, 2005, 2007; Bankaitis et al., 2005). Directly touching a patient's draining ear without the use of gloves and reusing an object such as an immittance probe tip, otoscope specula, or the bell portion of a hearing aid listening stethoscope whereby patients are indirectly exposed to contamination are examples of how contact transmission may occur in the audiology clinic. Furthermore, audiologists often touch and manipulate the ear and/or make direct or indirect contact with a patient's skin, natural orifices of the body that serve as portals of entry for microorganisms. To eliminate or minimize the potential spread of disease in the clinical environment, it is paramount for audiologist to deliver clinical procedures in a manner specifically designed to eliminate potential microbial transmission via direct and indirect contact as well as prevent the very same microorganisms to gain access to the human body via natural body orifices.

Audiology's scope of clinical practice is vast and diverse, involving many types of noninvasive and invasive patient contacts that potentially expose the clinician to bodily fluids to which appropriate barriers and infection control procedures must be used. For example, intraoperative monitoring, cerumen management, vestibular testing procedures that may result in patients getting sick, postoperative audiologic assessment of cochlear implant and middle ear implant recipients, and patients with healing surgical wounds can easily expose the clinician to cerumen, ear drainage, mucous, blood, and the like. Over the past several decades, as the scope of audiology practice has expanded, the incidence of exposure to blood and other bodily fluids and the subsequent risk of exposure to blood-borne pathogens substantially increase (Kemp and Bankaitis, 2000). The relevance of infection control in the clinic where audiology services are provided cannot be overstated.

Furthermore, audiology services are sought by a wide range of patients who vary across factors known to potentially comprise the integrity of the immune system. Although not an exhaustive list, a patient's age, underlying disease state (i.e., diabetes, cancer), nutritional status, socioeconomic background, and/or exposure to past and current pharmacologic interventions will influence how well a patient's body can fight off disease (Bankaitis and Kemp, 2003, 2005). Varying degrees of immunocompro-

mise manifest in unpredictable ways that are not necessarily evident or identifiable; although individuals with underlying disease may appear healthy, because their immune system is compromised in some way, they are inherently at greater risk for infection. The hallmark of immunocompromise is the susceptibility of individuals to opportunistic infections and diseased states caused by ubiquitous organisms residing in abundance throughout the environment that rarely cause disease or infection in healthy individuals; rather, these microbes take the opportunity to infect those exhibiting some degree of immunocompromise (Bankaitis and Kemp, 2003, 2005). Given the right conditions, these infections can be life threatening in some cases. For example, the bacterium *Staphylococcus* resides on skin surfaces. Given the universal nature of the bacterium, the assumption by clinicians may be that *Staphylococcus* is an innocuous bacterium for which infection control procedures are not necessary. On the contrary, although this bacterium is ever-present throughout the environment, it accounts for a high percentage of nosocomial or hospital-acquired infections (Murray et al., 1994). Since most hospital patients are sick and exhibit varying degrees of immunocompromise, despite the universal nature of *Staphylococcus*, these patient populations remain extremely susceptible to such microorganisms. From this perspective, audiologists must adhere to a proactive strategy to minimize the possibility of the inadvertent spread of disease in the clinical environment.

Finally, objects coming in direct or indirect contact with patients may be contaminated with potentially infectious microorganisms. Bankaitis (2002) documented the presence of light to heavy amounts of bacterial and/or fungal growth on the surface of hearing instruments removed from the ears of adult patients. The predominant organism recovered was *Staphylococcus*; however, each hearing aid was contaminated by a unique combination of bacterial and/or fungal microbial growth. A follow-up study conducted by Sturgulewski et al. (2006) revealed similar findings. Based on the findings of these studies, it is plausible to assume that other reusable objects used by audiologists with multiple patients may be contaminated with varying degrees of microbial growth. The relevance of infection control from this perspective cannot be overstated.

IMPLEMENTATION OF INFECTION CONTROL PRINCIPLES

In the United States, the CDC issued a number of similar recommendations and guidelines for minimizing cross-infection of blood-borne diseases to healthcare workers. These pronouncements were officially formalized into the Universal Blood and Blood borne Pathogen Precautions (CDC, 1987). The pronouncements were originally intended to protect healthcare workers from blood and blood-borne pathogens; however, these precautions have since been expanded to include all potentially infectious body substances.

TABLE 46.2

Standard Precautions as Issued by the Centers for Disease Control and Prevention

- Appropriate personal barriers (gloves, masks, eye protection, and gowns) must be worn when performing procedures that may expose personnel to infectious agents
- Hands must be washed before and after every patient contact and after glove removal
- Touch and splash surfaces must be precleaned and disinfected
- Critical instruments must be sterilized
- Infectious waste must be disposed of appropriately

Source: CDC. [1987] Recommendations for prevention of HIV transmission in healthcare settings. *Morb Mortal Wkly Rep.* 36 (suppl 2), 1S-18S.

The five general pronouncements are outlined in Table 46.2. The pronouncements are relatively straightforward; however, each is reviewed in more detail with specific attention placed on its application to clinical management of patients with communication, hearing, and swallowing disorders.

Appropriate Personal Barriers

Appropriate personal barriers refer to gloves, masks, eye protection, and/or gowns which must be worn during the provision of services and/or procedures that may expose audiologists to potentially infectious agents or substances.

GLOVES

Appropriately fit gloves are indicated during invasive procedures or those procedures where open wounds and/or visible blood are present. Wearing gloves is indicated when hands are likely to become contaminated with potentially infective material such as blood, body fluids, secretions, excretions, or mucous membranes, as well as in those situations to prevent gross microbial contamination of hands (CDC, 2002; WHO, 2004). Outside of the operating room environment, clean, nonsterile gloves may be used when touching potentially infective material (WHO, 2004). Table 46.3 provides a general guide as to when gloves should be worn by clinicians providing diagnostic or rehabilitative services to individuals with communication, hearing, and swallowing disorders.

The size of the glove is important and should be determined for each clinician separately to ensure an appropriate fit. As shown in Figure 46.1, gloves are considered to fit appropriately when the glove fits the hand tightly, adhering very close to the skin without being too tight. This will allow for effective manipulation of objects, items, or instruments during the provision of services without compromising manual dexterity. Gloves that fit too loosely (Figure 46.2) will hinder

TABLE 46.3

Glove Use Guidelines for Audiologists

- In the presence of an open wound and/or visible blood [at the level of patient's ears and/or clinician's fingers, palms, wrists]
- When handling hearing instruments or earmolds that have not been cleaned and disinfected first
- When removing cured earmold impressions from the ear canal
- When cleaning instruments contaminated with cerumen, mucus, or other bodily substances
- When submerging or removing reusable instruments into or from a cold sterilant
- When hands are likely to become contaminated with potentially infectious material including cerumen, saliva, mucous membranes
- In the operating room environment during patient preparation or any other procedures during or after the surgical procedure where hands could potentially come in contact with blood, bodily fluids, or other contaminated materials or contaminated objects

Source: Adapted from Bankaitis AU, Kemp RJ, Krival K, Bandaranayake DW. [2005] *Infection Control for Speech-Language Pathology*. St. Louis, MO: Auban, Inc. and Bankaitis AU, Kemp RJ. [2005] *Infection Control in the Audiology Clinic*. St. Louis, MO: Auban, Inc. Reprinted with permission by Auban, Inc.

the clinician's manual dexterity, creating potential frustration during the execution of procedures and/or increasing the likelihood for an accident to occur that could otherwise be avoided. One-size-fits-all gloves should be avoided since they are not designed to fit most hands appropriately.

Gloves are considered one-time use items and should not be reused. Furthermore, the same pair of gloves should not be used on different patients. After use, gloves should be properly removed and disposed. Unless grossly contaminated

FIGURE 46.1 Appropriately sized glove that fits tightly, adhering closely to the skin. Reprinted with permission by Auban, Inc.

FIGURE 46.2 Loosely fitted gloves inappropriate for audiologic procedures, resulting in loss of manual dexterity and difficulty handling and/or manipulating objects. Reprinted with permission by Auban, Inc.

with blood or other bodily fluids, gloves may be disposed of in the regular trash or according to the protocol dictated by the hearing care facility. It is highly unlikely for standard clinical procedures related to communication, hearing, and swallowing disorders to result in copious amounts of blood or bodily fluid contamination to require arrangements for hazardous waste removal.

MASKS, EYE PROTECTION, AND GOWNS

Disposable masks, safety glasses, and gowns must be worn when there is a risk of splash or splatter of blood, bodily fluids, secretions, or excretions or when the clinician may be at risk of airborne contamination. The protective barriers, masks and eye protection, should be worn when using buffing wheels or drills during hearing aid or earmold modification procedures. Clinicians providing services to hospital patients with tuberculosis (TB) must wear special TB masks when the diagnosed patient has not been on an antibiotic regimen for 10 days.

As with gloves, disposable masks are not reusable and should be disposed of properly. Eye protection may or may not be reusable as dictated by the specific manufacturer's intended design. Disposable eye protection must be disposed of according to the healthcare facility's established protocol. Conversely, reusable eye protection should be cleaned and properly decontaminated according to the manufacturers' instructions (WHO, 2004). Finally, contaminated or soiled gowns should be removed as soon as possible with disposable gowns being discarded appropriately; reusable gowns necessitating laundering must be routed to the appropriate laundering facility.

Hand Hygiene

Hand hygiene represents the single most important procedure for effectively limiting the spread of infectious disease (Bankaitis and Kemp, 2003, 2005). It is one of the most criti-

TABLE 46.4

Hand Hygiene Guidelines for Audiologists

- Prior to initial contact with patient, at the beginning of the patient appointment
- At the end of patient contact
- After glove use, immediately after removing gloves
- Before eating, drinking, smoking, applying lotion or makeup
- After eating, drinking, smoking, applying lotion or makeup
- After using bathroom facilities
- Any time it is felt necessary and appropriate

Source: Adapted from Bankaitis AU, Kemp RJ. [2005] *Infection Control in the Audiology Clinic*. St. Louis, MO: Auban, Inc. and Bankaitis AU, Kemp RJ, Krival K, Bandaranayake DW. [2005] *Infection Control for Speech-Language Pathology*. St. Louis, MO: Auban, Inc. Reprinted with permission from Auban, Inc.

cal components of a basic infection control program. Hand hygiene involves the process of washing hands with soap and water or using antimicrobial “no-rinse” hand degermers. Traditional hand washing involves the use of hospital-grade, liquid soap. Hospital-grade soap is gentler than household soaps and contains special emollients that moisturize the skin and are effective in reducing or minimizing chapping, chafing, or drying of the skin from excessive hand washing (Bankaitis and Kemp, 2003, 2005). Antimicrobial “no-rinse” products refer to the alcohol-based hand rubs that do not require the use of or access to running water. The availability and accepted use of alcohol-based, no-rinse hand degermers have led to a substantial increase in hand hygiene compliance among healthcare workers. The CDC specifies that hand hygiene procedures must occur prior to the initiation of invasive procedures, before providing services to patient, and after glove removal, and any time that the professional feels it is warranted (CDC, 2002). Table 46.4 provides a guideline as to when hand hygiene should be performed.

