HANDBOOK OF CLINICAL AUDIOLOGY

SEVENTH EDITION

EDITOR-IN-CHIEF

JACK KATZ, Ph.D.

Director
Auditory Processing Service
Prairie Village, Kansas
and Research Professor
University of Kansas Medical Center
Kansas City, Kansas and Professor Emeritus
University at Buffalo
State University of New York
Buffalo, New York

EDITORS

MARSHALL CHASIN, Au.D.

Director of Auditory Research
Musician's Clinics of Canada
Toronto, Ontario, Canada

KRISTINA ENGLISH, Ph.D.

Professor and Interim School Director
School of Speech Pathology and Audiology
University of Akron/NOAC
Akron, Ohio

LINDA J. HOOD, Ph.D.

Professor
Department of Hearing and Speech Sciences
Vanderbilt Bill Wilkerson Center
Vanderbilt University
Nashville, Tennessee, USA
Honorary Professor
University of Queensland
Brisbane, Australia

KIM L. TILLERY, Ph.D.

Professor and Chair
Department of Communication Disorders & Sciences
State University of New York at Fredonia
Fredonia, New York

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

DANIEL ARTHUR ABRAMS, Ph.D.

Research Associate, Department of Psychology and Behavioral Sciences
Stanford University
Palo Alto, California

ANGELA LOUCKS ALEXANDER, Au.D.

The Seventh Edition of the Handbook of Clinical Audiology is Dedicated to Raymond Carhart (1922–1975), who is recognized as the “Father of Audiology.” He talked about the shared responsibility of the clinician and the hearing scien-

tists (both of whom he considered as audiologists) to learn about the hearing process and develop ways to help persons living with hearing loss.

It is fitting that this book is dedicated to Dr. Raymond Carhart. He stated in a 1976 interview that he conceived of an audiologist “as someone who has a prime commitment to learning about hearing and its processes as well as a commitment to understanding and coping with its problems.” He talked about the shared responsibility of the clinician and the hearing scientists (both of whom he considered as audiologists) to learn about the hearing process and ways to help the persons with hearing impairment. The seventh edition of *Handbook of Clinical Audiology* book strives to do that, as have the previous editions.

Carhart has been referred to as the “Father of Audiology”—or sometimes the “Grandfather of Audiology.” Perhaps it would be most appropriate to call him the “Grand Father of Audiology.”

Although he came to the field somewhat indirectly, his contributions were enormous.

Dr. Carhart was born in Mexico City. He received his Bachelor’s degree from Dakota Wesleyan University in 1932 in speech pathology and psychology; his Master’s and Ph.D. degrees from Northwestern in 1934 and 1936, respectively, in Speech Pathology, Experimental Phonetics, and Psychology. He was an instructor in speech reeducation at Northwestern from 1936 to 1940 and then an assistant, and associate professor in 1943 in speech science.

Although Carhart initially worked in speech science, he was asked to replace C.C. Bunch following Bunch’s untimely death in June, 1942. Carhart then began to teach Bunch’s courses in hearing and became so interested in the problems that, as he said, “I’ve been working with them ever since.”

In 1943, Carhart joined the Medical Administrative Corps, U S Army, as a captain, he was assigned to DeShon Hospital in Butler, Pennsylvania as Director of the Acoustic Clinic and as Acoustic Physicist where he was asked to develop a program for veterans who had lost their hearing during the war. In that capacity he contacted the scientists at the Psycho-Acoustic Laboratory (PAL) at Harvard, who, among other things, had come up with word lists that might be used in evaluating a person’s ability to understand speech. He also developed a fairly comprehensive rehabilitation program that involved selecting and fitting hearing aids (which were not so complex or elaborate as they are today), and teaching the soldiers and veterans how to use them.

When Carhart returned to Northwestern in 1946, he convinced the dean to establish an academic program in Audiology, which was the name that Dr. Norton Canfield chose for the department at DeShon. He became the first professor of Audiology at Northwestern.

Carhart later said (in class if not in print) that sound—and especially speech—was comprised of many dimensions.

Four of those dimensions were (1) sensitivity (how faintly can one hear); (2) clarity of sound (speech or otherwise) in quiet; (3) clarity in noise; and (4) tolerance (how loud can sound be without becoming a problem). Two of these dimensions (sensitivity and clarity), which were detailed by Carhart in a 1951 paper, became the basis of Plomp’s (1978) two-component model of hearing loss involving audibility and distortion. Carhart said there were many more dimensions to hearing, but those four should always be measured when fitting hearing aids and working with patients with hearing loss.

Although Carhart worked as a speech scientist, a clinician (in speech and in hearing), a researcher in speech and especially in hearing, his primary contribution is probably as a teacher and educator. An educator can be described as one who conveys learning in which the knowledge, skills, and habits of a group of people are transferred from one generation to the next through teaching, training, or research, and that certainly describes Dr. Carhart.

In his capacity as an educator, Carhart directed some 35 dissertations, beginning in 1946 with a study by John Keys entitled “Comparative Threshold Acuity of Monaural and Binaural Hearing for Pure Tone and Speech as Exhibited by Normal and Hard of Hearing.” Although his primary interest was in speech and speech understanding, the dissertations he directed covered a range of hearing problems from difference limens, to effects of surgery and specific diseases on hearing, to auditory fatigue, loudness and many more topic areas. In addition, as an educator he taught some of the leaders in the field of audiology like James Jerger, Donald Dirks, Cornelius Goetzinger, Jack Willeford, and many more. Many of those went on to teach, and to educate other students in audiology programs at our most prestigious universities.

In 1949, he directed the dissertation of Miriam Pauls Hardy, who may have been the first female to graduate with a Ph.D. in audiology. Unlike some of the professors of the time, Dr. Carhart did not discriminate on the basis of gender. He believed that it was the mind—not the gender—that was important. He did, however, believe that one should do the work, not just talk the talk. He set an example in that one often found him in his office or laboratory in the evening and on weekends.

His early research interests at Northwestern were in conductive hearing loss (the “Carhart notch,” which can be an indicator of possible otosclerosis was named for him), including a method of checking the accuracy of bone conduction measurements before there was an artificial mastoid, let alone an ANSI standard. He was interested in masking (forward, backward, and perceptual, which we now call informational

masking), and did much to enhance our understanding of the way speech is processed by the damaged ear.

Before there were computers in our clinics and most academic research laboratories, he developed a key-sort system as a way of classifying audiograms so that one could better interpret the puretone audiogram.

Finally, Carhart believed that audiology was more than a clinical field and that the clinicians who practiced it should continue to explore and research the ways in which we hear and how to improve the lives of those who do not hear normally.

Raymond Carhart died at his desk in October 1975, leaving behind a legacy to the academic discipline of audiology, the numerous leaders in the field of audiology whom he had educated, and the greater understanding of audiologic assessment and hearing aid rehabilitation for which he is known as the father—or Grand Father of Audiology.

We dedicate this seventh edition to Dr. Carhart, because like him the *Handbook of Clinical Audiology* has educated so many leaders of our field and has inspired countless audiologists throughout the world. This edition of the Handbook will provide a broad perspective of the field of audiology by nearly 100 contributing experts in the field. They offer their knowledge, wisdom, and enthusiasm to help another generation of audiologists to fulfill their mission.

Laura Ann Wilber

For more than 40 years, the *Handbook of Clinical Audiology* (HOCA) has maintained an important role in the education of graduate students in audiology, both in North America and throughout the world. It also serves as a useful reference for audiologists, otologists, and speech–language pathologists who wish to have a comprehensive and practical guide to the current practices in audiology.

Each edition of the HOCA has been an update of the previous one, but we have also striven to make the newest edition better than the one that came before. For this edition, there are four highly skilled and knowledgeable editors plus one senior editor. We have worked together to select highly qualified contributors on topics that are both core and current for students and professionals in audiology. Online case studies and references have been added to this edition to enable the reader to go beyond the basic scope of this book.

THE FOREWORDS

In the previous edition of the Handbook the foreword was written by Moe Bergman, a distinguished gentleman with many years of audiology behind him. Moe Bergman, Ed.D., was in the very first group of audiologists who began this discipline more than 70 years ago. Starting prior to World War II and for decades following, Dr. Bergman was a clinician, administrator, professor, researcher, and writer, and after he retired from Hunter College in New York City, he went to Israel to establish audiology as a profession there. He is considered as the Father of Audiology in Israel. For many years, Dr. Bergman has continued to be active as an advisor and an officer in international professional organizations. His clarity about the events and developments so many years ago (see Bergman, 2002) makes him a treasured link to our roots.

This edition is dedicated to Raymond Carhart, “The Father of Audiology.” We are delighted to have the book’s dedication and foreword discussing Dr. Carhart; written by Laura Ann Wilber a former student of his and a distinguished audiologist in her own right. Dr. Carhart was her dissertation advisor and she worked with him and Tom Tillman to develop what later became the NU-6 word recognition test. When Laura Wilber earned her Ph.D. there were few women who were educated at that level in audiology and many people felt that it was a male profession. So Dr. Carhart’s acceptance of her and clearing a path for her was especially important.

It is worth noting that Laura Wilber has contributed to each edition of the Handbook since the first edition in 1972. She herself was honored by the editors of the HOCA in the previous edition by dedicating the book to her and to three other audiologists.

SECTIONS, CHAPTERS, AND CONTRIBUTORS

The strength of HOCA has always been the knowledge and expertise of the contributors in the many aspects of audiology. They have both clinical and research credentials in the topics they write about and most are also professors who are proficient in communicating with students. Audiologists looking down the list of contributors will recognize familiar and highly respected colleagues. They have contributed much to the field in the past and now contribute again by providing important and readable materials for both colleagues and students. We have made every effort to provide up-to-date, accurate, and clinically applicable information.

Each of the four main editors of this book has a distinguished record of teaching, research, writing, and clinical work. Each one took responsibility for significant portions of the book. Linda Hood helped to edit the Sixth Edition and decided to go “another round.” Her chapters deal primarily with physiological methods for audiologic diagnosis. Marshall Chasin, our first Canadian editor, edited the chapters dealing with amplification and other technical aspects. Kim Tillery edited the chapters dealing with central auditory processing disorders and shared in the final editing of all chapters. Kristina English edited the basic chapters and those dealing with re/habilitation. Jack Katz reviewed all of the chapters and saw to the overall manuscript issues.

The Handbook is divided into four sections. There are eight chapters dealing with Introduction, Basic Tests, and Principles. A chapter that summarizes diagnostic audiology and brings together the various contributions has been added in this edition. Other top-notch audiologists wrote on Puretone Air Conduction, Bone Conduction, and Speech Audiometry, as well as Masking and Case History.

The second section is made up of 14 chapters dealing with Physiologic Principles and Measures. This section of the book includes auditory measures starting with the conductive mechanism up to the brain and vestibular measures that assess from the inner ear to the brain. Some chapters include specialty areas such as intraoperative monitoring and therapy for vestibular disorders. Some of the most pronounced advances in recent years have been made in these areas.

The third section is devoted to a wide variety of Special Populations. It contains 14 chapters beginning with Newborn Hearing Screening, Assessment of Hearing Loss in Children and Educational Audiology and ends with Hearing Loss in the Elderly, Tinnitus/Hyperacusis, and Tele-Audiology. Four chapters deal with Central Auditory Processing Disorders and Central Auditory Functions.

The final section, Management of Hearing Disorders, is made up of 10 chapters. Five of the chapters deal with hearing aids and cochlear implants, two focus on management, and two more are on Room Acoustics and Assistive Technologies as well as Building a Successful Audiologic Practice. In addition, for the first time we will have a chapter dealing with infection control in audiology practice that was written by A.U. Bankaitis. This important topic relates to all aspects of audiology that deal with clinical patients and/or research subjects.

Sadly, during the writing of the chapter on electrocochleography with Rosamaria Santarelli, contributor Edoardo Arslan passed away. He was both her co-author and mentor.

NEW FEATURES

Six new chapters have been introduced in the seventh edition. They are Diagnostic Audiology, The Dizzy Patient and Vestibular Rehabilitation, Newborn Hearing Screening, Genetic Hearing Loss, Tele-Audiology, and Infection Control. At the close of every chapter is a new section called Food for Thought, which encourages readers to interact more deeply with the text.

thePoint

In this edition of this Handbook we have added supplemental materials (e.g., extended references and case studies) on thePoint companion website at <http://thepoint.lww.com/Katz7e>.

TERMINOLOGY

The following is an explanation of some of the spelling conventions used in the HOCA and briefly why we chose them. Further discussion may be found in Chapter 1.

Compound Words

In clinical audiology, as well as in English generally, compound words (two words written as one) are common. Compound words are simplifications of words that are frequently used together. For example, *brain* and *stem* are combined in the term *auditory brainstem response*. When two words are frequently used together to express a certain meaning, in time, they may be connected by a hyphen and eventually joined together into a single word (base ball, base-ball, baseball).

PURETONE

The terms *pure tone* and *pure-tone* are constantly used in audiology with or without a hyphen. This has encouraged us to combine them into a compound word, *puretone*. By choosing a single word it eliminates the inconsistencies that we see when they are used or misused with or without a hyphen.

SENSORY/NEURAL

On the one hand, while there is good reason to use *puretone* as a compound word, on the other hand, it would be beneficial for the term *sensorineural* to be separated into sensory or neural using a slash as we often use for “or” (i.e., *sensory/neural*). This makes it clear that the test or result it did not distinguish sensory from neural. From the term *sensorineural* it is often not clear what is intended as many professionals assume that *sensorineural* means sensory. This problem has led to important confusions and errors that can be easily remedied by the use of *sensory/neural* if it is unclear which is indicated (e.g., with no air-bone gap for puretone thresholds we do not know if it is sensory, neural, or both). If the specific region is identified (e.g., present Otoacoustic Emissions but absent Middle Latency Response) we indicate that it was specifically neural or retrocochlear. If it is both we state “both sensory and neural” or just “sensory and neural.”

EPILOGUE

We are pleased that the *Handbook of Clinical Audiology* (HOCA) is used widely by audiologists around the world. Interestingly when the HOCA first came out in 1972, we were living in the Turkish Republic. There the word *hoca* means a religious leader or a revered teacher. While HOCA is certainly not a religious leader, we do hope it will be a revered teacher for the many students and colleagues that read this book.

ACKNOWLEDGMENTS

We would like to thank the editors of Wolters Kluwer, especially Linda Francis and Meredith Brittain, not only for their fine editing of this book but also for advising us and keeping us to our deadlines. We would like to mention the following colleagues and other individuals who also helped us in many ways to make the Handbook as high quality a text and reference book that we could. They are Mark Chertoff, Robin Gashler, Jay Hall, Amy Lane, Larry Medwetsky, Marcello Peppi, Lynden Ronsh, and Natalie Turek. In addition, I appreciate the tremendous support from my family and would like to highlight those who made special contributions to the completion of this edition. They are Eric Kaseff, Lainie Kaseff, Mark Katz, and Miriam Kaseff. Another member of my family deserves very special mention. My wife Irma Laufer Katz has been heavily involved as reader, advisor, and organizer of most of my projects over the past 58 years. For the Handbook she was also the secretary who kept track of the 46 chapters as they came and went from authors to editors and back again in the various stages of completion. We must certainly mention the many authors who contributed their knowledge and skills to make this Handbook an important contribution to the education and practice of those in the field of Audiology. To all of them and, of course, to my fellow editors my thanks and gratitude.

SECTION I

Basic Tests and Procedures

A Brief Introduction to Clinical Audiology and This Handbook

Jack Katz

Audiology is the study of hearing and hearing disorders, a field devoted to helping those with auditory and vestibular dysfunctions. This work may involve evaluation, re/habilitation, counseling, education, research, and/or screening/prevention.

Audiology combines aspects of science and art with techniques that are based on both basic and clinical research. We use sophisticated equipment to provide precision in determining the type and extent of the problems. But audiology is also an art. It involves the ability to perform the various tasks precisely and to provide information and maximum support to the individuals affected and their families. Because of these intellectually and emotionally gratifying aspects, it makes audiology an exciting career.

In my more than 50 years in this field, audiology has continued to be interesting and rewarding work. It is a comparatively new field that emerged in the aftermath of World War II (WWII) to aid service members who suffered hearing impairments. It brought together speech-language pathologists, deaf educators, psychologists, and ear, nose, and throat (ENT) physicians. This interdisciplinary cooperation was responsible for the excellent services that were provided to the injured military personnel. At the same time these multidisciplinary activities helped to lay the groundwork for the field of audiology. Indeed this interdisciplinary aspect of the field of audiology remains one of its great strengths even today. Initially, audiologic work was carried out in military hospitals and then spread to universities and university clinics, afterward to hospitals and community clinics.

Presently there are about 12,000 members of the American Academy of Audiology and approximately 2,000 members of the International Society of Audiology. Also memberships continue to grow in local, state, and national associations around the world. Audiology has several peer-reviewed journals and other publications, both printed and digital, that report on research and clinical developments. The field of audiology is constantly expanding its horizons and developing deeper understandings of both normal and abnormal processes.

AUDIOLOGY FROM 1940s TO TODAY

As mentioned above, the field of audiology was founded during WWII. Prior to that time hearing testing was carried out using tuning forks and whispered speech by medical doctors, although some puretone audiometers that provided repeatable stimuli were also in use. The combined efforts of the different disciplines fostered the variety of procedures we have to address the problems caused by hearing impairment. Bone-conduction testing and speech audiometry were soon added to the clinical tools. Aspects such as lip reading/speech reading, auditory training, and counseling were borrowed from deaf education, psychology, and speech-language pathology. An important adjunct for the service members was the fitting of hearing aids which were quite limited by today's standards. Nevertheless for years after the war these veterans were still using and benefiting from the amplification and training that they had received from those early audiologists when the profession was in its infancy.

After leaving military service, the early audiologists began to train others at colleges and universities. Audiologists began to research the clinical problems that they faced and many of these approaches and solutions are still in use today. These procedures also led the way to important innovations. Because it was clear that we did not have enough diagnostic information to accurately measure and categorize hearing disorders, early on, there was a heavy emphasis on developing new diagnostic procedures. For a number of years the area of diagnosis was the primary focus in audiologic research and practice.

When audiologists began dispensing hearing aids, this caused an expansion of attention, from just evaluation and identification of hearing loss to include providing means of managing hearing difficulties and therapy to address the communication problems. Hearing aid fitting was also a major impetus for audiologists to go into private practice. At the same time there were major breakthroughs in physiological measurements. This began with what we now refer to as cortical responses, but after a few years, earlier responses were identified from the auditory nerve and even

the cochlea. The field of audiology has expanded to include the assessment of more complex functions at all levels of the peripheral and central auditory nervous system. Immittance measurements enabled audiologists to assess mechanical properties of the auditory system of the outer and middle ears, as well as middle-ear muscle responses that rely on auditory nerve and brainstem activity. Specialties such as auditory processing disorders, educational audiology, vestibular function, and interoperative monitoring have added to the breadth and depth of the field.

The growing sophistication and understanding of auditory functions and development can be seen in the lowering of the target ages for various services. In the mid-1950s it was taught that we should wait until deaf children are perhaps 10 years of age before testing them and presumably provide amplification after that. Given our current state of knowledge, in retrospect, this seems absurd and counterproductive. At that time we did not understand that developmental problems should be identified at the earliest possible time. Otherwise, the person could miss critical periods and lose plasticity, as well as fall further behind with reduced learning and more acquired misconceptions. Now, neonatal hearing screening is widespread and we strive to begin habilitation by 6 months of age. In fact, in the past, one audiologist was ridiculed when she advocated that audiologists fit hearing aids for children as young as 1 year of age. Once we realized the critical importance of the early years for later development, early identification and assessment procedures, as well as training procedures were targeted and developed.

As the field of audiology expanded so did the academic demands on the practitioners. Initially, a bachelor's degree was required to practice and then a master's degree was the entry level along with basic clinical certification. As in the past a Ph.D. was generally desired for university teaching and research. In more recent years (in the United States) the Doctorate of Audiology (Au.D.) degree was introduced to provide even broader clinical teaching and training experiences. Also, higher levels of competency and certification are generally required today to practice audiology. Students interested in a career that includes independent research continue to pursue a Ph.D. in audiology, hearing science, or related areas. Now many of the top university programs in audiology have both Ph.D. and Au.D. trained professors to provide the student the best of both worlds. We also see combined Au.D./Ph.D. programs that offer students excellent ground for both clinical and research endeavors.

We owe a debt of gratitude to those early audiologists who helped to form this vibrant and vital health profession. Although we cannot mention the many important contributors, it is perhaps appropriate to mention Raymond Carhart (1912 to 1975) who is generally recognized as "The Father of Audiology." He was an important contributor to the developing field of audiology and an excellent teacher. Many of his students from Northwestern University in

Evanston, Illinois went on to contribute significantly to the field of audiology in their own right.

ABOUT THIS HANDBOOK

The first edition of the *Handbook of Clinical Audiology* was published in 1972 and subsequent editions have served several generations of audiologists in the United States and increasingly throughout the world. It is used widely as both a text and reference book by students and professionals in various fields.

Currently, for this edition, we have five editors who have diverse areas of specialization in clinical, research, and teaching aspects for which they are responsible. To broaden our horizons and to be as inclusive as possible, in this edition we have tried to include more international voices and procedures.

We have squeezed in as much information in 1,000 pages as we could. The more than 90 contributors are highly regarded audiologists who also have clinical, research, and teaching experience. This makes the chapters authoritative, well organized, and geared for sharing our knowledge in a field that we love. We have always considered readability an important feature of this book and especially now that it is used by many people whose first language is not English.

The 46 chapters are divided into four sections. Section I deals with basic tests and procedures that are used by most audiologists for most of the people with whom they work. This involves puretone air and bone conduction, as well as standard speech audiometry. Calibration and case history chapters are also important components for any audiologic assessment. The Diagnostic Audiology chapter helps the reader to combine all of the previous information into a coherent diagnosis.

Section II introduces the various physiological and electrophysiological procedures used by audiologists at this time. These include immittance measures that primarily reveal the status of the middle ear. Electrocochleography and Otoacoustic Emissions provide detailed information about the responses from the cochlea, the end organ of hearing. Five chapters in this section discuss the electrophysiological responses from the auditory nerve, brainstem, and various areas of the brain. The chapter on intraoperative monitoring describes the analysis of the auditory system during surgery that informs the surgeons about the status and possible adverse effects of their manipulations of the auditory system. The final three chapters in this section deal with the vestibular system. They begin with the study of vestibular neurophysiology and end with vestibular rehabilitation.

Section III is called Special Populations. This recognizes that certain groups often require modifications in audiometric procedures or accommodations. Evaluation of young children offers a special challenge to the audiologist because they do not have the auditory or cognitive development needed for some of the tests, and it is sometimes

difficult to have them perform in the expected fashion. This chapter describes ways to obtain the desired results. Hearing, screening, and educational audiology generally involve the work carried out in schools with those who have normal hearing as well as those with auditory impairments. This section also includes chapters that deal with those who have multiple disabilities, hereditary hearing loss, and the elderly. Other special groups are those with noise-induced hearing loss, those who have tinnitus, and individuals who have “nonorganic” hearing loss. Four of the other chapters involve auditory processing disorders, which include the bases of central auditory problems, diagnostic procedures, and subsequent remediation. This section concludes with a chapter on tele-practice in which audiologists can work with people at far distances via communication systems.

Section IV deals with the management of hearing disorders. It begins with acoustical environments and technologies that are used to aid the hard-of-hearing person in reducing the influence of noise and other factors that can compromise communication. This is followed by four chapters related to various aspects of hearing aids and hearing aid fittings. Another chapter, which deals with implantable hearing devices, is a rapidly expanding area. The chapter discusses cochlear implants and other devices that are surgically imbedded into the person with a hearing loss. Two other chapters deal with management of those with hearing problems in the classroom and with rehabilitation of adults. There is also a chapter in this section that advises audiologists on how to start an effective audiologic practice.