Cleaning and Disinfecting

As outlined in Table 46.5, cleaning refers to procedures in which gross contamination is removed from surfaces or objects without killing germs (Bankaitis and Kemp, 2003, 2005). It does not necessarily involve any degree of germ killing; rather, it serves as an important precursor to disinfecting. Cleaning must occur prior to disinfection; the absence of precleaning a surface will diminish the effectiveness of disinfecting techniques (Kemp and Bankaitis, 2000). In contrast, disinfection refers to a process in which germs are killed. The degree of disinfection that can occur expands across a fairly wide continuum and depends on the specific type and number of microorganisms a product kills.

TABLE 46.5

Definition of Infection Control Terms

Cleaning	Removal of gross contamination without necessarily killing germs
Disinfecting	Process in which germs are killed
Sterilization	Process in which 100% of germs are killed, including associated endospores

Both touch and splash surfaces must be cleaned and then disinfected between patient appointments. Surfaces that come in regular direct or indirect contact with patients and/or clinicians are referred to as touch surfaces. Following each patient appointment and before commencing with the next appointment, countertops, tables, service areas, and the armrest of chairs must be cleaned and disinfected. Splash surfaces are essentially the same thing but involve surfaces that have been contaminated by particles expelled by a patient or clinician, such as when a patient coughs, sneezes, or drools on a surface. As with touch surfaces, splash surfaces must also be cleaned and disinfected after each patient appointment.

Critical Instruments and Sterilization

Critical instruments refer to instruments or objects that meet at least one of the following three criteria: (1) Reusable item introduced directly into the bloodstream (e.g., needles); (2) reusable, noninvasive instrument that comes in contact with intact mucous membranes or bodily substances (e.g., blood, saliva, cerumen, mucous discharge, pus); or (3) a reusable, noninvasive instrument that can potentially penetrate the skin from use or misuse (instruments used for cerumen removal, instruments inserted in the nose, mouth, etc.). Within the context of audiology, reusable items that make contact with mucous membranes, saliva, or cerumen and are intended to be used with multiple patients should be cleaned first and then sterilized. Although not necessarily an exhaustive list, examples of instruments reusable include immittance probe tips contaminated with copious amounts of cerumen and/or drainage and reusable cerumen removal instruments (curettes, hooks, suction tubes).

The term sterilization refers to killing 100% of vegetative microorganisms, including associated endospores (Table 46.5). When microbes are challenged, they revert to the more resistant life form called a spore (Kemp and Bankaitis, 2000). Sterilants, by definition, must neutralize and destroy spores because if the spore is not killed, it may become vegetative again and cause disease. Whereas disinfection involves killing germs, sterilization involves killing all germs and associated endospores each and every time (Bankaitis and Kemp, 2007).

There are several different sterilization techniques including the use of an autoclave or the application of cold sterilization techniques. Since the autoclave involves pressurized heat, most audiologists will be limited to utilizing cold sterilization techniques since reusable rubber, silicone, plastic, or acrylic objects will not withstand traditional heat pressurization sterilization techniques. Cold sterilization involves soaking instruments in liquid chemicals approved by the Environmental Protective Agency (EPA) for a specified number of hours. Only two ingredients have been approved by the EPA as sterilants: (1) Glutaraldehyde and (2) hydrogen peroxide. Products containing the active ingredient glutaraldehyde in concentrations of 2% or higher or those containing the active ingredient hydrogen peroxide (H_2O_2) in concentrations of 7.5% or higher may be used to sterilize instruments.

Reusable items to be sterilized must be cleaned first because organic material (e.g., blood and proteins) may contain high concentrations of microorganisms with chemical germicide properties that can negatively impact the sterilization process. In addition, it is imperative for cold sterilization procedures to be followed according to instructions provided by the product manufacturer. Soaking times necessary to achieve sterilization will differ from solution to solution. Whereas most glutaraldehyde-based products require 10 hours of soaking time to achieve sterilization, hydrogen peroxide products typically require 6 hours of soaking time. Removing instruments or objects prior to the necessary soaking time will result in high-level disinfection and not sterilization. Reviewing product information for instruction of use is critical.

Disposal of Infection Waste

Within the context of audiology, disposable items contaminated with saliva, mucous, discharge, cerumen, blood, or blood by-products may be disposed of in regular waste receptacles; however, in the event the item is contaminated with copious amounts, it should first be placed in a separate, impermeable bag (i.e., bio-hazard bag) and only then discarded in the regular trash (Bankaitis and Kemp, 2003, 2005). This practice will separate the contaminated waste from the rest of the trash and minimize the chance of maintenance or cleaning personnel coming in casual contact with it. Disposing of sharp objects such as razors or needles requires special consideration and must be disposed of in a puncture-resistant, disposable container (sharps container).

WRITTEN INFECTION CONTROL PLAN

Whereas standard precautions serve as the guideline as to how audiologists must modify diagnostic and/or rehabilitative procedures for purposes of minimizing the spread

TABLE 46.6**Required Sections of Written Infection Control Plan as Outlined by OSHA**

Employee exposure classification
Hepatitis B [HBV] vaccination plan and records of vaccination
Plan for annual training and records of training
Plan for accidents and accidental exposure follow-up
Implementation protocols
Postexposure plans and records

of disease, the written infection control plan serves as the guiding cornerstone of the specific clinic's global infection control plan, outlining exactly how infection control goals are to be achieved. OSHA requires each facility in the United States to have a written infection control plan and for that plan to be available to all workers. As listed in Table 46.6, the written plan must include specific requirements mandated by OSHA. The following sections review each required element in further detail.

Employee Exposure Classification

Employees must be assigned into one of three different categories according to the potential degree in which a specific employee may be exposed to blood and other infectious substances based on primary work responsibilities. Category one employees include personnel whose primary job assignment exposes them to potential cross-infection with blood-borne diseases or other potentially infectious microbes. This category typically includes physicians, nurses, paramedics, and dentists. Audiologists whose primary job responsibilities include intraoperative monitoring procedures may be categorized as category one employees. Category two employees include personnel whose secondary job assignment potentially exposes them to cross-infection. Most practicing audiologists will fall in this category, including AuD students in training. Finally, employees classified in category three include personnel whose job requirements in the office never expose them to blood or other bodily fluids including administrators and receptionists who do not provide clinical services.

Hepatitis B (HBV) Vaccination Plan and Records of Vaccination

Employers must offer employees in healthcare settings the opportunity to receive a HBV vaccination. The HBV vaccination must be offered to all category one and category two employees free of charge. The employee is not required to accept the offer of vaccination; in the event the employee refuses vaccination, a waiver must be signed noting the

refusal of the offered vaccine and filed in the employee records. OSHA requires that this record be retained for length of employment plus 30 years (Kemp et al., 1996).

Plan for Annual Training and Records of Training

OSHA requires a plan for annual training and maintenance of records documenting that such training occurred. Specifically, OSHA has outlined that infection control training must include explanations of symptoms and modes of transmission of blood-borne diseases, location and handling of personal protective equipment, information on the HBV vaccine, and follow-up procedures to be taken in the event of an exposure incident. Although the standard does not specify length of training, infection control training must be provided to new employees at the time of initial assignment and then minimally every year thereafter. Each facility is to conduct and document completion of annual infection control training for each employee. During the course of the year, if an update or new procedure is to be implemented, appropriate training must be conducted in a timely fashion to ensure that the new or updated procedures are understood and implemented. Established employees changing exposure classification categories must undergo infection control retraining within 90 days of the change in classification category. Records of these training sessions are to be filed with the infection control plan in a designated location.

Plan for Accidents and Accidental Exposure Follow-up

The fourth requirement of the written infection control plan involves outlining specific steps to be taken in the event an accident occurs within the clinical environment, which can expose individuals to blood-borne pathogens or other potentially infectious agents, and steps to be taken in the event an employee is accidentally exposed to blood-borne pathogens or other potentially infectious agents. For example, in the event a patient falls and suffers a nosebleed, or becomes sick, every staff member should know what steps to take to address the accident. In addition, accidental exposures to blood-borne pathogens require follow-up. Although these encounters may be relatively rare in audiology environments, an emergency plan must be created and put in place.

Implementation of Protocols

This section of the written infection control plan specifically outlines protocols that dictate how specific procedures will be executed in the clinical environment for purposes of minimizing exposure to potentially infectious

agents. Written procedures that outline how an audiologist is to execute a diagnostic or rehabilitative procedure in a manner designed to minimize or eliminate the likelihood of cross-contamination or exposure to a potentially infectious agent are referred to as a work practice control. Since the extent of services provided by a specific employer will differ from clinic to clinic, the types of work practice controls outlined will differ from clinic to clinic depending on what diagnostic and or rehabilitative services are being provided. For example, a clinic employing audiologists who only provide intraoperative monitoring will maintain different work practice controls within the organization's infection control plan than a public school employing an audiologist.

Furthermore, there exists a certain amount of flexibility as to how a diagnostic procedure can be appropriately executed. Whereas work practice controls are to be developed with the five standard precautions in mind, the degree to which a specific clinic chooses to be more conservative in infection control procedures remains an individual decision made by a particular clinic. For example, one clinic may determine that otoscopy can be performed with ungloved hands following hand hygiene procedures and only in those instances where ear drainage and/or abrasions at the level of the patient's ear and/or clinicians hands are not evident. If ear drainage and/or any abrasions are present, the use of gloves will be mandated. In contrast, another clinic may decide that any procedure requiring direct patient contact, such as otoscopy, will require audiologists to use gloves without exception. Either approach is acceptable and consistent with the goal of a written infection control plan. An inappropriate approach that would involve the development of a work practice control specifically designed, for example, to disallow the use of gloves from the perspective of saving money and reducing overhead costs is not appropriate. Developing audiology-specific work practice controls are beyond the scope of this chapter. For more detailed information on infection control work practice controls for audiology and access to infection control templates, the reader is referred to the book *Infection Control for the Audiology Clinic* by Bankaitis and Kemp (2005).

Postexposure Plans and Records

Finally, the last requirement of an infection control plan as dictated by OSHA involves record keeping of documents related to treatment and subsequent outcomes associated with exposure to potentially infectious pathogens, including HIV.

SUMMARY

Audiologists conduct a variety of diagnostic and rehabilitative procedures that pose a potential risk of exposure to

saliva, mucosal secretions, bodily fluids, cerumen, blood, and blood by-products. It is important to recognize the risks associated with exposure to such substances as well as the consequences of cross-contamination to the potential health of both the clinician and the patient. As reiterated throughout this chapter, these risks can be significantly minimized with the implementation and execution of appropriate infection control protocols. The goal of an infection control plan is to consciously manage the clinical environment for the specific purposes of eliminating or minimizing the spread of disease. Producing a written infection control plan is a requirement and associated work practice controls designed to outline how audiologic procedures will be executed must appropriately apply standard precautions.

FOOD FOR THOUGHT

1. I wear gloves whenever I take earmold impressions and remove any wax. Do I really need to use them only once? Isn't this more to protect me than my client? Gloves can be expensive.
2. I wash my hands so often in the clinic that they become cracked and dried out after several clinical days in a row. Do I really need to wash my hands after every client?
3. Instead of washing my hands, can't I just use some form of sanitizing agent? Can I also clean my audiological equipment such as probe tips in this same agent?

SECTION V

Appendices

Genetics Glossary (Terminology)

Here we provide definitions of terms used in Chapter 25 that may not be familiar to audiologists. While this serves as a supplement to the chapter on hereditary hearing loss, it is not all-inclusive. Curious readers are referred to several excellent online glossaries of genetics terminology. These include the glossary in Genetics Home Reference (<http://ghr.nlm.nih.gov/glossary>), the illustrated glossary found in GeneReviews (<http://www.ncbi.nlm.nih.gov/books/NBK5191/>) and the Talking Glossary of Genetics Terms produced by the National Genome Research Institute (<http://www.genome.gov/glossary/>).

Adenine: One of the four chemical bases in *DNA* and *RNA*. The others are *cytosine*, *guanine* and *thymine* (*uracil* in *RNA*). It pairs with thymine on the complimentary *DNA* strand. Adenine is represented by the letter A.

Allele: One version of a *gene* or a specified location (*locus*) on a *chromosome* (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Amino acid: Molecules that are the building blocks of *proteins*. There are a total of 20 amino acids encoded by *nucleotides* in *DNA*. A series of three nucleotides (or one *codon*) encodes a specific amino acid. Many amino acids are strung together in long chains to form proteins.

Aneuploidy: One or more extra or missing *chromosomes*. For example, *trisomy* or *monosomy*.

Anterior lenticonus: Eye disorder in which the lens bulges in an anterior direction (toward the front of the body). Diagnosis can be made by microscopic examination of the eye. This finding is a characteristic feature of Alport syndrome.

Autosomal/autosomes: Refers to any of the *chromosomes* other than the sex-determining chromosomes (i.e., the X and Y); can also refer to the *genes* on the nonsex chromosomes (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Autosomal dominant: Type of inheritance pattern in which a single mutant copy of a *gene* on any one of the nonsex *chromosomes* is required for expression of a condition or characteristic. That is, one *wild-type* allele and one mutant allele are sufficient to confer disease.

Autosomal recessive: Type of inheritance pattern in which two mutant copies of a *gene* (i.e., two mutant *alleles*) on a *homologous* pair of any of the nonsex *chromosomes* are required for expression of a condition or characteristic.

Base pairs: Pairs of chemical bases that bond to each other in the double strands of *DNA*. *Adenine* always pairs with *thymine*, and *cytosine* always pairs with *guanine*.

Biallelic: Involving both *alleles* of a *gene*.

Biotinidase deficiency: *Heritable* condition in which the body is unable to process the vitamin biotin appropriately. Treatment with biotin supplements helps to reduce or prevent symptoms, including hearing loss.

Centromere: Constricted region that separates the long arm (*q arm*) and short arm (*p arm*) of the *chromosome*.

Choana (pl. choanae): Either one of the paired openings of the nasal cavity into the nasopharynx.

Chromosome: Physical structure consisting of *DNA* and supporting *proteins* called chromatin. Human cells normally contain 46 chromosomes identified as 23 pairs; 22 pairs are *autosomes* and 1 pair are the sex chromosomes (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Codon: Set of three adjacent *nucleotides* that collectively code for an *amino acid*, or the initiation (start codon) or end (stop codon) of *translation* of coding *DNA* into amino acids.

Coloboma: Congenital malformation, often described as a hole, in a structure of the eye (e.g., iris, retina, lid, optic nerve, etc.).

Compound heterozygote: Individual who has two different mutant *alleles* at a particular *locus*, one on each *chromosome* of a pair; usually refers to individuals affected with an *autosomal recessive* disorder (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Consanguineous: Term used to describe individuals with common ancestry; related by blood

Consanguinity: State of being *consanguineous*.

Cytogenetics: Branch of biology concerned primarily with studying *chromosomes*.

Cytosine: One of the four chemical bases in *DNA* and *RNA*. The others are *adenine*, *guanine*, and *thymine* (*uracil* in *RNA*). It pairs with guanine on the complimentary *DNA* strand. Cytosine is represented by the letter C.

Deletion: Loss of genetic material, ranging from a single *nucleotide* to an entire piece of a *chromosome*. An analogy of one type of deletion at the molecular level is shown in Table 25.1.

De novo mutation: Genetic *mutation* that occurs in the germ cell (i.e., sperm or egg) or fertilized embryo; a new mutation. The mutation is not carried by either parent.

Digenic inheritance: Additive disease-causing interaction of *mutations* of two different *genes* at different *loci* (vs. recessive conditions where mutations occur at corresponding *alleles* at the same locus).

DNA: Deoxyribonucleic acid; the molecule that encodes the *genes* responsible for the structure and function of an organism and allows for transmission of genetic information from one generation to the next (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Duplication: Type of *mutation* in which there is an extra copy of a *gene* or segment of contiguous *DNA* resulting in extra genetic material on the *chromosome*.

Dysmorphic: Structural abnormality of the anatomy, often congenital.

Dystopia canthorum: Lateral displacement of the inner canthus of the eyes that gives the appearance of a wide nasal bridge.

Encephalomyopathy: Disorder or disease of the brain or spinal cord; often referring to global dysfunction in these structures.

Euploidy: Normal number of *chromosomes*. In humans there are 23 pairs of chromosomes, 46 in total; 44 of these chromosomes are *autosomes*, and 2 are sex chromosomes (X or Y). This is typically expressed as 46, XX in females and 46, XY in males.

Exome: Collectively, all of the *exons* in the *genome* of a given organism or cell.

Exon: Sequence of *DNA* that remains present (i.e., is not removed) in the mature messenger *RNA* and that codes for the amino acids of the protein product (modified from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Expansion: Type of genetic *mutation* in which a segment of *DNA* is aberrantly repeated within a sequence. An analogy of expansion at the molecular level is shown in Table 25.1.

Expression: In genetics (1) the detectable outcome(s) of a *gene*; the observable effect of a gene in traits. For example, if a person has a mutation in a gene that is critical for hearing and as a result, that person has a hearing loss. The *genotype* has caused a hearing loss *phenotype* (i.e., the hearing loss trait is *expressed*). Also (2), expression of a gene to produce a protein product.

Frameshift mutation: Type of genetic *mutation* when an *insertion* or *deletion* of *nucleotides* occurs by some multiple other than three so that all subsequent *codons* will be affected, thus shifting the entire reading frame of the remaining sequence. An analogy of a frameshift mutation is provided in Table 25.1.

Gene: The basic unit of heredity, consisting of a segment of *DNA* arranged in a linear manner along a *chromosome*. A gene codes for a specific *protein* (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Gene therapy: Altering the *expression* of abnormal *genes* with genes that function normally in an attempt to treat a genetic condition.

Genetic markers: Identifiable segment of *DNA* with enough variation among individuals that its inheritance and coinheritance with *alleles* of a given *gene* can be traced (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Genetic modifiers: See *modifier genes*.

Genome: Entirety of an organism's genetic material. This includes *DNA* sequences that code for *genes* and *DNA* sequences that are noncoding.

Genotype: An organism's specific genetic composition; the combination of *alleles* specific to an individual. Also can refer to a specific pair of alleles at a given *locus*.

Guanine: One of the four chemical bases found in *DNA* and *RNA*. The others are *adenine*, *cytosine*, and *thymine* (*uracil* in *RNA*). It pairs with cytosine on the complementary *DNA* strand. Guanine is represented by the letter G.

Hemizygous: Refers to an individual with only one copy of a *gene* pair or one member of a *chromosome* pair. For example, males are hemizygous for many genes on both the X and Y chromosomes because they have only one copy of each of these genes.

Heritability: Ability of a trait to be inherited (i.e., passed from parent to offspring); the proportion of observable traits related to genetic factors.

Heterogeneity: In genetics, when mutations of different *genes* independently result in a single *phenotype*. For example, hereditary hearing loss can result from mutations in many different genes (i.e., it is a *heterogeneous* condition).

Heteroplasmy: The situation in which, within a single cell, there is a mixture of mitochondria, some containing mutant *DNA* and some containing normal *DNA* (from GeneReviews: <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Heterozygous: Refers to an individual with two different variations of the paired *alleles* of a *gene*; in such cases the person is heterozygous for that gene.

Homologous (chromosomes): A pair of chromosomes—one maternally derived and one paternally derived. The organization of *loci* on each chromosome should be the same.

Homozygous: Refers to an individual with identical copies of the paired *alleles* of a *gene*; in such cases the person is homozygous for that gene.

Insertion: Type of genetic *mutation* when segments of *DNA* ranging from one to several *nucleotides* in length are incorrectly inserted within a sequence. An analogy of insertion at the molecular level is shown in Table 25.1.

Intron: Noncoding segment of *DNA* interspersed among *exons*; a portion of a *gene* that does not function in coding for *amino acids*. The functions of introns are not entirely understood, but they are removed during the process of *RNA* editing to produce the mature *RNA* that is *translated* into a protein product.

Inversion: When a segment of a *chromosome* breaks off and is reinserted in a reverse order within the same chromosome.