New Chapters in This Edition

- a. *Diagnostic Audiology* serves an important purpose in bringing together the information from the basic evaluation procedures in this book to form an audiologic interpretation and an understanding of the patient's needs. This chapter will also discuss some procedures that are not covered in the preceding chapters, as well as mentioning what our tests do not tell us.
- b. *The Dizzy Patient and Vestibular Rehabilitation* chapter is an extension of a former Handbook chapter, applying diagnostic information to enable appropriate treatment decisions for patients with vestibular problems. It will describe audiologic procedures designed to relieve patient's symptoms, as well as the role of physical therapy and the necessity of collaboration among healthcare professionals.
- c. *Hearing Screening* discusses newborn hearing screenings, school screenings, and other screening procedures using universal approaches and targeted population approaches. The specific procedures, their value, and outcomes of screening programs will be discussed.
- d. *Hereditary Hearing Loss* describes much-needed information for audiologists related to genetic aspects of hearing loss that may be nonsyndromic or part of a

known syndrome. Since audiologists are often the first professionals to suspect a genetic basis for a hearing loss, it is important to have current information available as well as the knowledge of resources.

- e. *Audiology Tele-practice* follows the global trend to provide appropriate services at a distance from the professional. Using a range of communication technologies and appropriate training of para-professionals, audiologists can treat individuals in remote places who might otherwise not receive care. Tele-practice also provides convenience to patients who live relatively close by, but nonetheless find it challenging to visit the clinic for routine problems. By making oneself available using tele-technology, the audiologist helps patients conserve their physical energy, time, and travel expenses, while keeping abreast of the patient's challenges as they develop.
- f. The topic of *Infection Control* relates to every aspect of audiology, because it is important not to harm the people whom we are here to help. Infection control is part of every aspect of our work and for this reason it is the first of many chapters, in the future, that will be available from the Point on internet.

Other New Features in This Handbook

In this edition of the Handbook we have reduced the number of references provided in each chapter, but there are extensive lists of references for the interested students, professors, and researchers on the Point. In this way the reader is not encumbered with reading through or skipping over many references when trying to understand the concepts and to remember the facts in this book. At the same time there are thousands of references organized by chapters online for those who are interested in research or for greater depth on the topics covered in this book.

Another new feature is the thought questions at the end of each chapter. They will ask how and what you would do in dealing with, or solving, problems associated with the information in the chapter. This is not another hoop to jump through but a valuable exercise. The student must take what they have learned from the chapter and combine it with their other knowledge to figure out a good solution to a problem/question. In this way they take what was on page and internalize it, while it is fresh in their minds, and put the information to a practical use. This will help you to internalize the information and make the material your own.

Terminology

Most of the terms used in this edition are standard in the field at this time. However, when a change is made it should be for a worthwhile purpose and not one that creates important problems. For example, this writer was pleased to

see a recent change back to a previous term. What was once called *Central Auditory Processing* was changed to *Auditory Processing* and recently was changed back to the clearer and more specific *Central Auditory Processing* again (American Academy of Audiology, 2010).

SENSORY/NEURAL

A conductive loss is a mechanical impairment of hearing, associated with the outer and/or middle ears. For many years a nonconductive loss had been called a “nerve loss.” After WWII it was changed to “sensory-neural loss” when ENT doctors and audiologists were then able to separate sensory (cochlear) from neural (acoustic nerve or brainstem) disorders. For example, cochlear problems (such as Meniere’s disease) were demonstrated by a rapid growth of loudness when a sound was presented above the person’s threshold of hearing. On the other hand with retrocochlear losses (e.g., auditory nerve or brainstem) there was no accelerated growth of loudness with sounds above the neural hearing level (as with a person who had an auditory nerve tumor). However, after a number of years the term sensory-neural was changed to “sensorineural.” There was little reaction to this minor change.

I was shocked, however, to receive an angry phone call from a doctor who claimed that I made a mistake which caused him to delay surgery for his patient’s auditory nerve tumor. From a review of my report it was abundantly clear that the patient had retrocochlear characteristics that are consistent with an “eighth nerve or brainstem involvement” and not cochlear involvement. How could that have been misinterpreted? The physician only had read up to the first test result, that puretone testing showed a “sensorineural loss in the right ear.” On seeing the term “sensorineural” he incorrectly concluded that it was a cochlear problem and not a very dangerous auditory nerve tumor. He did not know that the term *sensorineural* could represent two importantly different types of hearing loss. Puretone thresholds distinguish conductive from both sensory and neural disorders.

Later on similar mistakes, with the term *sensorineural*, were made by knowledgeable audiologists in two separate publications. This convinced me that the term *sensorineural* can create serious problems that should be less problematic with the original term *sensory-neural*.

Since the second edition of the Handbook we have used the term *sensory-neural* to avoid the errors caused by sensorineural (Katz, 1978). If those who coined the term *sensorineural* originally did not try to combine two auditory components that we try hard to distinguish from one another, it is likely that fewer problems would have occurred. Other authors have recognized the problem with the term *sensorineural*. Jacobson and Northern (1991) suggest using just sensory or neural, when it is clearly one or the other. Martin and Clark (2012) avoid the confusion by using the term *sensory/neural* which is also a good way to clarify the term.

For this edition we will combine both the Jacobson and Northern and the Martin and Clark approaches as this seems to be better than sensory-neural and avoids the problems that ‘sensorineural’ has caused.

PURETONE

The reader might infer that the writer does not like compound words (two words that are combined to form a composite of the two, e.g., flashlight, textbook). We rarely combine opposites (e.g., dogcat, daynight, or even sensorineural). But when two words are frequently spoken together (e.g., *base* and *ball*) often the first step is to hyphenate them (base-ball) and when people get used to this expression, they are often combined and made a compound word (*baseball*).

The term “pure tone” is shown one or more times on every audiogram and appears in almost every report and is a very common type of audiometer (but in that case it might be hyphenated because it is followed by a noun, e.g., pure-tone audiometer). Because (1) we have to explain this to students and often have to decide if it needs a hyphen when we are writing, and (2) it is surely time to graduate from pure-tone to puretone, this change seems appropriate. In this case there is no compelling reason for doing so (as it would be in the case of sensorineural) but it seems that it is time for “pure” and “tone” to be officially married and to be a compound word forever more.

ESPECIALLY FOR STUDENTS— SOME SUGGESTIONS

As a student, it is most helpful to educate yourself broadly in your profession and related subjects. You may benefit from speech, psychology, and many other courses as much as from some of your audiology courses. The ability to take a broader view is certainly an advantage no matter how you plan to practice audiology.

When you have a choice in taking your first job, it is well to take one that covers a wider area of professional activity over one that is narrow. You may find that an area that previously did not seem too interesting is one that you realize is very interesting or gratifying. Also, if you have a broad experience you can qualify for more opportunities later on.

As you get deeper into your areas of major interest you will necessarily reduce how broadly you can practice. But having a prior background or learning can help you in what you are doing and perhaps provide variety in your professional activities. Later on, if you have specialized in one area then an exciting and enriching aspect is to carry out research to improve your success or simply to obtain a better understanding. One way to repay your profession for training you is to supervise students in your external practicum site. Mentoring students and sharing what you have learned can be most rewarding, but in addition you may learn some

new concepts from the students that you may have missed or learn from having to answer their questions.

It is our pleasure to provide you with this book full of knowledge that was written by dozens of audiologists who have enjoyed sharing with you their hundreds of years of experience in this wonderful field. Finally, as professionals we should be committed to helping those we serve. We also need to follow the rules. Of course, in addition your work needs to provide you with the necessities of life. Despite these constraints, to a great extent, your profession is pretty much what you make of it.

FOOD FOR THOUGHT

1. What personal characteristics and experiences do you have that you think will be helpful to you as an audiologist?
2. You are the Director of an Audiology Department at a medical center. There is a need to establish guidelines for the audiologists to provide a degree of consistency (e.g., in reports). You have seen “sensorineural” spelled like that and also as sensory/neural. Consider

the main reason for choosing each of them for your department.

3. If you were the editor of *Handbook of Clinical Audiology* and could only add one chapter to this edition, based on what you know or imagine, which of the six new chapters (see above) would you choose and why?

Calibration

Laura Ann Wilber and Robert Burkard

WHY CALIBRATE?

In some ways, calibration can be compared to exercising. We know it is good for us, but some of us would prefer not to participate. However, unlike exercising, if one does not calibrate, it hurts others (our clients) more than it does us. For years, many clinicians felt that calibration was something that researchers did but that such procedures were not necessary in the clinic. Today, that basic attitude has changed dramatically. The Occupational Safety and Health (OSHA) regulations (1983) require that audiometric equipment be regularly checked. Some state regulations for hearing aid dispensers and/or for audiologists also require that equipment calibration (and records of calibration) be maintained. Furthermore, many state health departments concerned with school screening also insist on having calibration checked on a routine basis. Thus, we *must* calibrate if we are to meet the current regulations, and we *should* calibrate to make sure our results are within specified tolerances.

Initial audiometric calibration provided by the manufacturer is insufficient to guarantee that the audiometer will function correctly over time. Although modern digital audiometers are less likely to arrive out of calibration and are less likely to develop problems later than the older vacuum tube machines, even brand new audiometers that have just arrived from the factory, as well as audiometers that were in perfect calibration when they were new, can show variations in sound level, frequency, distortion, to name a few. Problems are often related to the transducers (earphones, bone vibrators, loudspeakers), but the electronic components can also lead to the audiometer failing to remain in calibration. It is the responsibility of the user (i.e., the audiologist) to either check its calibration personally or to arrange for regular calibration of the equipment by an outside service. The audiologist who has demonstrated that the clinic equipment is “in calibration” can then feel confident in reporting the obtained results. Calibration checks can determine if an audiometer meets appropriate standards and also whether the instrument has changed over time.

The purpose of this chapter is to tell the audiologist or student how to check audiometers to determine if they meet current national (or international) standards. Through-

out this chapter, we will refer to various standards. In the United States, we (mostly) rely on standards that have been approved by the American National Standards Institute (ANSI). Nonetheless, we will also refer standards written and approved by the International Electrotechnical Commission (IEC) and the International Organization for Standardization (ISO). Since these standards do not have the status of law, it is important to understand how, and perhaps why, they are developed: Standards are developed so that manufacturers of equipment (from all countries) and users of the equipment are all on the same page. According to its website (http://www.ansi.org/about_ansi/overview/overview.aspx?menuid=1), ANSI is “a private, nonprofit organization (501(c) 3) that administers and coordinates the U.S. voluntary standardization and conformity assessment system.” Its “mission is to enhance both the global competitiveness of U.S. business and the U.S. quality of life by promoting and facilitating voluntary consensus standards and conformity assessment systems, and safeguarding their integrity” (ANSI, 2004). Some values (e.g., the “0” hearing level [HL]) have both international and national approval. In most cases, ANSI standards and ISO and IEC standards are technically very similar (in current jargon, this is called harmonization). Harmonization of ANSI and international standards enhances commercial interchange between nations. If, for example, the ANSI audiometer standard was radically different from the IEC standard, manufacturers would have to build instruments solely for the American market and solely for the European or World market. In a relatively small-volume industry (such as audiometric instrumentation), this would be impractical at best.