- Iris heterochromia:** Differently colored areas of the same eye, or each eye being a different color.
- Karyotype:** Collective number, structure, and organization of *chromosomes*; can refer to the chromosomal character of either an individual or a species.
- Locus (pl. loci):** Specific physical location of a *gene* on a *chromosome*.
- Matrilineal inheritance:** Traits passed from parent to offspring, only through the female (maternal) line. This is typically via *mtDNA*.
- Meiosis:** A phase of nuclear cell division that results in four daughter cells that each contain half the number of *chromosomes* of the parent cell. Meiosis results in the production of sperm and oocytes containing exactly one of each chromosome.
- Mendelian inheritance:** Process by which traits are passed from parent to offspring via a single *gene locus* following a set of principles proposed by Gregor Mendel: The Law of Segregation (one copy of each gene pair is inherited separately from each parent) and the Law of Independent Assortment (separate genes for different traits are inherited independently of each other).
- Messenger RNA (mRNA):** One of the three types of ribonucleic acid (RNA), mRNA is the spliced, or processed, transcript that is exported from the cell nucleus to the ribosomes in the cytoplasm where transcription occurs. *Amino acids* encoded by the mRNA are assembled to form *proteins*.
- Missense mutation:** Type of genetic *mutation* in which a single *nucleotide* is substituted for another, the outcome of which causes the substitution of a different amino acid. An analogy of a missense mutation is shown in Table 25.1.
- Mitochondria:** Subunit of a cell (organelle) with a primary role of supplying the chemical energy within the cell.
- Mitochondrial DNA (mtDNA):** The unique *DNA* of mitochondria, which is separate from nuclear *DNA*. Because sperm cells lose their mitochondria during fertilization, mtDNA is only inherited from the female parent (*matrilineal inheritance*) and is passed on to all of her offspring.
- Mitosis:** A phase of cell division where the replication of cells results in two daughter cells that carry the exact *chromosomes* and nuclear *DNA* as the parent cell.
- Modifier genes:** *Genes* that alter, or modify, the *expression* of a different gene. These can influence the onset, progression, and severity of disease.
- Monogenic inheritance:** When *heritable* conditions or traits are caused by a mutation in a single *gene*.
- Monosomy:** Total or partial loss of one copy of a *chromosome* pair.
- Mosaicism:** When a single organism has some cells that carry a different *genome* than other cells in the body.
- Multifactorial inheritance:** Inheritance related to multiple factors, at least one of which is genetic; can describe the direct and indirect interaction between *genes* and environmental exposures that, collectively, results in disease.
- Mutation:** A mutation is an alteration in the *nucleotide* sequence of a *gene*. A mutation may be benign with no functional consequence (*polymorphism*), it may cause disease or dysfunction, or it may be beneficial to the organism.
- Nonsense mutation:** Type of genetic *mutation* in which a single *nucleotide* is substituted for another, resulting in the production of a premature *stop codon*. An analogy of a nonsense mutation is shown in Table 25.1.
- Nonsyndromic:** Not part of a *syndrome*; a disorder that occurs in isolation. For example, hearing loss in the absence of other clinical signs.
- Nucleotide:** Molecules composed of a nitrogenous base, a five-carbon sugar (ribose or deoxyribose) and at least one phosphate group. Nucleotides are the basic building blocks of *DNA* and *RNA*.
- Obligate Carriers:** Family members who have one copy of a genetic *mutation* in question based on the pattern of inheritance and genotype of their offspring.
- p arm:** Short arm of a *chromosome*.
- Pathognomonic:** Indicative of disease; a finding or findings characteristic of a particular disease and not observed with other conditions; a diagnostic marker.
- Patrilineal inheritance:** Traits passed from parent to offspring, only through the male (paternal) line. This is typically via the *Y chromosome*.
- Pedigree:** Visual representation of a family's health history through a common set of symbols; charting tool used to catalog the occurrence and presentation of *phenotypes*, with genetic relationships traced through connecting lines and across generations.
- Penetrance:** Percentage of individuals with a genetic *mutation* that express the associated trait; often related to *dominant inheritance*, the percentage of individuals who carry a dominant *mutation* who actually *express* the trait. *Modifier genes* also affect penetrance.
- Phenocopy:** Condition in which an environmentally caused trait mimics an inherited trait. For example, hearing loss from chemotherapy versus hereditary hearing loss.
- Phenotype:** Manifestation of *genes* into observable traits; the observable properties of an organism (e.g., eye color, height, hearing loss).
- Pleiotropy:** Multiple, seemingly unrelated *phenotypes* that result from a single genetic *mutation(s)*.
- Point mutation:** Type of genetic *mutation* in which a single *nucleotide* is substituted for another, but the total number of nucleotides in the sequence remains unchanged.
- Polygenic inheritance:** Cumulative effect of many *genes* on a *phenotype*; in contrast to effects from a single gene or pair of genes.
- Polymorphism:** Variations in a *gene*, or *DNA* sequence that occur with high frequency in a population. They can range from a single nucleotide polymorphism (SNP) to changes in large segments of *DNA*, but they are nondisease causing.

Polyploidy: Extra copy of an entire set of *chromosomes*; common in some species, but lethal in humans.

Proband: First affected family member to come to medical attention.

Protein: Class of molecules made up of long chains of *amino acids*, encoded by *DNA* or *RNA*. Proteins have wide-ranging functions including structure, function, and regulation of organs and tissues in the body.

q arm: Long arm of a *chromosome*.

Retinitis pigmentosa: Degenerative disease of the retina in the eye; characterized by decreased vision at night and loss of peripheral vision.

Ribonucleic acid (RNA): Biological molecule with vital roles in coding, decoding, regulation, and expression of *genes*. It is composed of a single strand of bases (A, C, G and U) and a ribose–phosphate backbone.

Ribosomal RNA (rRNA): RNA component of the *ribosome*. rRNA directs the translation of mRNA into *proteins*.

Ribosome: Cellular complex that helps bind *amino acids* to form *proteins* during the process of *translation*.

Segregation: Separation of *phenotypic* or *genotypic* elements within a population.

Sex-linked inheritance: Type of inheritance pattern in which there is a *mutation* in a *gene* on one of the sex *chromosomes*. When the mutated gene is on the X chromosome, this pattern is termed X-linked inheritance. When the mutated gene is on the Y chromosome this pattern is termed Y-linked inheritance.

Start Codon: Specific group of three *nucleotides* in a coding region of a *gene* that encode the beginning of the chemical *translation* into a *protein*.

Stop Codon: Specific group of three *nucleotides* in a coding region of a *gene* that encode the end of the chemical *translation* into a *protein*.

Syndromic: The co-occurrence of related symptoms or signs associated with disease. For example, individuals with Usher syndrome have hearing loss and retinitis pigmentosa.

Telomere: Region of repetitive *nucleotide* sequences at each end of the *chromosome*.

Thymine: One of four chemical bases in *DNA*. The others are *adenine*, *cytosine*, and *guanine*. It pairs with guanine on the complimentary DNA strand. Thymine is represented by the letter T. Thymine is replaced by *uracil* (U) in *RNA*.

Transcription: The process of synthesizing *RNA* from a *DNA* template.

Transfer RNA (tRNA): Located in the cytoplasm of a cell, transfer RNA delivers an *amino acid* to the ribosome that corresponds to each three-*nucleotide codon* of *mRNA*. The amino acid is transferred to the growing polypeptide chain on the ribosome to make *proteins*.

Translation: The process of synthesizing an *amino acid* sequence (*protein* product) from the *messenger RNA* (mRNA) code (from GeneReviews, <http://www.ncbi.nlm.nih.gov/books/NBK5191/>).

Translocation: Change of location. In genetics this typically refers to transfer of a segment of a *chromosome* to a new position, most often on another chromosome.

Trisomy: Total or partial gain of one copy of a *chromosome* pair.

Uracil: One of the four chemical bases in *RNA*. The others are *adenine*, *cytosine*, and *guanine*. Uracil is represented by the letter U. *Thymine* on *DNA* is replaced by uracil on *RNA*.

Variable expressivity: Variation in the *phenotypic* expression among individuals who carry the same genetic *mutation* (e.g., varying degrees of hearing loss).

Wild type: The *genotype* or *phenotype* most commonly observed in nature.

IDEA 2004 Key Regulations Pertaining to Deaf Education and Audiology

PART B: RELATED SERVICES 34 CFR 300.34(b)

Exception; services that apply to children with surgically implanted devices, including cochlear implants.

- [1] Related services do not include a medical device that is surgically implanted, the optimization of that device's functioning (e.g., mapping), maintenance of that device, or the replacement of that device.
- [2] Nothing in paragraph (b)(1) of this section:
 - (i) Limits the right of a child with a surgically implanted device (e.g., cochlear implant) to receive related services (as listed in paragraph (a) of this section) that are determined by the IEP Team to be necessary for the child to receive FAPE.
 - (ii) Limits the responsibility of a public agency to appropriately monitor and maintain medical devices that are needed to maintain the health and safety of the child, including breathing, nutrition, or operation of other bodily functions, while the child is transported to and from school or is at school; or
 - (iii) Prevents the routine checking of an external component of a surgically implanted device to make sure it is functioning properly, as required in §300.113(b).

PART B: DEFINITION OF AUDIOLOGY 34 CFR 300.34(c)(1)

Audiology includes:

- (i) Identification of children with hearing loss;
- (ii) Determination of the range, nature, and degree of hearing loss, including referral for medical or other professional attention for the habilitation of hearing;
- (iii) Provision of habilitation activities, such as language habilitation, auditory training, speech reading (lip-reading), hearing evaluation, and speech conservation;
- (iv) Creation and administration of programs for prevention of hearing loss;
- (v) Counseling and guidance of children, parents, and teachers regarding hearing loss; and
- (vi) Determination of children's needs for group and individual amplification, selecting and fitting an appropriate aid, and evaluating the effectiveness of amplification.

PART C: DEFINITION OF AUDIOLOGY 34 CFR 303.12(d)

Audiology includes:

- (i) Identification of children with impairments, using at risk criteria and appropriate audiological screening techniques;
- (ii) Determination of the range, nature, and degree of hearing loss and communication functions, by use of audiologic evaluation procedures;
- (iii) Referral for medical and other services necessary for the habilitation or rehabilitation of children with auditory impairment;
- (iv) Provision of auditory training, aural rehabilitation, speech reading and listening device orientation and training, and other services;
- (v) Provision of services for the prevention of hearing loss; and
- (vi) Determination of the child's need for individual amplification, including selecting, fitting, and dispensing of appropriate listening and vibrotactile devices, and evaluating the effectiveness of those devices.

PART B: INTERPRETING SERVICES 34 CFR 300.34(c)(4)

Interpreting services includes:

- (i) The following when used with respect to children who are deaf or hard of hearing: Oral transliteration services, cued language transliteration services, and sign language transliteration and interpreting services, and transcription services, such as communication access real-time translation (CART), C-Print, and TypeWell; and
- (ii) Special interpreting services for children who are deaf-blind.

PART B: ASSISTIVE TECHNOLOGY 34 CFR 300.105(a)(2)

On a case-by-case basis, the use of school-purchased assistive technology devices in a child's home or in other settings is required if the child's IEP Team determines that the child needs access to those devices in order to receive FAPE.

PART B: ROUTINE CHECKING OF HEARING AIDS AND EXTERNAL COMPONENTS OF SURGICALLY IMPLANTED MEDICAL DEVICES 34 CFR 300.113

- (a) *Hearing aids.* Each public agency must ensure that hearing aids worn in school by children with hearing impairments, including deafness, are functioning properly.
- (b) *External components of surgically implanted medical devices.*
 - (1) Subject to paragraph (b)(2) of this section, each public agency must ensure that the external components of surgically implanted medical devices are functioning properly.
 - (2) For a child with a surgically implanted medical device who is receiving special education and related services under this part, a public agency is not responsible for the postsurgical maintenance, programing, or replacement of the medical device that has been surgically implanted (or of an external component of the surgically implanted medical device).

PART B: DEVELOPMENT, REVIEW, AND REVISION OF IEP, CONSIDERATION OF SPECIAL FACTORS 34 CFR 300.324(2)(iv)

The IEP Team **must**:

- (iv) Consider the communication needs of the child, and in the case of a child who is deaf or hard of hearing, consider the child's language and communication needs, opportunities for direct communications with peers and professional personnel in the child's language and communication mode, academic level, and full range of needs, including opportunities for direct instruction in the child's language and communication mode; and
- (v) Consider whether the child needs assistive technology devices and assistive technology services.

ASSISTIVE TECHNOLOGY; PART B: 34 CFR 300.5-.6 AND C: 34 CFR 303.12

Assistive technology device means any item, piece of equipment, or product system, whether acquired commercially

off the shelf, modified, or customized, that is used to increase, maintain, or improve the functional capabilities of children with disabilities. The term does not include a medical device that is surgically implanted, or the replacement of such device.