All standards are reviewed periodically. If they are reaffirmed (and not changed), then the standard will read, for example, ANSI S3.39-1987 (R2012). This means the standard was approved in 1987 and was most recently reaffirmed in 2012. If the standard is revised, then the date changes (e.g., ANSI S3.6-2010, which was previously ANSI S3.6-2004). An announcement is made when the standard is going to be voted on so that interested parties can obtain a copy and comment to the person or persons who will be voting. For example, audiologists might contact the American Speech-Language-Hearing Association (ASHA) or the American Academy of Audiology (AAA), both of which are voting

members. This is the basic procedure for development and approval of standards. For more information on the standards process, the reader is referred to Melnick (1973) and Wilber (2004). There are three primary sources of funding for the production of standards in acoustics: financial support from Acoustical Society of America (ASA), fees paid by the voting members of an Accredited Standards Committee, and income from the sales of standards. Through your purchase of standards, you are supporting the efforts of those professionals who donate their time and effort to develop and maintain ANSI standards. Contact information of the secretariat of ANSI S1, S2, S3, and S12 is:

PARAMETERS OF CALIBRATION

The first step in learning how to check calibration should always be to read the appropriate manual(s) that accompany the audiometric equipment that you have purchased. Additional resources include electronic parts, stores that often have basic manuals on test equipment, ASHA and ASA. A number of books have also discussed procedures for acoustic measurements and equipments that might be used in such measurements (Beranek, 1988; Decker and Carrel, 2004; Silverman, 1999). The United States Government Printing Office is also a good source of information on basic test procedures. The specific parameters that must be checked in an audiometer are outlined in standards provided by the ANSI and the IEC. See Table 2.1 for a listing of standards relevant to calibration of audiometric equipment. It is beyond the scope of this chapter to discuss each area of calibration in detail. For the readers who intend to perform their own calibration of audiometric equipment, they need to purchase copies of the latest standards to verify the exact parameters to be checked and their permissible variability. To better understand the procedures for checking calibration, one must first understand the parameters that need to be checked, as well as the equipment used to perform these calibration checks. For puretone and speech audiometers, the three parameters are (1) frequency, (2) level (sound pressure level [SPL] or force level or [FL]), and (3) time. These parameters apply whether one is using a portable audiometer, a standard diagnostic audiometer, or a computer-based audiometric system.

Some organizations, such as ASHA and OSHA, specify time intervals at which calibration checks should be made. With current solid-state electronic circuitry, frequency, and time, parameters should be checked when the audiometer is first acquired and at yearly intervals thereafter. Older equipment should be checked at least biannually. For newer

equipment, if daily listening checks are strictly enforced, transducers should be verified at least annually, unless there is reason to suspect that the output has changed. If daily listening checks are not strictly enforced more complete checks might be necessary. In addition to regularly scheduled checks, audiometers should be tested *whenever* the clinician notices anything unusual in their performance.

Sometimes test results themselves reveal the need for an immediate calibration check (e.g., when the same air-bone gap is obtained for two successive patients). It is always better to check the audiometer first rather than assume the problem lies with the client or clinician. A quick biologic check (described later) can always be performed. If this confirms the probability of an equipment problem, then a more elaborate electroacoustic check should be carried out.

If the audiologist discovers that the frequency or time components of the audiometer are out of calibration, then in most instances the manufacturer or a local representative should be contacted for immediate repair and/or proper calibration of the instrument. However, if there is a stable deviation in output level at a given frequency, calibration corrections can be made by adjusting the trim pots (potentiometers) on the audiometer, by using the audiometer's self-calibrating mechanism, or by posting a note on the front of the audiometer indicating the corrections. If paper corrections must be used, then the adjustment in decibels (plus or minus) that should be made at the various frequencies should be shown for each transducer. Note that if the SPL output is too high (e.g., by 5 dB), then you must increase their audiometric threshold (e.g., by 5 dB HL). Most modern audiometers provide some sort of internal (typically software based) calibration system for earphones, and many also provide this for bone conduction or sound field. If one plans to use bone vibrators for both mastoid and frontal bone testing or two sets of earphones with the same audiometer (e.g., supra-aural earphones and insert receivers), it is probably advisable to use "paper corrections," rather than trying to adjust trim pots between each transducer's use. If frequent level adjustments are required, it is probably wise to check with a qualified technician.

INSTRUMENTATION

As mentioned earlier, the calibration of an audiometer requires the use of various pieces of electroacoustic and electronic instrumentation. Most, if not all, graduate audiology programs will have the instrumentation needed to at least evaluate whether the audiometer meets the reference equivalent threshold sound pressure level (RETSPL), frequency, linearity, and distortion standards specified in ANSI S3.6 Specification for Audiometers. In this section, we will review the use of several basic instruments, including sound level meter (SLM), multimeter, frequency counter, oscilloscope, and digital spectrum analyzer. More details on acoustics and instrumentation can be found in numerous

TABLE 2.1

ANSI, IEC, and ISO Standards for Audiometers and Audiometric Testing

Number	Title
ANSI S3.1-1999 [R 2008]	Maximum Permissible Ambient Noise for Audiometric Test Rooms
ANSI S3.2-2009	Method for Measuring the Intelligibility of Speech Over Communication Systems
ANSI S3.6-2010	Specification for Audiometers
ANSI S3.7-1995 [R 2008]	Coupler Calibration of Earphones, Method for
ANSI S3.13-1987 [R 2012]	Mechanical Coupler for Measurement of Bone Vibrators
ANSI S3.20-1995 [R 2008]	Bioacoustical Terminology
ANSI S3.21-2004 [R 2009]	Method for Manual Pure-Tone Threshold Audiometry
ANSI S3.25-2009	Occluded Ear Simulator
ANSI S3.36-2012	Specification for a Manikin for Simulated In Situ Airborne Acoustic Measurements
ANSI S3.39-1987 [R 2012]	Specifications for Instruments to Measure Aural Acoustic Impedance and Admittance [Aural Acoustic Immittance]
ANSI S1.4-1983 [R 2006]	Specifications for Sound Level Meters
IEC 60318-1:2009	Electroacoustics: Simulators of Human Head and Ear. Part 1—Ear Simulator for the Calibration of Supra-aural and Circumaural Earphones
IEC 60318-4:2010	Electroacoustics: Simulators of the Human Head and Ear. Part 4—Occluded-Ear Simulator for the Measurement of Earphones Coupled to the Ear by Means of Ear Inserts
IEC 60318-6:2007	Electroacoustics: Simulators of Human Head and Ear. Part 6—Mechanical coupler for the measurement on bone vibrators

NOTE: All ANSI, ISO, and IEC Standards referred to in this chapter are listed in this table.

texts (e.g., Decker and Carrell, 2004; Harris, 1998; Rosen and Howell, 1991; Speaks, 1996).

Multimeter

The term “multimeter” indicates that this device can be used to make multiple measurements. In most cases, a multimeter will allow one to make measurements of voltage, current, and resistance. Each of these measurements is made differently, and we will limit our discussion herein to making voltage measurements. To measure voltage, we must make the measurement in parallel to (across) the device of interest. For example, if we are interested in attenuator linearity, we want to place the leads of the multimeter across the earphone leads, with the earphone plugged into the audiometer output. We can replace the earphone with an equivalent impedance (in most cases, a 10-, 50-, or 300-ohm resistor for ER-3 A, TDH-39, TDH-49, or TDH-50 earphones). Simply unplugging the earphones and plugging in the multimeter will likely produce inaccurate results, because this approach in most cases will change the load impedance of the audiometer output. It is important to purchase a true root mean square (RMS) multimeter for accurate RMS voltage readings. It is important to set the meter to AC, or alternating current (vs. DC, or direct current), voltage. The meter is most accurate when set to the lowest voltage range possible. In most cases, the voltage range is set in powers of 10, where the listed voltage is the maximum voltage possible for that voltage range. When this maximum voltage is exceeded, an overload is indicated (see multimeter manual for the overload indicator for your multimeter). You adjust the multimeter range until you have the most sensitive range (lowest maximum voltage) where the output is NOT overloaded.

Frequency Counter

This might be a stand-alone device, or it might be an option on your multimeter. In the case of a stand-alone device, a frequency counter will often have a trigger adjust (the voltage level and direction: positive-going or negative-going) that determines when an event is triggered. The frequency counter combines an event counter with an accurate clock. The ratio of events (i.e., cycles) divided by the time elapsed gives you the frequency (in hertz). Thus, if 20 events are measured in 10 ms (one-hundredth of a second), then the cycles per second (or hertz) = $20 \text{ cycles}/0.01 \text{ s} = 2,000 \text{ cycles/s (Hz)}$. If the counter does not trigger (no events counted), you need to reduce the trigger level or turn up the signal (e.g., increase the dB HL on the audiometer dial). If the frequency counter reads a number substantially larger than expected, then it is possible that the trigger level is set too low (or the signal presented is set too high) and that multiple triggers per cycle are occurring. In this case, turning the signal level down or increasing the trigger level of the frequency counter should

correct this problem. If the frequency counter is an option in a multimeter, there is often no adjustable trigger level, and the signal level must be changed to correctly trigger the counter function.

Sound Level Meter

The SLM is actually multiple instrumentation components provided in a single instrument. You can combine separate instruments into a usable device when an SLM is not available. At a minimum, for checking the calibration of RET-SPL (i.e., 0 dB HL values on the audiometer), you need an acoustic calibrator, an appropriate coupler (2 cc and/or 6 cc), a microphone, and the SLM. SLMs used for checking the calibration of audiometers should be Type 1, as should microphones used for such calibrations. The most commonly used Type 1 microphone is a condenser microphone. Condenser microphones come in four standard sizes (referring to their diameter): 1/8", 1/4", 1/2", and 1". For calibration of a supra-aural earphone, a 1" microphone is specified in ANSI S3.6-2010 (because of its sensitivity—see the statement that follows). In general, the smaller the microphone is, the higher its upper frequency cutoff and the less its sensitivity. Sensitivity is a measure of its efficiency transferring sound pressure into voltage and is commonly reported as millivolts per pascal, or in dB re: 1 V/Pa. Many condenser microphones require a DC polarization voltage of 200 V. Some condenser microphones are prepolarized and hence do not require an externally applied polarization voltage. Microphones also come as pressure microphones (to be used in a coupler), free-field microphones (to be used in sound field recordings such as when measuring the ambient noise in the sound booth), or random-incidence microphones (for measures in, e.g., reverberant environments). More detailed information about microphones and SLMs can be found in Johnson et al. (1998) and Yeager and Marsh (1998). It is important that your SLM and microphone be compatible (i.e., provide the correct polarization voltage), or equipment damage and/or incorrect SPL measures may result.

The SLM also contains amplifiers (whose gain is changed when you change the SPL range), time-weighting circuits (for fast, slow, and possibly impulse and peak time weightings), various filter settings (e.g., dBA, dBC, and octave and/or third-octave band filters), as well as a display function (this could be a volume unit (VU) meter, an LED indicator, and/or a digital readout). The gain of an amplifier in the SLM must be adjusted to account for the sensitivity of each microphone. For example, a 1" microphone might have a sensitivity of 50 mV/Pa, whereas a 1/4" microphone might have a sensitivity of 1 mV/Pa. If the SLM were adjusted appropriately for the 1/4" microphone, then when 1 Pa of pressure was presented to the microphone diaphragm, the SLM would read 94 dB SPL [$20 \log(1 \text{ Pa}/0.0002 \text{ Pa}) = 94 \text{ dB SPL}$]. If we replaced the 1/4" microphone with the

1" microphone but did not change the SLM amplifier gain, the 1" microphone would read 128 dB SPL [94 dB SPL + $20 \log(50 \text{ mV}/1 \text{ mV})$]. How, then, do we calibrate the SLM so that it displays the correct SPL? In most instances, we would use a device that presents a known SPL to the diaphragm of the microphone. Two types of calibration devices are commercially available for this purpose: pistonphones and acoustic calibrators. The former produces sound by a mechanical piston, whereas the latter uses an electrical oscillator and a transducer to produce the tone. Each calibrator produces a specified SPL at a specified frequency, and this calibrator should be periodically sent back to the manufacturer to assure it remains within specified tolerances of frequency and SPL. These calibrators can accommodate a variety of microphone sizes by inserting nesting adapters. Using an acoustic calibrator is very simple: turn on the SLM, place the calibrator snugly over the microphone, and turn on the calibrator. Making sure that the frequency response of the SLM is wideband (flat, or dBC if flat weighting is not available), adjust the gain of the SLM (by trimming a calibration potentiometer using a screwdriver or via software) until the specified output of the calibrator (e.g., 114 dB SPL) is displayed on the SLM.