Assistive technology service means any service that directly assists a child with a disability in the selection, acquisition, or use of an assistive technology device. The term includes:

- (a) The evaluation of the needs of a child with a disability, including a functional evaluation of the child in the child's customary environment;
- (b) Purchasing, leasing, or otherwise providing for the acquisition of assistive technology devices by children with disabilities;
- (c) Selecting, designing, fitting, customizing, adapting, applying, maintaining, repairing, or replacing assistive technology devices;
- (d) Coordinating and using other therapies, interventions, or services with assistive technology devices, such as those associated with existing education and rehabilitation plans and programs;
- (e) Training or technical assistance for a child with a disability or, if appropriate, that child's family; and
- (f) Training or technical assistance for professionals (including individuals providing education or rehabilitation services), employers, or other individuals who provide services to, employ, or are otherwise substantially involved in the major life functions of children with disabilities.

PART B: DEFINITIONS 34 CFR 300.8(b)

- [1] *Deaf-blindness* means concomitant hearing and visual impairments, the combination of which causes such severe communication and other developmental and educational needs that they cannot be accommodated in special education programs solely for children with deafness or children with blindness.
- [2] *Deafness* means a hearing impairment that is so severe that the child is impaired in processing linguistic information through hearing, with or without amplification that adversely affects a child's educational performance.
- [3] *Hearing impairment* means an impairment in hearing, whether permanent or fluctuating, that adversely affects a child's educational performance but that is not included under the definition of deafness in this section.

Functional Skills Screening for Children with Hearing Loss¹

This functional skill screening is designed to gain a profile of a child's general development as well as skills that are specifically impacted by hearing impairment. It may also be used to monitor a child's development over time. Information may be obtained through observation, review of records, interview with family members, or the child directly. Tools such as Ida's *My World* may also be helpful in gaining an understanding of the child's perceptions. Any concerns raised in this process should be discussed with the child's parents, early intervention provider, teacher of the deaf, speech–language pathologist, classroom teacher, or other appropriate personnel so that they are addressed in the child's developmental or educational program.

Name _____ Date _____ AGE _____ Person completing form _____

PROFILE

Domain	Skill Area	1	2	3	4	5
Cognitive/ Behavioral/ Social	Thinking/Reasoning					
	Learning Style/Attention					
	Social/Classroom Behavior					
	Life Skills					
Self-Advocacy	Knowledge					
	Application					
Communication	Expressive					
	Receptive					
Physical	Vision					
	Use of Limbs					
	Balance					
	Overall Physical Health					
Language	Receptive					
	Expressive					
Speech Intelligibility	Skills					
Auditory & Listening Skills	Use of Amplification					
	Audition & Listening					

Directions: Rate each domain using the scale that follows. Then complete the profile by checking the box that corresponds with the score for each skill area of each domain.

- 1 Age Appropriate
- 2 Mild Limitation
- 3 Moderate Limitation
- 4 Moderately Severe Limitation
- 5 Severe Limitation

¹Cheryl DeConde Johnson (2013). Adapted from the Colorado Individual Performance Profile (CIPP) (2004), Colorado Department of Education; Karchmer & Allen (1999), *The Functional Assessment of Deaf/Hard of Hearing Students* 144(2), 68–77; and from Liebermann & Gott (1984), *Hearing Impaired Performance Profile – Revised Edition (HIPP-R): An Assessment Integration Document*, The School Board of Broward County, Florida.

DIRECTIONS: Rate the child's skills using the following scale as defined by each domain description below:

① Age Appropriate ② Mild Limitation ③ Moderate Limitation ④ Moderately Severe Limitation ⑤ Severe Limitation

Domain: Cognitive/Behavioral/Social					Score	
Thinking/ Reasoning	① Child thinks and reasons normally, plays games, solves puzzles, and problems comparably to other students of the same age.	② Between 1 & 3	③ Child is slow to solve age-appropriate puzzles and problems or learn new things, but may acquire these intellectual skills with instructional supports.	④ Between 3 & 5	⑤ Child has considerable difficulty solving age-appropriate puzzles and problems, lags far behind peers and may require individualized instruction to master even simple tasks.	<input type="text"/>
Learning Style/ Maintaining Attention to Classroom Tasks	① Child has skills needed to independently engage in learning tasks; usually attends to classroom instruction sufficiently to learn material; requires minimal teacher support to complete class work.	② Between 1 & 3	③ Child has some skills needed to independently engage in learning; attention in class is frequently off-task, sufficient to impede learning; child can master classroom tasks with close monitoring and instructional support.	④ Between 3 & 5	⑤ Child is unable to independently engage in learning; exhibits extreme difficulty attending to classroom material, even for short periods of time; may act impulsively or withdraw frequently from classroom activities.	<input type="text"/>
Social Interaction/ Classroom Behavior	① Child exhibits social skills and behavior that are appropriate for his/her age.	② Between 1 & 3	③ Child exhibits some inappropriate behavior that may include fighting, biting, hitting, screaming; however, behavior is not disruptive enough to require frequent separation of the child from the classroom.	④ Between 3 & 5	⑤ Child frequently exhibits inappropriate social behavior and is often disruptive of classroom activities; often needs to be separated from the class.	<input type="text"/>
Life Skills	① Child is able to take care of personal possessions, dress, toilet, follow rules, travel, and use money independently similar to other students of the same age.	② Between 1 & 3	③ Child exhibits some inappropriate behavior that may include fighting, biting, hitting, screaming; however, behavior is not disruptive enough to require frequent separation of the child from the classroom.	④ Between 3 & 5	⑤ Child frequently exhibits inappropriate social behavior and is often disruptive of classroom activities; often needs to be separated from the class.	<input type="text"/>
Domain: Self-Advocacy					SCORE	
Knowledge	① Child understands personal medical status and health needs including concepts of hearing and hearing loss and interpretation of audiogram; hearing and other assistive technologies; accommodations (e.g., strategies to address learning and communication needs) and consumer rights (e.g., disability and access rights).	② Between 1 & 3	③ Child understands basic aspects of personal medical status and health needs (e.g., can describe basic components of hearing loss and basic communication implications), hearing and other assistance technologies (e.g., describes basic aspects of personal hearing instruments and other assistive technologies used), and basic accommodations (e.g., priority seating, assistive technology).	④ Between 3 & 5	⑤ Child has no understanding of personal medical status and health needs, use of hearing and other assistance technologies, or accommodations.	<input type="text"/>

Application	<p>1 Child consistently assumes responsibility for personal health and medical needs including management and appropriate use of hearing and other assistive technologies, applying accommodations (e.g., strategies to address compromised learning and communication needs) and advocating for consumer rights (e.g., disability and access rights).</p>	<p>2 Between 1 & 3</p>	<p>3 Child assumes some responsibility for some personal health and medical needs including basic use and troubleshooting of hearing and other assistance technologies and applying some basic accommodations (e.g., priority seating, assistive technology, closed captioning).</p>	<p>4 Between 3 & 5</p>	<p>5 Child does not assume any responsibility for personal health and medical needs, management of hearing and other assistive technologies or accommodations.</p>	<div style="border: 1px solid black; width: 40px; height: 40px; margin: 0 auto;"></div>
--------------------	--	----------------------------	--	----------------------------	--	---

Domain: Communication **SCORE**

Note: If the child uses a sign language interpreter, evaluate functioning in reference to communication through that interpreter.

Expressive Communication	<p>1 Child expressively communicates with his/her teacher and peers fluently and easily using appropriate pragmatic skills (e.g., listening, turn-taking, stays on topic).</p>	<p>2 Between 1 & 3</p>	<p>3 Child has some difficulty expressing him/herself and using pragmatic skills (e.g., interrupts inappropriately, switches topics without informing others) with the mode of communication generally used in the classroom; these difficulties can be overcome by prompting, repetition, and explanation.</p>	<p>4 Between 3 & 5</p>	<p>5 Child has considerable difficulty expressing him/herself and using appropriate pragmatic skills in the mode of communication generally used in the classroom.</p>	<div style="border: 1px solid black; width: 40px; height: 40px; margin: 0 auto;"></div>
---------------------------------	--	----------------------------	---	----------------------------	--	---

Receptive Communication	<p>1 Child comprehends the communication of others in the classroom accurately and easily.</p>	<p>2 Between 1 & 3</p>	<p>3 Child has some difficulty comprehending communication from others in the classroom using the mode of communication generally used for classroom interaction. Difficulties can be remediated by repetition and explanation.</p>	<p>4 Between 3 & 5</p>	<p>5 Child has considerable difficulty comprehending communication from others in the classroom, even when accommodations such as interpreters, assistive listening devices, etc., are used.</p>	<div style="border: 1px solid black; width: 40px; height: 40px; margin: 0 auto;"></div>
--------------------------------	--	----------------------------	---	----------------------------	--	---

Domain: Physical **SCORE**

Vision	<p>1 Child sees with normal acuity, using corrective lenses if necessary.</p>	<p>2 Between 1 & 3</p>	<p>3 Even with corrective lenses, student has some problems seeing the blackboard or objects in visual periphery, or reading small print, and requires minimal additional accommodations, e.g., preferential seating, magnification of reading materials.</p>	<p>4 Between 3 & 5</p>	<p>5 Even with corrective lenses or other accommodations, student cannot see and comprehend visual communication (such as sign language) from across a room; requires significant accommodations, e.g., large print, Braille, mobility training, deaf-blind interpreter.</p>	<div style="border: 1px solid black; width: 40px; height: 40px; margin: 0 auto;"></div>
---------------	---	----------------------------	---	----------------------------	--	---

Use of hands, arms, legs	<p>1 Child uses hands, arms, and legs normally in daily activities, e.g., walking up and down stairs, using a pencil to write, participating in physical activities.</p>	<p>2 Between 1 & 3</p>	<p>3 Child has some limitations in the use of hands, arms, and/or legs, but is ambulatory and can use hands and arms for simple daily activities.</p>	<p>4 Between 3 & 5</p>	<p>5 Child is nonambulatory or is severely limited in his/her use of hands and arms.</p>	<div style="border: 1px solid black; width: 40px; height: 40px; margin: 0 auto;"></div>
---------------------------------	--	----------------------------	---	----------------------------	--	---

Balance (dizziness, motion sickness, coordination in the dark)	1 Child participates normally in all physical activities without losing balance, falling down, or experiencing dizziness.	2 Between 1 & 3	3 Child reports dizziness, nausea, falling down, or shows some mild lack of coordination when participating in physical activities.	4 Between 3 & 5	5 Child often stumbles or falls due to lack of balance, and/or frequently reports feeling dizzy or sick while in motion.	
Overall physical health	1 Child has the usual health problems and illnesses typical for children the same age. Absences from school due to illness typical for children the same age.	2 Between 1 & 3	3 Child has frequent or ongoing health problems, but they are either mild or medically controllable and do not significantly impair educational progress.	4 Between 3 & 5	5 Child has frequent or ongoing health problems that are either not well controlled or result in near-total restriction of activities.	