Once the SLM is calibrated, you must remove the acoustic calibrator (or pistonphone) and place an appropriate coupler over the microphone: a 2-cc coupler for insert earphones (e.g., Etymotic ER3 A earphones) or a 6-cc coupler for supra-aural earphones (such as TDH-39, TDH-49, or TDH-50 earphones). ANSI S3.6-2010 has RETSPL values for both insert and supra-aural earphone for several 6-cc (National Bureau of Standards [NBS] 9-A, IEC 318) and 2-cc (HA-1, HA-2, occluded ear simulator) couplers.

Oscilloscope

The oscilloscope, in its most common display mode, presents voltage as a function of time. Oscilloscopes come in analog and digital types. In the analog oscilloscope, the output of an electron gun transiently illuminates the screen of a cathode ray tube. Freezing the display on the oscilloscope screen involves repeated triggering of the oscilloscope on a fixed phase of the stimulus. Specialized analog oscilloscopes that can freeze a display for prolonged periods of time are called storage oscilloscopes. A digital oscilloscope is similar to an analog oscilloscope, except that instead of electron guns and a cathode ray tube, the signal is recorded by an analog-to-digital converter and displayed on a flat panel display. Digital oscilloscopes often have features that are not typically available on analog oscilloscopes (e.g., storage of waveforms, cursor functions, and summary statistics such as peak-to-peak and RMS voltage calculations). Simple amplitude and voltage measurements are easily performed on a signal using an oscilloscope. Manipulations of the time base (in time per division) and amplitude (in volts per division), as well as the appropriate adjustment of the trigger,

allow the “freezing” of the signal on the oscilloscope. To measure, for example, peak-to-peak voltage, one counts the number of vertical divisions (usually a division is a centimeter) extending from the positive to the negative extremes and multiplies this number of divisions by the voltage per division to obtain the peak-to-peak voltage. It should be noted that measurements made on an analog oscilloscope are assumed to have an error of 5% or more.

Spectrum Analyzer

Numerous devices can be used to provide a frequency-domain representation of a signal (including the octave or third-octave band filters available on many SLMs). In this section, we will limit our discussion to instruments referred to as digital spectrum analyzers. These instruments may be stand-alone hardware devices or might be part of a computer-based hardware/software application. These devices convert an analog input signal to digital format by use of an analog-to-digital converter. It is important that the reader understand that if the sampling rate used during analog-to-digital conversion is too slow, it can cause the generation of “false frequencies” in a process called aliasing. Many spectrum analyzers preclude aliasing by judicious use of a low-pass filter (called an antialiasing filter). It should also be noted that not all possible signal amplitudes can be encoded following analog-to-digital conversion, but signal level is rounded off (“quantized”) and that the magnitude of possible quantization error is related to the voltage range and the resolution (related to the number of bits) of the analog-to-digital converter. The time-domain signal is digitized over a limited time period, called the time window or the time epoch. Once the signal is digitized into a time epoch, it is converted into the frequency domain by Fourier transformation. (See Rosen and Howell, 1991 for a more complete explanation of aliasing, antialiasing, quantizing, and digitization.) The fast Fourier transform (FFT) is one of many algorithms that have been developed to convert a time-domain (voltage over time) signal into a frequency-domain (amplitude across frequency) signal. Another term for the frequency-domain representation is the spectrum. In addition to the possibility of quantization errors and aliasing, you must be aware that signal processing prior to Fourier transformation can have an influence on the results. Because of some underlying assumptions about the periodic nature of the discretely sampled signal, the spectrum of the signal is distorted unless an integer number of cycles of all frequencies is contained in the time epoch over which the signal is digitized. To prevent the distortion (often called leakage) that occurs when a noninteger number of cycles is contained in the time epoch, the digitized time epoch can be shaped. This shaping multiplies the signal by values at or near zero, near the beginning and end of the time window and weights them at or near 1, near the middle of the time window. One popular windowing function is the

Hanning window. A given windowing function trades amplitude uncertainty for frequency resolution. Once the data are converted to the frequency domain, the amplitude of a given Fourier coefficient (e.g., frequency) can be determined using a cursoring function. It should be noted that Fourier transformation produces multiple discrete harmonically related (i.e., integer multiples) spectral components. The lowest frequency (fundamental frequency) and, hence, the frequency interval between components are related to the recorded time-domain signal. If the time-domain signal is, for example, 200 ms (0.2 s), then the lowest frequency is $1/0.2$ s, or 5 Hz. The longer the time window is, the better the spectral resolution.

BASIC EQUIPMENT

The basic calibration equipment for checking output levels of an audiometer should include (1) a voltmeter or multimeter; (2) condenser microphones (both pressure and free-field types); (3) acoustic calibrator; (4) a 6-cc coupler (NBS 9-A or IEC 318); (5) a 2-cc coupler (ANSI HA-1 or HA-2 or IEC occluded ear simulator); (6) a 500-g weight; (7) a mechanical coupler for bone vibrator measurements (artificial mastoid); and (8) an SLM (or equivalent). When purchasing any of the above components, it is wise to check with others who use similar types of equipment to find the best specific brands available locally.

Other equipment such as a digital oscilloscope, frequency counter, and/or a spectrum analyzer will also prove to be invaluable in checking the acoustic parameters of audiometers. In many instances, this equipment can be shared by more than one facility. If one has only one or a few audiometers, a service contract is most sensible. If one has a substantial number of pieces of audiometric test equipment, an SLM (with appropriate couplers, microphone(s), and acoustic calibrator) and a multimeter should be purchased and used. If the accuracy of the audiometer is questioned, it necessitates shutting down the equipment or retesting patients at a later date. This translates into time and financial loss, not to mention more serious consequences in surgical or medicolegal cases. In a busy practice, such a loss would surely be equivalent to the cost of one or more pieces of electronic test equipment that would prevent this problem. This of course assumes that someone working in that practice setting is competent to check the calibration of the audiometric equipment.

CHECKING THE CALIBRATION OF PURETONE AUDIOMETERS

Basic Signal

As soon as one obtains a new audiometer, the manual should be read and, if any calibration instructions are provided, they should be followed.

Biologic Check

After the audiometer has been installed, plugged in, turned on, and allowed to warm up, the operator should listen to the signal at different dial settings through each transducer (earphone, loudspeaker, and bone vibrator). With a little practice, one can hear basic faults in the equipment. A vague complaint to the audiometer technician or distributor that it “sounds funny” is as futile as telling an auto-repair person the same thing. However, a specific description of the sound and when it occurs can help determine the source of the trouble. If the technicians are given a detailed description of the problem, then the fault may be found more quickly, without wasting their time and your money.

Much information on the source of the problem may also be obtained by inspecting the audiometer. Following are some areas of potential malfunction that the audiologist should check periodically (normally on a daily basis):

1. Check the power, attenuator, earphone, and vibrator cords for signs of wear or cracking. Listen to the tone through the transducer at a comfortable level while twisting and jiggling the cords. A defective cord will usually produce static or will cause the tone to be intermittent. Tightening the earphone screws and/or resoldering the phone plug connections might fix the problem. If this does not alleviate the problem, it is wise to replace the cord.
2. If the audiometer has dials, check for loose dials or for dials that are out of alignment. If such faults exist, the dial readings will be inaccurate. Defective dials should be repaired immediately (sometimes this just requires tightening the set screws that hold the dial to the audiometer), and the audiometer should be recalibrated to determine outputs at the “new” dial settings. Check to see that incremental changes are correctly reflected in the readout.
3. The audiologist should listen for audible mechanical transients through the earphone when the dials or switches are manipulated. The ANSI S3.6-2010 standard (section 5.4.4) suggests that two normal-hearing listeners should listen at a distance of 1 m from the audiometer with the earphones in place but disconnected and with a proper load resistance (coinciding with the impedance of the earphone at 1,000 Hz) across the circuit while manipulating the presenter/interrupter switch, and so on, to make sure that there are no audible signals that would inform the subject to the presence of the test signal. A mechanical transient can often be detected more easily by listening than through the use of electronic equipment.
4. To determine if electronic transients are audible, it is wise to listen to the output both at a moderate hearing level (e.g., 60 dB) and below the threshold of hearing. Electronic transients will show up on an oscilloscope as an

irregularity when the problem switch or dial is manipulated. The danger of an audible transient, whether mechanical or electronic, is that the patient may respond to the transient rather than the stimulus tone. Sometimes an antistatic or contact-cleaner spray can alleviate the problem of electronic transients.

5. The audiologist should listen for hum or static with the hearing level dial at a high value, both when a stimulus signal is present and when it is absent. One should not hear static or hum at levels below 60 dB HL on the dial.
6. "Cross-talk" may occur between earphones, that is, the signal that is sent to one earphone may be heard in the contralateral earphone. Such a problem could greatly affect the audiometric thresholds obtained on that audiometer, especially for cases with unilateral hearing loss. Cross-talk may be detected by unplugging one earphone, sending a signal to that phone, and listening to the other earphone. As before, when removing the earphone, a proper resistive load must be put in its place. The signal at a suprathreshold dial setting (e.g., 70 dB HL) should not be heard in the opposite earphone when a signal is presented in the normal manner. Cross-talk may be

caused by faulty external wiring between the examiner's booth and that of the test subject or within the audiometer itself. Cross-talk must be corrected before any testing is carried out.

7. The clinician should listen to the signal while the attenuation dial is changed from maximum to minimum levels. For instance, a tone may be present at 20 dB HL on the dial, whereas no tone is present at 15 dB HL on the dial. In some cases, the tone stays at the same hearing level from 20 dB HL to -10 dB HL on the dial. These problems are easily detected by listening to the audiometer.
8. Finally, the threshold of the clinician (or a person with known hearing thresholds) should be checked with the earphones and bone vibrators to make sure that the outputs are approximately correct. If the levels are not within 10 dB of the previous threshold values, the output levels should be checked electronically.

Aside from these gross problems, which can be detected by looking or listening (see Figure 2.1 for an example of a form that may be used to aid the clinician in carrying out the listening check), the precise accuracy of the output levels

FIGURE 2.1 Form for biologic check of audiometer. [Reprinted from Wilber L. [1972] Calibration: pure tone, speech and noise signals. In: Katz J, ed. *Handbook of Clinical Audiology*. 1st ed. Baltimore, MD: The Williams & Wilkins Company; pp 11–35, with the permission of Lippincott Williams & Wilkins.]

must be evaluated when the audiometer is first purchased and at regular intervals thereafter. Frequency, output level, linearity of attenuation, and percentage of harmonic distortion should all be checked electronically, in addition to the biologic check. Section 5.4 of ANSI S3.6-2010 describes various checks for unwanted sound from the transducer or audiometer.

Frequency Check

The frequency output from the audiometer should be checked by using an electronic frequency counter. This instrument will tell the exact frequency of the output signal. Quite accurate frequency counters are often included in a digital multimeter. The electrical output from the audiometer may be routed directly to the instrument (i.e., unplug the earphone, then plug in the frequency counter input to the audiometer output) because the frequency is determined by an oscillator in the audiometer rather than the transducer. By using an electronic frequency counter, one can easily determine if the output from the audiometer corresponds to the nominal frequency. The standard for audiometers allows a tolerance of $\pm 1\%$ of the indicated frequency value for Type 1 and 2 audiometers; $\pm 2\%$ for Type 3 and 4 audiometers; and $\pm 3\%$ for Type 5 audiometers. For example, if the audiometer dial reads 1,000 Hz, then the actual output must be between 990 and 1,010 Hz for a standard diagnostic (Type 1) audiometer.

Frequency should be checked on initial receipt of the audiometer and at yearly intervals thereafter. Nevertheless, it is appropriate to listen to the audiometer each day to judge whether the frequencies are maintaining reasonably good accuracy.