Domain: Language**SCORE**

Receptive Language	1 Child understands all 8 functions of language appropriate for age: Directions, Explanation, Narration, Description, Negotiation/ Persuasion, Conversation, Questions, Writing (written language).	2 Child understands 6/8 functions of language appropriate for age and needs support to maintain them.	3 Child understands language within 1 year of age level (e.g., understands a variety of sentence patterns, assimilates new language with ease, follows and completes multi-step tasks- oral & written).	4 Child understands language between 1 and 2 years below age level (e.g., limited variety of sentence patterns, assimilates new language after repeated instruction, follows and completes a two to three part task [oral & written], has limited comprehension of idioms).	5 Child understands language at level more than 2 years below age (e.g., understands concrete language).	
Expressive Language	1 Child understands all 8 functions of language appropriate for age (see receptive language).	2 Student understands 6/8 functions of language appropriate for age and needs support to maintain them.	3 Child uses language within 1 year of age level (e.g., varies sentence patterns, assimilates new language, uses some idioms, uses some multiple word meanings).	4 Child uses language between 1 and 2 years below age level (e.g., limited variety of sentence patterns, assimilates new language after repeated instructions, conveys meaning despite numerous structural errors).	5 Child uses language at level more than 2 years below age (e.g., conveys meaning by using a variety of communication systems).	

Domain: Speech Intelligibility**SCORE**

1 Child's speech is completely intelligible to a variety of listeners.	2 Child's speech is generally intelligible to a variety of listeners (e.g., vocal quality appropriate for age and sex, uses intonation and rhythm patterns to convey meaning, has few articulation errors).	3 Child's speech is fairly intelligible to a variety of listeners (e.g., intelligible to listener when topic is unknown, minimal problems in voicing and pitch and varying intonation and/or rhythm patterns).	4 Child's speech is very difficult to understand by a variety of listeners (e.g., vocalizes spontaneously but only isolated words and/or phrases are understood, voicing and pitch are irregular with significant difficulty with intonation and/or rhythm patterns).	5 Child's speech is unintelligible to an untrained listener or child does not use speech (e.g., only vocalizes on demand, imitates just a few speech sounds, poor voice quality [nasal, guttural, raspy], pitch is irregular).
---	--	---	--	---

Domain: Auditory and Listening Skills**SCORE****Use of Amplification**

❶ Child consistently uses and manages amplification (personal and assistive technology) as prescribed (e.g., independent use and care, reports problems when they occur).

❷ Child successfully uses prescribed amplification about 75% of the time, requires some prompting; can independently care for instruments and report problems.

❸ Child requires prompting and assistance to use prescribed amplification; may decline use of assistive technology; needs assistance with use and care, does not consistently report problems.

❹ Child refuses to use prescribed amplification or only uses upon demand; needs regular assistance with use and care; does not report problems when they occur.

❺ Child does not benefit from amplification or prefers not to use amplification.

Audition & Listening

❶ Child uses audition as the primary modality for receptive communication (e.g., listens attentively, understands spoken language and idioms including stress patterns for meaning and inferring discrete emotional information such as sarcasm).

❷ Child uses audition, supplemented by visual supports when needed for receptive communication (e.g., listens attentively, understands speech auditorially) has some difficulty relating stress patterns to meaning, has difficulty inferring fine emotional information (such as sarcasm) based on intonation.

❸ Child uses a combination of auditory and visual modalities for receptive communication (e.g., understands speech when “face-to-face” with speaker, interprets an auditory speech signal when given structural cues, has difficulty inferring gross emotional information such as anger based on intonation).

❹ Child realizes some benefit from auditory modality but primarily relies on visual or tactile input for receptive communication (e.g., uses audition only for awareness of sound, recognizes common environmental sounds).

❺ Child does not use the auditory modality for listening or communication.

Self-Advocacy Skills Checklist

Self-Advocacy Competencies: Elementary School

Health/Medical Access	<p>Basic concepts of hearing</p> <ul style="list-style-type: none"> <input type="checkbox"/> Describes how we hear <input type="checkbox"/> Describes basic problems that cause hearing loss <p>Basic parameters of the audiogram</p> <ul style="list-style-type: none"> <input type="checkbox"/> Describes degrees of hearing loss <input type="checkbox"/> Describes basic implications of hearing loss
Hearing Technology and Usage	<p>Responsibility for equipment</p> <ul style="list-style-type: none"> <input type="checkbox"/> Understands and reports when amplification devices are functioning (i.e., ON/OFF) <input type="checkbox"/> Reports other malfunctions such as static, interference, etc. <input type="checkbox"/> Learns to manage daily maintenance of equipment—charging Hearing Assistance Technology (HAT), changing batteries, basic earmold cleaning <input type="checkbox"/> Uses a calendar to report daily use and device functioning <p>Use of individual amplification devices</p> <ul style="list-style-type: none"> <input type="checkbox"/> Knows the basic parts of the personal amplification used (i.e., earmold, microphone, battery door) <input type="checkbox"/> Knows the basic parts of HAT used (transmitter vs. receiver, attachment of audio shoes)
Educational Services	<p>Communication challenges and needs</p> <ul style="list-style-type: none"> <input type="checkbox"/> Describes basic characteristics of successful communication <input type="checkbox"/> Identifies basic accommodations to address personal communication needs (e.g., priority seating)

Self-Advocacy Competencies: Middle School

Health/Medical Access	<p>Concepts of hearing and hearing loss</p> <ul style="list-style-type: none"> <input type="checkbox"/> Describes own hearing loss (degree and configuration) <input type="checkbox"/> Describes cause of HL (if known) <input type="checkbox"/> Describes basic communication implications of hearing loss <input type="checkbox"/> Describes basic hearing loss prevention strategies
Hearing Technology and Usage	<p>Responsibility for equipment</p> <ul style="list-style-type: none"> <input type="checkbox"/> Transports equipment to and from various school environments <input type="checkbox"/> Understands and is able to notify teacher or speaker when devices are not working properly <input type="checkbox"/> Understands the flexibility of the devices (i.e., ability to couple to audio devices—computers, TV, PA system) <p>Use of individual amplification devices</p> <ul style="list-style-type: none"> <input type="checkbox"/> Understands basic functioning of personal and HAT devices <ul style="list-style-type: none"> <input type="checkbox"/> program options in HA/CI/BAHA <input type="checkbox"/> limitations of technology <input type="checkbox"/> Utilizes the devices in different environments (i.e., lectures, small groups, pass around) <input type="checkbox"/> Actively participates in training of staff on equipment <p>Use of assistive technologies</p> <ul style="list-style-type: none"> <input type="checkbox"/> Identifies and demonstrates basic understanding of other assistive technologies to accommodate hearing loss (e.g., telephone, captioning, alerting devices)

- Educational Services Strategies to address communication challenges
- Describes communication challenges and strategies that work
 - Identifies needed accommodations and presents them at IEP meeting
 - Describes needed accommodations to instructors
- Legal rights
- Understands basic legal rights under IDEA

Self-Advocacy Competencies: High School

- Health/Medical Access
- Concepts of hearing and hearing loss
- Provides detailed description of own hearing loss (type, degree, configuration, cause, implications for communication)
 - Develops and rehearses a script for disclosing hearing loss information and required accommodations
 - Explains communication implications to others
- Access to hearing health professionals
- Identifies pertinent medical and health specialists, their supporting roles, and how to locate them (audiology, otology, genetics, mental health/counseling)
 - Identifies own medical/health support persons
- Hearing Technology and Usage
- Responsibility for equipment
- Demonstrates ability to troubleshoot all hearing and HAT and follows predetermined procedures for getting equipment serviced
- Use of individual amplification devices
- Understands how to manipulate technology in more difficult listening situations
 - Understands how to connect equipment into other audio devices independently
 - Demonstrates knowledge of HAT use beyond the classroom
- Use of resources
- Demonstrates use of web to locate information and resources about hearing and HAT
 - Describes funding options for hearing, HAT, and other assistive technologies
- Use of other assistive technologies to accommodate hearing loss
- Describes characteristics of other assistive technologies such as telephone, captioning, alerting devices, text messaging
- Educational Services
- Educational history and current status
- Explains educational strengths and challenges
 - Identifies academic support needs
 - Formulates present levels of functioning for IEP and IEP goals
 - Describes achievements and performance levels for **Transition Plan Summary of Performance**
- Personal Profile and Accommodations Letter (PPAL)
- Develops a PPAL that identifies needed accommodations and presents profile at IEP meeting
 - Describes needed accommodations to instructors
 - Develops alternative strategies/solutions when accommodations not provided/available
- Transition
- Describes and differentiates IDEA, 504, ADA as it relates to hearing loss including eligibility criteria
 - Provides evidence of successfully submitted scholarship applications when pursuing higher education or employment applications if pursuing employment
 - Provides evidence of meeting with office of disabilities services to identify available services for higher education or human resource office for employment

Self-Advocacy Competencies: Adult

- | | |
|------------------------------------|--|
| Health/Medical Access | <input type="checkbox"/> Utilizes health and medical support when needed |
| Hearing Technology and Usage | <input type="checkbox"/> Utilizes HAT and personal amplification devices in occupational, social, professional contexts
<input type="checkbox"/> Demonstrates knowledge of where to access information about new technology and its related benefits |
| Educational and Consumer Awareness | <input type="checkbox"/> Describes educational history and current performance levels (educational test scores, learning styles, communication abilities)
<input type="checkbox"/> Describes PPAL to instructors, employers, disability coordinators, VR counselor, community settings
<input type="checkbox"/> Use 504 and ADA to obtain accommodations
<input type="checkbox"/> Develops plan to access disability support services when pursuing higher education or accommodations for employment |

Nonauditory Effects of Noise Exposure

Nonauditory effects of noise exposure are those effects that do not cause hearing loss. Some of these are seen by changes in body functions, such as heart rate, and in learning/cognition in children. Nonauditory effects of noise exposure have been noted as far back as 1930 (Smith and Laird, 1930). In that specific study, nonauditory effects pertain to stomach contractions in healthy human beings when exposed to noise.

There are both laboratory and field studies of nonauditory effects. Laboratory studies set up well-controlled conditions and, therefore, are more suited to examine specific changes but are typically unsuited for examining long-term effects that may result in disease or cognitive/educational problems (Bronzaft, 1991). While laboratory studies can be more precise than field studies, they may or may not have any bearing on reality. In contrast, field studies are inherently less well designed in order to control for unwanted variables, but their conclusions may be more applicable to reality. Field studies are well suited to look at the long-term effects of disease and/or educational effects. For example, Stansfeld et al. (2000) demonstrate that, although transportation (truck) noise can disturb sleep patterns in a well-controlled laboratory setting, this is generally not the case in field studies because people tend to adapt over time to environmental noise. A major difficulty with all research into nonauditory factors is that subjective responses not based on intensity or duration may be quite significant. There are three classic studies from the early 1980s that provide an excellent overview for the interested reader: Cohen and Weinstein (1981) and DeJoy (1984) and Thompson (1981). Although there are more recent studies, these have found similar results. High variability and questionable applicability continue to plague research in this very difficult area.