Harmonic Distortion Check

Linearity measurements may also help detect distortion in a transducer or in the audiometer itself. Distortion may appear as a lack of linear attenuation, especially at high output levels (90 dB HL and above). Harmonic distortion must be checked through the transducer itself. Excessive harmonic distortion is rarely caused by the audiometer but often arises in the various transducers. The maximum permissible total harmonic distortion in the current standard (ANSI S3.6-2010) is 2.5% for earphones and 5.5% for bone vibrators. The standard also shows the maximum permissible distortion for the second, third, fourth, and higher harmonics, as well as the subharmonics, across audiometric frequency.

Rise–Fall Time

The rise–fall time of the tone is a basic parameter of the audiometer, which may be checked by taking the output directly from the audiometer and routing it into a digital

or storage oscilloscope. When gating the signal on, rise time is the length of time it takes for the signal to increase from -20 to -1 dB (10% to 90%) of its final steady-state value. The fall time is the length of time between -1 and -20 dB (90% to 10%) relative to its steady-state value. This is usually checked at a hearing level of 60 dB HL or less. ANSI S3.6-2010 specifies a rise time as well as a fall time of not less than 20 ms and not more than 200 ms. A detailed description of the rise and fall characteristics is given in section 7.5.3 of ANSI S3.6-2010.

Linearity Check

Attenuator linearity (the hearing level dial) may be checked electrically, directly from the audiometer, or acoustically through its transducer (earphone or bone vibrator). If measurements are to be made electrically, the earphone should remain in the circuit and the voltage should be measured in parallel to the earphone, or a dummy load that approximates the earphone impedance should replace the transducer. To check linearity, the audiometer should be turned to its maximum output and then attenuated in 5-dB steps until the output can no longer be read. Each attenuator on the audiometer should be checked separately. To meet the ANSI S3.6-2010 standard, the attenuator should be linear within 0.3 of the interval step or by 1 dB, whichever is smaller. That is, if you change the level in 5-dB steps, the audiometer must attenuate between 4 and 6 dB per step. If the attenuation step is 2 dB, then the reading should be between 1.4 and 2.6 dB per step (0.3×2 dB = 0.6 dB, which is less than 1 dB). As noted in section 7.2 (and section 7.3.3) of ANSI S3.6-2010, the SPL or FL of earphones, speakers, or bone vibrators can vary by no more than ± 3 dB from 125 to 5,000 Hz and no more than ± 5 dB at 6,000 Hz and above, at any dB HL dial setting.

Attenuator linearity should be checked annually. If a “fixed loss pad” (i.e., a device that automatically changes the signal level by a set amount, e.g., 20 dB) is present in the audiometer, its attenuation must also be checked. If the audiometer attenuates in 1- or 2-dB steps, then these smaller attenuation steps should be checked if they are used clinically.

EARPHONE LEVEL CALIBRATION

Real Ear Methods

There are two basic approaches for the calibration of earphones. One is the “real ear” method and the other is the “artificial ear” or coupler method. With the original real ear method, one simply tested the hearing of a group of normal-hearing persons, averaged the results, and checked to see that the average hearing of this group was at zero on the dial for each frequency. Although this is theoretically feasible with a large population sample, it is not a recommended

procedure. ANSI S3.6-2010, Appendix D, describes probe tube, loudness balance, and threshold procedures that may be used for this purpose. Clearly, these procedures are possible but quite unwieldy. For audiometers, this approach is technically incorrect because the ISO 389-1:1998 reference (which is also used in ANSI S3.6-2010) is not tied to normal hearing per se, but simply refers to an arbitrarily accepted SPL (i.e., the RETSPL or FL). If the audiologist wishes to use a new earphone (that is not listed in ANSI S3.6-2010 Standard, its appendix, or any subsequent revision), a real ear procedure might be the only way to check calibration, but if generally accepted earphones are used, it is much easier and more efficient to use an artificial ear/coupler method.

Artificial Ear (Coupler) Methods

The most commonly used procedure today is that of the “artificial ear,” which consists of a condenser microphone and a 6-cc coupler (for supra-aural earphones) or 2-cc coupler (for insert earphones). The 6-cc coupler was originally chosen because it was thought that the enclosed volume was approximately the same as the volume under a supra-aural earphone for a human ear (Corliss and Burkhard, 1953). However, since volume displacement is only one component of acoustic impedance, it cannot be assumed that the coupler actually represents a human ear. Burkhard and Corliss (1954) pointed out that the impedance characteristics of a 6-cc coupler probably simulates the impedance of the human ear over only a small part of the frequency range. Because the 6-cc coupler does not replicate the impedance of the human ear, it cannot be considered a true artificial ear. Subsequent work by Cox (1986), Hawkins et al. (1990), Killion (1978), and Zwislocki (1970, 1971) has quantified the differences between real ear and coupler values. In an attempt to solve this problem, the IEC 318 coupler was developed. However, there is still some disagreement as to the accuracy of this ear simulator (formerly called an artificial ear) because its impedance characteristics are also not exactly those of a real human ear. However, it is clearly more accurate than the present NBS 9-A coupler.

In addition to the problem of acoustic impedance characteristics, the NBS 9-A coupler is known to have a natural resonance at 6,000 Hz (Rudmose, 1964). This interferes with the measurement of the output of an audiometer earphone around that frequency. Other coupler problems are its size, its shape, and the hard walls that permit the possibility of standing waves at frequencies above 6,000 Hz. Despite these difficulties, the NBS 9-A coupler remains the accepted device (by ANSI S3.6-2010) for measuring the acoustic output from the audiometer through a supra-aural earphone. A coupler developed by Zwislocki (1970, 1971, 1980) appears to very closely approximate the acoustic impedance of the human ear. It is used in KEMAR (a manikin that has a pinna and an ear canal, as well as a coupler and microphone) (Burkhard, 1978; Burkhard and Sachs, 1975). This manikin

is described in ANSI S3.25-2009, but RETSPLs are not given for supra-aural or insert receivers using the Zwislocki coupler or the manikin.

When checking the audiometer earphone output, the supra-aural earphone is placed on the coupler and a 500-g weight is placed on top of it. If using an SLM (rather than a microphone preamplifier), the output is read in dB SPL, where $SPL = 20 \log_{10} P/P_{ref}$ (where P is the observed sound pressure and $P_{ref} = 20 \mu\text{Pa}$). After the earphone is placed on the coupler, a low-frequency tone (125 or 250 Hz) is introduced and the earphone is reseated on the coupler until the highest SPL value is read. This helps assure optimal earphone placement on the coupler. The output from the earphone is then compared to the expected values at each frequency. The standard SPL values that are used are given in (1) ISO 389-1:1998, often referred to as ISO-1964 because of its initial publication date, and (2) ANSI S3.6-2010. These values evolved through a “round robin” in which several earphones were measured on various couplers at a group of laboratories throughout the world (Weissler, 1968).

The current ANSI standard includes RETSPLs for the TDH-type earphones, as well as insert earphones. It also provides values for both the IEC and NBS couplers for supra-aural earphones and values for insert phones using an occluded ear simulator, HA-1 or HA-2 coupler. Figure 2.2 shows an audiometer earphone calibration worksheet, which contains the expected values at each frequency with TDH-39 or TDH-49 (or TDH-50) earphones in Telephonics type 51 cushions on an NBS 9-A coupler and insert receivers using an HA-1-type coupler. ANSI S3.6-2010 allows a tolerance from the listed values of ± 3 dB from 125 to 5,000 Hz and ± 5 dB at 6,000 Hz and higher.

The supra-aural output measurements referred to above are only valid when a supra-aural-type earphone cushion (which touches the pinna) such as the Telephonics 51 is used and not when a circumaural cushion (which encircles the pinna) is used. ANSI S3.6-2010 provides RETSPL values for several circumaural earphones (Sennheiser HDA200 and Koss HV/1 A) with an IEC 60318-2 coupler and a type 1 adapter (Sennheiser earphone) or type 2 adapter (Koss earphone). When the output of the audiometer through the earphone has been established, it is compared to the appropriate standard to determine whether it is in calibration or not. If possible, the audiometer trim pots (or by software adjustments in newer digital audiometers) should be used to bring the audiometer into calibration. However, when this is not possible or when different earphones will be used with the same audiometer, and when corrections are less than 15 dB, a calibration correction card may be placed on the audiometer showing the discrepancy from the established norm. It should be noted that if the output of the audiometer is, for example, 10 dB too low, then the dB HL correction sheet must be decreased by 10 dB. Such corrections must then be taken into consideration when an audiogram is plotted. If an audiometer is off by more than 15 dB at any frequency

or by 10 dB at three or more frequencies, it is advisable to have the audiometer put into calibration by the audiometer manufacturer or their representative. If the audiometer is new, it should meet ANSI S3.6-2010 tolerances. With current digital audiometers, deviations in desired output are usually due to the transducer rather than the audiometer, so sometimes it is easier to bring the audiometer into calibration by replacing the offending transducer(s).

BONE VIBRATOR CALIBRATION

Real Ear Procedures

Checking the calibration of a bone vibrator presents a different problem than that of an earphone. Whereas earphones can be checked easily using a microphone as a pickup, bone vibrators cannot. The original technique for checking bone vibrator calibration was a real ear procedure (American Medical Association, 1951), which was somewhat different than that used for earphones. The method assumes that air- and bone-conduction thresholds are equivalent. If 6 to 10 normal-hearing subjects are tested for both air and bone conduction with an audiometer whose air-conduction sys-

tem is in proper calibration, bone-conduction corrections for the audiometer can be determined by using the difference obtained between air- and bone-conduction thresholds. This procedure makes a few assumptions that are not always met. For example, it presupposes that true thresholds can be obtained for all the normal-hearing subjects using the given audiometer. Because (1) many audiometers do not go below 0 dB HL and (2) the ambient noise in test booths often does not allow assessment below 0 dB HL, it is not always possible to determine the true threshold. To avoid these problems, Roach and Carhart (1956) suggested using individuals with pure sensory/neural losses for subjects in the real ear procedure. Such an approach eliminates the problems of ambient noise and lack of audiometric sensitivity, thus increasing the probability that one will obtain “true” thresholds. However, it can be problematic to find a group of subjects with “pure sensory/neural” losses (i.e., those who have no conductive component) and who have thresholds that do not extend beyond the bone-conduction limits of the audiometer. A more basic problem with real ear bone vibrator calibration is the supposition that air- and bone-conduction thresholds are equivalent in the absence of conductive pathology. Although this is certainly true, on

average, for a large group of people, it cannot be expected to be true for any individual or for small groups (Studebaker, 1967; Wilber and Goodhill, 1967).

Artificial Mastoid Procedure

The preferred procedure for calibrating bone vibrators involves the use of a mechanical coupler, often referred to as an artificial mastoid. Artificial mastoids were proposed as early as 1939 by Hawley (1939). However, it was not until Weiss (1960) developed his artificial mastoid that they became commercially available. Just as replication of the acoustic impedance of the human ear is difficult with a coupler, replication of the mechanical impedance of the head is difficult with an artificial mastoid. Because no commercially available artificial mastoid met the mechanical impedance requirements of the ANSI (S3.13-1972) or IEC (IEC 60373:1971) standards, both the ANSI and IEC standards were revised to conform more closely to an artificial mastoid that *is* available (ANSI S3.13-1987; IEC 60318-6:2007). ANSI S3.6-2010 gives threshold values in reference equivalent threshold force levels (RETFLs) that are appropriate for a bone vibrator such as the B-71 or B-72, or one meeting the physical requirements described in section 9.4.3 of ANSI S3.6-2010. The ISO standard (ISO 389-3:1994) gives one set of values that are to be used for all bone vibrators having the circular tip described in the ANSI and IEC documents. These values are also used in the ANSI standard. It is important to recognize that both the ANSI and the ISO values are based on unoccluded ears using contralateral masking. Thus, the values presuppose that masking will be used in the contralateral ear when obtaining threshold. One can use the same type of worksheet for bone as for air—substituting the appropriate RETFL values. In both earphone and bone vibrator calibration, it is important to check distortion as well as overall level through the transducer. Distortion may be measured directly with software integrated into the SLM or by routing the output of the artificial mastoid and SLM to a spectrum analyzer. As mentioned earlier, allowable distortion values for bone vibrators are more lenient than for earphones. This is because bone vibrators have more distortion than earphones. In addition to the earlier mentioned physical measurement procedures, the importance of just listening to the audiometer output through the bone vibrator cannot be overstated. The normal ear (with audiologist attached) should be able to perceive gross attenuation and distortion problems. The electroacoustic procedures, however, serve to quantify the problems that the human ear can only identify subjectively.