CARDIOVASCULAR EFFECTS

In well-defined laboratory studies, the “noise/stress hypothesis is well understood: Noise activates the pituitary–adrenal–cortical axis and the sympathetic-adrenal-medullary axis. Changes in stress hormones including epinephrine, norepinephrine, and cortisol are frequently found in acute and chronic noise experiments. The catecholamines and steroid hormones affect the organism’s metabolism” (Babisch, 2002, p. 1). However, few measurable biologic changes are directly or indirectly related to clinical changes in a population.

Most of the studies on cardiovascular effects have been performed in the laboratory on animals (mostly on rats). However, DeJoy (1984) commented that the rat may not be an appropriate model and that a primate species may be more appropriate. When primates were used in the laboratory, it was also found that blood pressure increased as the noise levels increased, but there was a large degree of variability in the studies.

In the few field studies on humans, blood pressure has been measured, but again, the level of variability is great. Sloan (1991, p. 23), reviewing available data, notes that when taken as a whole “although there are inconsistencies in the findings...they generally support the assertion that exposure to noise is associated with higher levels of blood pressure.” Data are still limited, however, and the results may depend on many uncontrolled factors, such as subjective response, the exact nature of physiologic assessment, and the animal model. In addition, it is still not known whether increased blood pressure in a noisy environment will lead to cardiovascular disease. Stansfeld et al. (2000) echo this concern and demonstrate that although laboratory studies show an association between noise and cardiovascular disease, field studies show only a weak relationship.

The physiologic rationales of the effects on body chemistry as a result of increased exposure to noise are beyond the scope of this chapter, but the interested reader is referred to Babisch (2002) and Raymond (1991).

Effects of Noise on Sleep

Pollak (1991, p. 41) noted that “(1) noises are more annoying when they occur at times when people expect to rest or sleep, (2) noise can interrupt sleep, and (3) noise can also have subtle effects on sleep...that are detectable only with specialized instruments.” Most laboratory studies use truck and aircraft noise as stimuli and measure the effect on a range of sleep study parameters. Noise can delay sleep and shift the sleep stages upward (i.e., more shallow sleeping). Upward sleep stage shifts have been observed even in relative quiet with 25- to 30-dB sound pressure level (SPL). Cardiovascular changes are usually not noted until the stimulus level is just below the arousal level for that individual. Thiessen (1978, 1983) found that as peak noise intensity increased, there was a linear increase in the probability of a change in sleep stage. Similar results have been found by Matheson et al. (2003) and Ouis (2002).

Effects of Noise on Fetal Development

There are some data suggesting an increased risk of noise-induced damage in fetuses, but this is still a very controversial issue. The interested reader is referred to Ryals (1990) and Stansfeld et al. (2000) for more information.

Nakamura (1977) noted low birth weights when the pregnant mother was exposed to high levels of occupational noise. Schell (1981) found that noise may in fact decrease birth weight. However, Edmonds et al. (1979) found that aircraft noise exposure had no significant effect on fetal development in pregnant women. Stansfeld et al. (2000), in laboratory studies, found no evidence that noise exposure contributes to congenital birth defects or low birth weight.

Effects of Noise on Learning

When speech is masked by background noise (e.g., at a noisy party), this is similar to having a hearing loss (with equivalent masked hearing thresholds). Children with even slight hearing losses have been shown to have decreased educational and cognitive performance. Davis (1985) found that children with a minimal (25 dB) hearing loss scored almost two full grade levels lower in reading comprehension by grade 4 (despite having minimal differences in the first grade).

Specifically with respect to normal-hearing children in a noisy school environment, Cohen et al. (1973) found that children whose classrooms were on the street level (nearer to truck and car noise) performed poorer in reading ability than children whose classrooms were in quieter locations. Bronzaft and McCarthy (1975) studied the reading ability of children in one school near elevated train tracks. Half the classrooms faced the train track, and the other half were on the quieter back part of the school. Students in the quieter classrooms did better on reading achievement tests, and by grade 6, those in the quieter classrooms were a full grade point ahead of those in the noisier classrooms. Green et al. (1982), in studying children near a New York airport, found that as noise level increased, the percentage of those children falling below grade reading level also increased. Wachs (1982) noted that children were slower to develop language skills in noisier homes. Matheson et al. (2003) noted similar results with low but statistically significant correlations between neuroendocrine tests, blood pressure measurements, and educational success.

Again, it should be stressed that presence of biologic measures, such as heightened hormone or blood pressure levels, does not necessarily relate to long-term clinical changes in a population. While these changes may have long-term effects, there is no current evidence to support this extrapolation.

NOISE STANDARDS AND THEIR HISTORY

The earliest regulations designed to protect workers' hearing from NIHL were adopted by the US armed forces as a result of the tremendous amount of NIHL suffered by US service members in World War II (Gasaway, 1985). The first recommended exposure limit was issued by the US Air Force (USAF) in 1948, followed by the first enforceable hearing conservation regulation (also by the USAF) in 1956 (Suter, 1988). The 1956 USAF regulation identified five aspects of hearing conservation which still form the basis of modern standards, that is:

- Noise reduction efforts
- Measurement of noise exposure
- Education of workers
- Use of hearing protection
- Audiometric surveillance

These requirements evolved from research and recommendations made by CHABA (Suter, 1988). After initial development by the armed forces, several groups, most notably the American Conference of Governmental Industrial Hygienists (ACGIH), established recommended exposure limits for the civilian workforce. In 1969, ACGIH issued a voluntary Threshold Limit Value (TLV) for noise that represented a greatly simplified version of the CHABA recommendations (Suter, 1988). In 1969, the TLV was adopted by the Occupational Safety and Health Administration (OSHA) under the Walsh-Healey Public Contracts Act, which applied to large federal contracts, and separately under the Federal Coal Mine Health and Safety Act (Suter, 1988). Then, in 1971, following the establishment of the OSHA, the Walsh-Healey exposure requirements were promulgated as a Permissible Exposure Limit (PEL) for noise in general industry and construction (Suter, 1988). This PEL remains in force today, and specifies a Time-Weighted Average (TWA) exposure limit (referred to as a Criterion Level, or L_C) of 90 dBA over an 8-hour workshift, with a 5-dB exchange rate (OSHA, 1981). The PEL requires that employers attempt to reduce noise exposures above 90-dBA TWA through noise controls, though subsequent OSHA policy interpretation effectively raised this level to 100 dBA. Workers exposed above the 90-dBA TWA limit must use hearing protection devices, and hearing protectors are further required for exposures that exceed 115 dBA for 1 second or more. OSHA also recommends hearing protectors for exposures above 140 dB SPL regardless of duration. To provide further protection to noise-exposed workers, OSHA promulgated the Hearing Conservation Amendment in 1983, which requires employers to provide baseline and annual hearing conservation training to workers exposed above an Action Level 85-dBA TWA, requires baseline and annual audiometric surveillance, and requires that workers exposed between 85 and 90 dBA

be offered hearing protectors. OSHA's Hearing Conservation Amendment does not apply to workers in a number of industries, including agriculture, construction, oil and gas extraction, and offshore marine work. Miners are covered by an essentially equivalent PEL administered by the Mine Safety and Health Administration (MSHA), railroad workers fall under a similar regulation administered by the Federal Railroad Administration, and offshore workers fall under the jurisdiction of the US Coast Guard, which administers, though rarely enforces, a similar regulation.

The National Institute for Occupational Safety and Health (NIOSH), established in 1971, is tasked with conducting occupational health and safety research and recommending best practice exposure limits (as compared to OSHA, which uses public rulemaking to set mandatory exposure limits, and therefore must include factors such as economic feasibility in their rulemaking efforts). In 1972, NIOSH established a Recommended Exposure Limit (REL) of 85-dBA TWA L_C with a 5-dB exchange rate (Suter, 1988). However, in 1998, NIOSH revised its REL to incorporate a 3-dB exchange rate, while retaining the 85-dBA exposure limit. This is consistent with the TLV for noise, which was updated to these same specifications in 1994. Both of these voluntary limits recommend that audiometry, noise controls, and use of hearing protection begin at TWA exposures of 85 dBA, and may therefore be considered more protective than the OSHA regulation. The US Department of Defense, as well as the USAF, US Army, and US Navy, have all moved to exposure limits that are consistent with the current NIOSH REL and TLV. Individual states in the United States can opt to have state OSHA programs that administer regulations at least as protective as those promulgated by federal OSHA. None of the state OSHA programs have PELs or hearing conservation requirements that differ considerably from the federal OSHA programs, though several states, including Washington and Oregon, extend coverage to industries such as construction and agriculture.

Noise regulations around the globe are much simpler to describe. Virtually every high-income country in the world, and many medium- and low-income countries as well, has adopted exposure regulations that specify an 85-dBA TWA L_C and 3-dB exchange rate. For example, these limits are required in countries within the European Union. Outside of the United States, only a handful of countries—including Brazil and Israel—use regulations consistent with the OSHA PEL, or a mix of the OSHA PEL and NIOSH REL (e.g., an 85-dBA TWA exposure limit combined with a 5-dB exchange rate). A summary of US and worldwide noise standards and regulations can be found at http://sitemaker.umich.edu/neitzel/files/hearing_loss_references.pdf.

In addition to these regulatory and voluntary occupational exposure limits, limits have been recommended for the protection of public health. Specifically, both the US Environmental Protection Agency (EPA, 1974), and World

Health Organization (WHO, 1999) have recommended a 24-hour exposure limit of 70 dBA with a 3-dB exchange rate. This is equivalent to an 8-hour exposure at 75 dBA, with no noise exposure for the other 16 hours per day; note that this represents a strong and highly debatable assumption in modern societies. This 24-hour exposure limit is intended to protect against any hearing loss at 4000 Hz among any exposed individual, and can be considered truly “safe”—whereas many occupational exposure limits accept some level of excess risk of hearing loss (e.g., as many as one-third of workers with sound exposures at the OSHA PEL of 90-dBA TWA daily over a 40-year period are expected to sustain a material hearing impairment).

All noise regulations and standards specify—either implicitly or explicitly—methods to determine individual workers' noise exposures. Such determinations can be simple, as is the case when comparing a measured TWA exposure level for a worker to the relevant exposure limit. However, when noise measurements are made with a sound level meter and involve exposures to different noise levels for varying periods of time, it becomes necessary to convert these noise levels and durations into an accumulated personal noise dose. This is done by comparing the ratio of exposure time (C) at each given level to the allowable time (T) at that level, as shown in the equation below:

$$Dose\% = 100 (C_1/T_1 + C_2/T_2 + \dots + C_n/T_n)$$

Allowable times can be determined by referencing the relevant exposure standard: For compliance purposes, these times are located in Appendix A in the OSHA Noise Regulation (29 CFR 1910.95), whereas the NIOSH best practices recommendation can be found in Chapter 1 of the 1998 Criteria Document for Noise Exposure (DHHS/NIOSH report number 98-126, NIOSH, 1998). Example T values from each standard are based on the data in Table 32.2 presented earlier.

If a worker had an exposure of 4 hours at 95 dBA, 2 hours at 90 dBA, and 2 hours at 85 dBA over the course of a workshift, their OSHA dose would be computed as follows:

$$\begin{aligned} Dose\% &= 100 (4/4 + 2/8 + 2/16) \\ &= 100 (1.0 + 0.25 + 0.125) \\ &= 100 (1.375) \\ &= 137.5\% \end{aligned}$$

For comparison purposes, the NIOSH dose for the same exposure would be 605%.