SPEECH AUDIOMETERS

Because running speech fluctuates in SPL (as well as frequency content) over time, the preferred method is to introduce a puretone (1,000 Hz) into the microphone, tape, or

compact disc (CD) input of the speech circuit of the audiometer. The input level should be adjusted so that the monitoring VU meter on the face of the audiometer reflects the appropriate level, usually 0 dB. The output from the transducer is then measured. For most speech stimuli used for audiologic purposes, there is a 1,000 Hz tone on the tape or CD (or in other digital forms) that has an RMS voltage that is similar to the RMS voltage of the speech stimuli. Details concerning the calibration of the speech circuit of an audiometer are given in section 6.2 of ANSI S3.6-2010.

ANSI S3.6-2010 states that the speech output for the 1,000-Hz tone at 0 dB HL should be 12.5 dB above the RETSPL for the earphone at 1,000 Hz. Bone vibrators should be calibrated separately. All subsequent speech testing must be carried out with the monitoring meter peaking at the same point as during the calibration check. If, for example, one prefers -3 dB on the meter rather than 0 dB, then calibration of the 1,000-Hz tone must be peaked at -3 dB, or an appropriate correction must be made in reporting measurements.

The required flatness of the frequency response of the speech audiometer circuit is defined as ± 3 dB for the frequencies of 250 to 4,000 Hz and from 0 to -10 dB between 125 and 250 Hz and ± 5 dB between 4,000 and 6,000 Hz. ANSI S3.6-2010 gives specific requirements for checking the microphone circuit as well as the other speech input circuits. If the puretone and speech audiometers are separate machines, then the speech audiometer must also be checked for cross-talk, internal noise, and attenuator linearity as described earlier. More specific information on calibration of the speech circuit may be found in section 6.2.10 of ANSI S3.6-2010.

MONITORING METER

Monitoring (or VU) meters are indicators of signal level and are found on the face of most audiometers. The monitoring meter is calibrated relative to the input signal that it monitors and should not be interpreted as yielding any absolute values such as 0 dB SPL. On a speech audiometer, the meter is used to monitor the speech signal or to aid the audiologist in adjusting the input calibration tone that precedes the recorded speech materials. The specifications for the meters may be found in section 6.2.10 of ANSI S3.6-2010. In general, it is important that the meter be stable, that there is minimal undershoot or overshoot of the needle indicator relative to the actual signal, and that any amplitude change is accurately represented on the meter. The audiologist may check the meter and its entire accompanying input system as described below.

A puretone should be fed from an oscillator through an electronic switch to the input of the audiometer. The tone should be monitored by a voltmeter or an oscilloscope. By activating the electronic switch to produce a rapidly interrupted signal, one can watch the meter to ascertain whether

there is any overshoot or undershoot relative to the signal in its steady state. One must also check the response time of the needle on the VU meter. A computer-generated or tape-recorded tone may be used to ensure that the needle reaches its 99% state deflection in 350 ± 10 ms. In addition, the overshoot should be no more than 1.5%. One can insert a linear attenuator in the line between the oscillator and the audiometer input, one may reduce the output from the oscillator and the audiometer input, or one may reduce the output from the oscillator by a known amount (as monitored by a voltmeter or oscilloscope). The change in input should be accurately reflected by a corresponding change on the monitoring meter.

SOUND FIELD TESTING

ANSI S3.6-2010 describes the primary characteristics of sound field testing in section 9.5. This includes the test room, frequency response, method for describing the level of the speech signal, and the location of the speakers. Table 9 of the standard also gives specific RETSPL values for band-limited stimuli (frequency-modulated tones or narrow bands of noise) for binaural and monaural listening. An ASHA working group prepared a tutorial for sound field testing that discusses some of the problems of setting up the test procedure (ASHA, 1991). Characteristics of the frequency-modulated signals are given in section 6.1.3 of ANSI S3.6-2010. In addition, the characteristics of narrowband noise levels are presented in table 4 of the standard. The level for speech in sound field should be comparable to the corrected free-field response for earphones.

When calibrating stimuli is present in the sound field, it is important to place some sort of marker (such as a ring suspended from the ceiling) at the place where the subject's head will be. A free-field microphone should be placed so that the diaphragm is facing toward the direction of the plane-propagated wave (called frontal incidence). If a pressure microphone is used, the microphone diaphragm should be placed facing at a right angle to the direction of the plane-propagated wave (called grazing incidence). In either case, the microphone should be placed at the place where the subject's head will be during testing. There should be nothing between the speaker and the calibration equipment.

The amplifier hum or internal noise of the loudspeaker system should be checked. This may be done by adjusting the attenuator dial to some high setting (between 80 and 90 dB HL) and then measuring the output from the loudspeaker when no signal is present. That is, everything is in normal position for testing except that there is no signal presented to the speaker. The equipment noise (in SPL) should be at least 50 dB below the dial setting (in HL; i.e., if the dial reads 80 dB HL, then the equipment noise should be <30 dB SPL).

CALIBRATION OF ANCILLARY EQUIPMENT

Masking Generator

ANSI S3.6-2010 defines white noise, weighted random noise for masking of speech, and narrowband noise. Instead of HL, masking noise is discussed in terms of effective masking (dB EM), meaning that, for example, a 20-dB EM noise is that noise level that perceptually masks a 20-dB HL signal. The bandwidths for narrow bands of noise are specified by frequency with RETSPL corrections for third-octave and half-octave measurements. Cutoff values are given in the standard (see table 4 of the standard). When checking the bandwidth of the narrowband noise, it is necessary to have a frequency analyzer or spectrum analyzer (or a computer program that allows one to produce a Fourier analysis of the noise) to determine if the noise bandwidths from the audiometer conform to specifications. The same transducer that will be used when delivering the masking sound should be used to make final calibration measurements. However, because the characteristics of various transducers are quite different from one another, it is sensible to first do an electronic check directly from the audiometer to verify that any variation from the bandwidth is due to the transducer rather than the electrical output of the audiometer.

The masking sound should be checked periodically through the transducers used to present it. The examiner should be careful to use a signal that is high enough in level to avoid interference by ambient room noise (generally about 80 dB HL). In the case of narrowband noise, the SPL values measured should be within ± 3 dB of the RETSPLs for the geometric center frequency and corrected appropriately for masker bandwidth. If broadband white noise (noise that has equal level across frequency) is the only masking signal on the audiometer, one need only check the output through the earphone with a linear setting (no filter) on the SLM. The overall output and attenuation characteristics should be checked in the same basic manner as described for pure tones using an appropriate coupler.

When making noise measurements, the characteristics of the measuring equipment are critical. Since noise is not a "clean" (i.e., uniform and unvarying) signal, it is highly susceptible to errors of overshoot and undershoot on a meter and to damping on a graphic level recorder. A spectrum analyzer that is capable of frequency-domain averaging and with storage capabilities is optimal for checking calibration of noise. Unfortunately, most clinics do not have such sophisticated equipment.

COMPACT DISC AND TAPE PLAYERS

CD or tape players that are used in a clinic for reproducing speech signals, filtered environmental sounds, or other test

stimuli should be checked electroacoustically at least once every 12 months. However, if the CD or tape player is in regular use, weekly maintenance should be carried out (such as cleaning and demagnetizing the heads for tape players). The instruction manuals normally outline the procedures to be used with the particular tape or CD player. If not, any good audio equipment dealer can explain the procedure. In addition, the frequency response and time characteristics of the tape player should be checked.

At present, there are no standards for tape players used with audiometers. However, the frequency response and time characteristics of the tape player may be checked by using a standard commercial tape recording of puretones of various frequencies. If you do not have access to such a tape, it is possible to make one by introducing puretones from an audio oscillator into the machine, recording them, and playing them back. This enables the operator to check both the record and playback sections of the tape recorder. Unfortunately, if both the record and playback are equally reduced (or increased) in frequency, the output will appear at the nominal frequency. The output from the oscillator should be monitored with a voltmeter to make certain that a constant voltage signal is used. Distortion of the puretone from the tape player should also be checked. If none of this is possible, the speed of the tape player can be checked grossly by marking a tape and then, after timing a segment as it goes across the tape head, measuring to see how many inches passed over the heads per second. Also, if the machine is badly out of calibration, it will be audible as a pitch change in the recorded speech (higher if too fast, lower if too slow).

AUTOMATIC (AND COMPUTERIZED) AUDIOMETERS

A calibration check of automatic (or Bekesy) audiometers begins with frequency, level, cross-talk, and other aspects described for manual puretone audiometers. In addition, the attenuation rate and interruption rate for pulsed signals should be checked. ANSI S3.6-2010 requires that a rate of change of 2.5 dB/s be provided for Type 1, 2, and 3 audiometers. Permissible rates for all types of audiometers are given in the ANSI S3.6-2010 standard. As in manual audiometers, the permissible variance in level per step is 1 dB or 0.3 of the indicated step size, whichever is smaller. The attenuation rate may be measured quite easily with a stopwatch. After starting the motor, a pen marking on the chart is started at the same instant as a stopwatch is started. One reads the chart to determine how far the signal was attenuated (or increased) during the measured time interval. By dividing the duration (in seconds) into the decibel change in level, one can find the decibel per second attenuation rate. The audiometer should be checked for signals both increasing and decreasing in level.

To check the pulsed stimulus duration, one may go from the “scope sync” output on the back of the audiometer (if such exists) to an electronic counter, or if that is not

available, one can record across the terminals of the timing mechanism inside the audiometer. It is difficult to check the pulse speed on a graphic level recorder because of pen damping, but it is possible to check it on a digital or storage oscilloscope. It is not difficult to estimate whether there is roughly a 50% duty cycle (on half the time and off half the time), but it is quite difficult to judge whether the signal is on for 200 ms versus 210 ms. The characteristics of the pulsed tone are described in section 7.5.4 of ANSI S3.6-2010.

If both pulsed and continuous signals are used, it is important to check the relative level of the pulsed and continuous signals. If they are not equal, this should be corrected. The relative levels can be compared by observing the envelope of the waveform on an oscilloscope or by recording the output with a graphic level recorder if there is no damping problem. The attenuation rate and pulse rate should be checked annually unless there is a reason to suspect a problem earlier.

Computerized audiometers are becoming commercially available. It should be noted that computerized audiometers, just like manual audiometers, must meet all of the technical specifications included in ANSI S3.6-2010.

AUDITORY-EVOKED POTENTIAL INSTRUMENTS

There is an IEC standard for auditory test signals of short duration for audiometric and neuro-otologic purposes (IEC 60645-3:2007). There is also an IEC standard for auditory brainstem response instruments (IEC 60645-7:2009 Electroacoustics—Audiometric Equipment—Part 7: Instruments for the measurement of auditory brainstem responses). ISO 389-6:2007 reports RETSPLs for clicks and standard (2–1–2 cycle) tonebursts. There is currently no ANSI standard that provides RETSPL for clicks and tonebursts.

The basic parameters of the acoustic signals used for auditory-evoked potentials (AEPs) are the same as for conventional audiometry. One must check output level, frequency, and time. When calibrating acoustic transients from an AEP instrument, the instrumentation used to calibrate an audiometer may be inappropriate. It is especially important to check the output from the AEP unit acoustically as well as electrically. It is easy to display the electrical output from the AEP unit on an oscilloscope, but to analyze that display, one needs to repeat it very rapidly or, preferably, use a digital or storage oscilloscope. Determination of the acoustic level of these acoustic transients requires an SLM that can record true peak SPL (pSPL) or that allows routing the output to an oscilloscope to determine pSPL or peak equivalent SPL (peSPL).