Allowable times that are not specifically listed in the relevant standard can be computed directly using the equation below:

$$T = 480 \text{ minutes} / 2^{((L_p - L_C)/ER)}$$

Where L_C is the criterion level, L_p is the measured SPL in dBA, and ER is the exchange rate (in dB).

The dose value resulting from a dosimeter measurement or computed using the equation above can be computed into a TWA value using the equation below:

$$TWA = (ER/\log 2) \times \log 10 (D/100) + L_C$$

Where ER is the exchange rate, D is the dose, and L_C is the criterion level. In the case of the worker described earlier, the OSHA TWA (using a 5-dB exchange rate and 90-dBA L_C) would be 92.3 dBA, whereas the NIOSH TWA (using a 3-dB exchange rate and 85-dBA L_C) would be 92.8 dBA.

Recommendations and Counseling

The rehabilitative process begins at the end of the evaluation when the audiologist shares results, describes treatment options (using decision aids) and discusses patient preferences, so that an informed decision can be reached. Insuring that the patient and communication partner are involved in decisions regarding treatment options will promote compliance with recommendations. The patient's stage of readiness in combination with considerations regarding physical, sociologic, cognitive, and psychosocial status must inform the discussion. Integral to patient-centered care is that treatment options are concordant with the patient's values and motivations. The patient has come in with questions and should walk away with concrete answers, an action plan and a roadmap regarding next steps. The audiologist should attempt to determine stage of readiness (e.g., precontemplation, action) using simple questions such as "*I know I have a hearing problem, and I intend to take action to solve it soon*" as the response will inform the counseling sessions and decisions regarding targeted treatment interventions. Hence, an individual with a mild hearing loss with significant participation restrictions who experiences difficulty in a variety of listening situations and who is in the action stage of readiness might be a candidate for hearing aids; whereas someone with a mild hearing impairment with difficulty understanding the television may benefit from a conversation about devices for the television. It is very important that before the patient leaves, most questions are answered and they understand that the interventions available can help promote ease of listening, can improve enjoyment of activities important to them, and that it is beneficial to act early to insure that the consequences of hearing loss become an intolerable burden. When appropriate, and depending on auditory processing abilities it is wise to recommend an interactive computerized auditory-cognitive training program such as the Listening and Communication Enhancement (LACE) software to improve skills lost due to normal age-related change in such cognitive functions as executive control, speed of processing, and working memory. This "physical therapy for the ears" may be beneficial for many persons with ARHL including those not yet motivated or ready to purchase hearing aids, or people in whom hearing aids are not effectively compensating for their communication breakdowns (Sabes & Sweetow, 2007). To reiterate, basic to client-centered care is that the audiologist present intervention options and the person with hearing loss and their communication partner share in the decision-making process.

CASE PRESENTATION

Mr. R., an active 75-year-old executive, recently returned to work part-time after 1 year of full-time retirement from a family business. The case history revealed that he is in excellent health and enjoys being productive. He indicated that his work entails small group meetings with colleagues and that he has considerable difficulty when noise is present in the room and when he is sitting around large conference room tables. He also finds that he has more difficulty understanding female than male voices. Because of these problems, he scanned the internet for information on hearing loss and came to several websites that conducted hearing screenings. Mr. R. completed an online screening version of the HHIE. His hearing profile revealed a score of 20, suggesting a mild-to-moderate self-perceived hearing handicap indicative of necessity for a referral to a local audiologist. The site directed him to a list of audiologists in his geographic area. Mr. R. scheduled an appointment with the audiologist armed with considerable information about hearing loss and hearing aids and with questions regarding the virtues of hearing aid use.

The audiometric evaluation revealed that, indeed, Mr. R. had mild bilateral sensory/neural hearing loss in both ears with excellent word recognition ability, which belied his experiences in the real world. The audiologist administered the QuickSIN and scores revealed a moderate SNR loss. Responses to the HHIE-S revealed a score of 22, suggesting a mild handicap. Questioning regarding Mr. R.'s social engagement revealed that recently, he was reluctant to engage in previously enjoyed activities given his struggle understanding others. The PHQ-9 was administered to screen for depressive symptoms and a score of 9 emerged which is consistent with mild depression. The MMSE score was 24, consistent with mild cognitive impairment. In light of the latter test results, the patient was referred back to his primary care physician and it was noted that the untreated hearing impairment may be a variable contributing to his scores on the MMSE and PHQ-9.

The audiologist suggested to his physician that Mr. R. might benefit from bilateral digital hearing aids given his desire to remain socially connected and his frustrations communicating with friends, colleagues, and family members. Mr. R.'s physician administered the PHQ-9, the MMSE, and the deJong Giervald short scales of emotional and social loneliness and responses suggested that Mr. R.

is feeling lonely and socially disconnected. The possibility of an antidepressant was discussed as was possible auditory interventions such as amplification with hearing aids. Mr. R. was reluctant to take medication and decided to try hearing aids to see if in fact his recent feelings of social disconnectedness were linked to his difficulty understanding others. Mr. R. returned to the audiologist with his wife. Mr. R. decided to purchase hearing aids for a 1-month trial and agreed to use the online version of the Listening and Communication Enhancement (LACE) software to improve listening skills and to foster improved auditory processing (Sabes & Sweetow, 2007).

At the 3-week postfitting appointment, verification and validation studies were conducted including perceived ease of listening studies in different noise backgrounds. Audibility of speech was high according to score on the Speech Intelligibility Index (SII) verifying that speech was audible and usable with his hearing aids (Hornsby, 2004). HHIE scores revealed a significant reduction in self-perceived handicap with aided scores improving to 6, suggesting with 95% confidence that this was a true change in the HHIE score from the unaided condition. Score on the MMSE and PHQ-9 improved slightly which was of interest and responses to the loneliness scale improved, as well.

Mr. R. completed the HHIE 3 months after the fitting and continued to be deriving considerable benefit from the hearing aids. Tracking of scores on the LACE at the 3-month

postfitting revealed improved scores on each of the subscales relative to baseline. This case was of interest because he presented with a mild hearing impairment yet expressed communication difficulties and frustrations when communicating; this suggested challenges beyond what could have been predicted from basic pure-tone testing. The more thorough examination confirmed the speech understanding difficulties in adverse listening situations and some psychosocial sequelae. His physician noted a definite improvement in Mr. R.'s affect and as an aside he commented that it was much easier to communicate with him when he was wearing his hearing aids. The comprehensive client-centered examination and partnering with the primary care physician enabled Mr. R. to obtain the assistance he needed and, more importantly, to satisfy the communicative needs presented by his particular lifestyle. He is now a strong advocate for hearing aids and has been instrumental in helping some of his friends purchase hearing aids. He also is an advocate for use of LACE in combination with hearing aids as he attributes his improved ease of listening in noisy situations to the exercises he did with the LACE online.

Iowa Tinnitus Activities Questionnaire

IOWA TINNITUS ACTIVITIES QUESTIONNAIRE MAY 05

Name: _____

Date: _____

Please indicate your agreement with each statement on a scale from 0 [completely disagree] to 100 [completely agree].

#	Statement	0-100
1.	My tinnitus is annoying.	
2.	My tinnitus masks some speech sounds.	
3.	When there are lots of things happening at once, my tinnitus interferes with my ability to attend to the most important thing.	
4.	My emotional peace is one of the worst effects of my tinnitus.	
5.	I have difficulty getting to sleep at night because of my tinnitus.	
6.	The effects of tinnitus on my hearing are worse than the effects of my hearing loss.	
7.	I feel like my tinnitus makes it difficult for me to concentrate on some tasks.	
8.	I am depressed because of my tinnitus.	
9.	My tinnitus, not my hearing loss, interferes with my appreciation of music and songs.	
10.	I am anxious because of my tinnitus.	
11.	I have difficulty focusing my attention on some important tasks because of tinnitus.	
12.	I just wish my tinnitus would go away. It is so frustrating.	
13.	The difficulty I have sleeping is one of the worst effects of my tinnitus.	
14.	In addition to my hearing loss, my tinnitus interferes with my understanding of speech.	
15.	My inability to think about something undisturbed is one of the worst effects of my tinnitus.	
16.	I am tired during the day because my tinnitus has disrupted my sleep.	
17.	One of the worst things about my tinnitus is its effect on my speech understanding, over and above any effect of my hearing loss.	
18.	I lie awake at night because of my tinnitus.	
19.	I have trouble concentrating while I am reading in a quiet room because of tinnitus.	
20.	When I wake up in the night, my tinnitus makes it difficult to get back to sleep.	

Scoring

Area	Questions	Score
Emotions and Thoughts	1, 4, 10, 12	%
Hearing and Communication	2, 6, 14, 17	%
Sleep	13, 16, 18, 20	%
Concentration	3, 7, 11, 15, 19	%

Loudness and Annoyance of Everyday Sounds

Some everyday sounds are loud and some are soft. Some everyday sounds are annoying and some are not. Please rate the **loudness** and the **annoyance** of the following sounds. Do not consider the annoyance when rating the loudness and do not consider the loudness when rating the annoyance. For

example, a sound may be very loud, but not annoy you. Likewise, a sound may be very soft, yet be very annoying. Rate the sounds using a scale from 0 (not loud/annoying) to 100 (unbearably loud/annoying).

Sound	Loudness (0-100)	Annoyance (0-100)
1. Standing next to a dog barking		
2. Someone stacking dishes in the same room		
3. Hearing music on the radio in a car when the volume is adjusted for normal-hearing listeners		
4. Hearing music on the radio in a quiet room when the volume is adjusted for normal-hearing listeners		
5. Telephone ringing in the same room		
6. Television in the same room when the volume is adjusted for normal-hearing listeners		
7. Standing next to a lawnmower		
8. Standing next to a car door closing		
9. Talking with someone in a noisy restaurant		
10. Baby crying in the same room

The Relative Handicap of Hearing Loss, Tinnitus, and Hyperacusis

The following questions relate to hearing loss, tinnitus, and hyperacusis. Hyperacusis is either when sounds that are moderately loud for other people are *too* loud for you

or when you find sounds annoying. Please rate your agreement/disagreement with the following statements, using a scale from 0 (completely disagree) to 100 (completely agree).

	Because of Your Hearing Loss [0-100]	Because of Your Tinnitus [0-100]	Because Some Sounds are too Loud or Annoying [0-100]
1.	You avoid shopping		
2.	You do not go out with your friends		
3.	You have given up some hobbies		
4.	You do not go to restaurants		
5.	You avoid being in crowds		
6.	You feel depressed		
7.	You feel anxious		
8.	You are not able to concentrate		
9.	Your quality of life is poor		
10.	You are not able to perform tasks or jobs as well		

Tyler RS, Bergan C, Preece J, Nagase S. (2003). Audiologische Messmethoden de Hyperakusis. In: Nelting M, ed. *Hyperakusis* (39-46). Stuttgart: Georg Thieme Verlag.