Calibration of Acoustic Transients

Acoustic transients must be calibrated utilizing specialized instrumentation and procedures. For clinical procedures,

it is prudent to use earphones that can be coupled to either a 6- or a 2-cc coupler. TDH-39s, TDH-49s, and TDH-50s housed in MX 41/AR or Telephonics type 51 cushions can be coupled to a 6-cc (NBS 9-A) coupler. Etymotic insert earphones (ER-1, ER-2, ER-3 A) can be coupled to a 2-cc coupler. At the base of a 2- or a 6-cc coupler is (typically) a space designed to house a 1" condenser pressure microphone, but for some couplers, they are designed to house a ½" microphone. The microphone output can be routed to either an SLM or to a conditioning amplifier that provides the polarization voltage for the condenser microphone and (in some instruments) provides voltage amplification (gain). The measurement of the SPL of an acoustic transient with an SLM is complicated by the time constants used for the SPL measurement. Most SLMs have at least two exponential-time-weighted averaging modes: fast and slow. Fast exponential-time-weighted averaging has a measurement time constant of 125 ms, whereas slow exponential-time-weighted averaging has a measurement time constant of 1,000 ms (Yeager and Marsh, 1998). In either case, clicks or tonebursts have durations that are much shorter than the time constant of even the fast exponential-time weighting, and you will underestimate the true SPL of the toneburst using fast (or worse yet slow) exponential-time-weighted averaging. There are several solutions to this measurement problem. **First**, if you can turn the toneburst on for several seconds, you can record the level of the tone in the fast or slow exponential-time-weighted averaging mode. If you measure over three time constants (375 ms in fast, 3,000 ms in slow), the recorded value will closely approximate the true exponential-time-weighted SPL of the stimulus. This is one method to obtain what is commonly referred to as the peSPL of the toneburst. This approach will not work for a click stimulus, as increasing the duration of the electrical pulse will alter the spectrum of the stimulus. **A second approach** for determining the level of an acoustic transient is to purchase an SLM that records the largest instantaneous pressure (the "peak" pressure) and "holds" this value in the display until the meter is reset. This peak-hold measurement may vary with the specific SLM, as the measurement interval over which this "peak" is evaluated (the time constant) varies with the particular SLM. It is desirable to use a meter with a pSPL time constant of several tens of microseconds, or less. **A third approach** is to use an oscilloscope and an SLM that has an analog (AC) output. This type of output enables you to route the analog voltage output of the microphone to the oscilloscope. This technique can be used with any transient, including a click, and this approach is another method to determine the peSPL. Figure 2.3 diagrams two procedures for determining click peSPL.

In the first procedure, referred to as the baseline-to-peak peSPL procedure, the click (in this case) or other transient is routed through the earphone/coupler/microphone/SLM to the oscilloscope. The click (or other transient) stimulus is

FIGURE 2.3 The procedure for obtaining peSPL [both baseline-to-peak and peak-to-peak measures] is shown. [Reprinted from Burkard R, Secor C. [2002] Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. Baltimore, MD: Lippincott Williams & Wilkins; pp 233–248, with the permission of Lippincott Williams & Wilkins.]

presented and the baseline-to-peak voltage is measured on the oscilloscope. Making sure not to change the SPL range on the SLM, a tonal stimulus is routed through the earphone, and the level of the tone is adjusted until the baseline-to-peak voltage on the oscilloscope is identical to that measured for the click. The reading on the SLM is the baseline-to-peak peSPL of the click.

The second method of determining peSPL involves measuring the peak-to-peak voltage of the click (or other transient) on the oscilloscope, and adjusting the sine wave until its peak-to-peak voltage is equal to the peak-to-peak voltage of the click. The SPL value displayed on the SLM is recorded as the peak-to-peak peSPL of the click (or other transient). The baseline-to-peak peSPL can never be less than the peak-to-peak peSPL. If the voltages of the positive and negative phases of a click (or other transient) are equal, then the baseline-to-peak and peak-to-peak peSPL values will be numerically equal. If the click is critically damped and shows a voltage deflection in only one direction (positive or negative), then the baseline-to-peak peSPL will be 6 dB larger than the peak-to-peak peSPL. As the baseline-to-peak peSPL and the peak-to-peak peSPL values can differ by as much as 6 dB, it is imperative that the measurement technique used when reporting peSPL is reported.

A fourth approach to measuring the level of a transient is to eliminate the SLM and to use a coupler, microphone, microphone conditioning amplifier and oscilloscope. The click (or other transient) stimulus is presented, and the peak

voltage on the oscilloscope is measured. The microphone is calibrated by using a sound source with a known SPL (i.e., a pistonphone or acoustic calibrator), or the microphone sensitivity curve can be used to convert microphone output voltage to input sound pressure (and ultimately to SPL). The acoustic calibrator is coupled to the microphone, and the voltage out of the microphone conditioning amplifier is measured. In this way, a given voltage is produced when a specified SPL is present at the microphone diaphragm. For example, an acoustic calibrator produces 114 dB SPL, and 1 V is measured at the conditioning amplifier output. Then, a 2-cc coupler is placed on the microphone. An Etymotic ER-3 A insert microphone is then mated to the coupler. A sine wave is presented through the earphone, and 50 mv is measured. The SPL is

$$20 \log (50 \text{ mv}/1,000 \text{ mv}) + 114 \text{ dB SPL} = 88 \text{ dB SPL}$$

The first part of the formula estimates the dB re: 114 dB SPL, which is -26 dB; 114 is added to convert from “dB re: 114 dB SPL” to “dB SPL.”

Using the sensitivity curve of the microphone, the peak voltage on the oscilloscope is converted to peak pressure (e.g., in Pascals). The sensitivity of a microphone relates the voltage out of the microphone to the sound pressure at the microphone diaphragm, in for example, millivolts per pascal. Then the pressure is converted to SPL. For example, a peak voltage of 100 mV is measured. The microphone sensitivity is 50 mV/Pa. If 50 mV represents 1 Pa, then 100 mV represents 2 Pa. Converting to pSPL,

$$\begin{aligned} \text{pSPL} &= 20 \log (2 \text{ Pa}/0.00002 \text{ Pa}) = 20 \log 10,000 \\ &= \sim 100 \text{ dB pSPL} \end{aligned}$$

This value should correspond to the pSPL produced by an SLM in peak-hold mode, although if the time constant of the SLM is too long (say 100 μ s), then the SLM may produce a lower value. For a given stimulus, the baseline-to-peak peSPL value should be 3.01 dB less than the true pSPL value. This is because the peSPL value is actually referenced to a RMS measure of a sine wave, rather than a peak measure. To obtain the true pSPL value, 3.01 dB must be added to the peSPL (using the baseline-to-peak procedure), because the crest factor (ratio of peak to RMS) of a true sine wave is 1.414, or 3.01 dB (3.01 dB = 20 log 1.414).

In addition to the overall level, it is important to determine the frequency characteristics of the signal (i.e., its spectrum) as it is played through the transducer. The acoustic spectrum of a signal is not necessarily identical to the spectrum of the electrical signal. This is because each system has its own transfer function (i.e., filtering characteristics), and the acoustic spectrum of the stimulus will be affected by both the earphone and the coupler used to mate the earphone to the SLM microphone. The spectrum of the signal can be measured by routing the acoustic signal through a coupler, condenser microphone, and microphone conditioning/preamplifier or SLM. Finally, the output of the

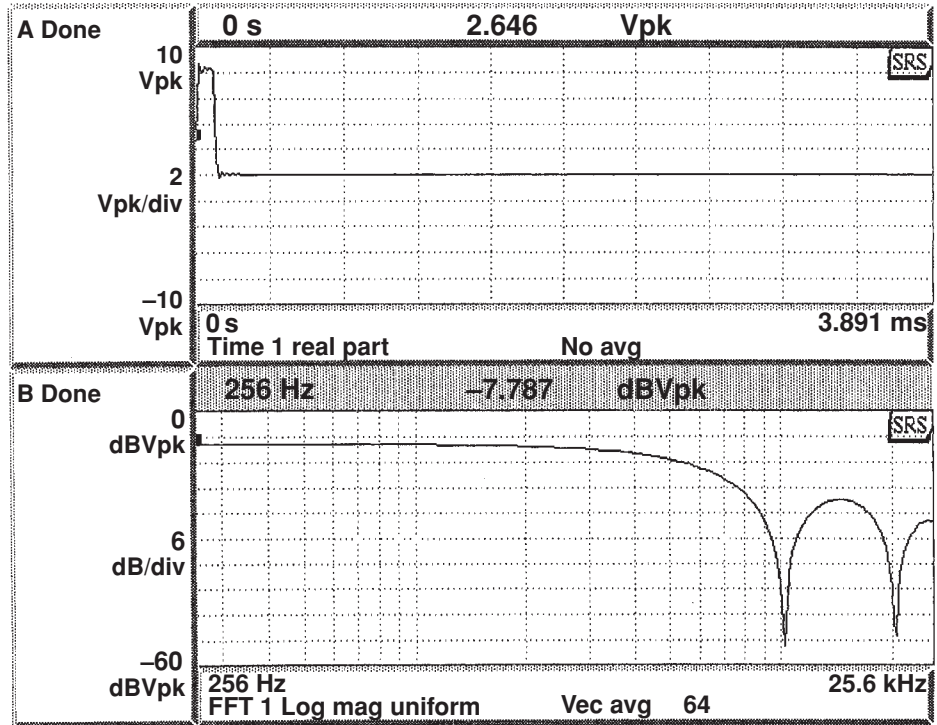

microphone conditioning/amplifier or SLM is routed to a spectrum analyzer or to an analog-to-digital converter to a computer that is programmed to do a Fourier analysis of the signal. In each case, a display of the spectrum of each signal type can be obtained. NOTE: Most clinics will likely not have the instrumentation or perhaps the expertise to do the calibration of transient stimuli. These calibration guidelines will thus be most useful to the manufacturers and to the technician who periodically calibrates the AEP instrumentation.

Many AEPs are elicited by presentation of brief acoustic transients. The two most commonly used transients are clicks and tonebursts. A click is produced by exciting a transducer with a brief-duration electrical pulse. For use with human subjects, a common click duration is 100 μ s. In a pulse with duration d , there are spectral zeroes (energy at that frequency dips toward zero) at frequencies that are integer multiples of $1/d$. Thus, for an electrical pulse with a duration of 100 μ s, the first spectral zero occurs at 10,000 Hz, with spectral zeroes occurring at 20,000, 30,000, 40,000 Hz, and so on. The acoustic representation of this 100- μ s pulse, as recorded through a TDH-50 earphone in a 6-cc coupler, is shown in Figure 2.4. It is important for the reader to understand that the click has energy over a wide range of frequencies, and thus is a broadband stimulus. It is also important to understand that the spectrum of a transient (indeed, of any signal) can and is influenced by not only the earphone, but also the coupler (and perhaps the microphone) used in the calibration process.

Clicks are often the stimuli of choice when using the auditory brainstem response (ABR) for hearing screening, site-of-lesion testing, and intraoperative monitoring. In contrast, when interested in obtaining an electrophysiological estimate of the behavioral audiogram, then a broadband stimulus is not optimal. Several approaches have been used to elicit responses from a limited cochlear region. The various approaches can be broken down into two strategies: (1) using stimuli with narrow spectra and/or (2) using masking procedures to eliminate the contribution of specific regions of the cochlea. The latter approach (the use of masking procedures) goes beyond the scope of the present chapter, but is considered later in this book (Chapter 11: Introduction to auditory-evoked potentials).

One approach to generating a limited-spectrum stimulus is to present a sine wave for a brief duration. ANSI S3.6-2010, which reviews technical specifications for audiometers, states that for audiometric purposes a tone must be presented for a duration of not less than 200 ms, and have a rise time and fall time ranging between 25 and 100 ms. Figure 2.5 (upper panel) shows a toneburst with a carrier frequency of 2,000 Hz. The time required for the toneburst envelope to increase from zero to its maximal amplitude is termed its rise time. The time that the toneburst envelope remains at this maximal amplitude is called its plateau time. The time required for the toneburst envelope to

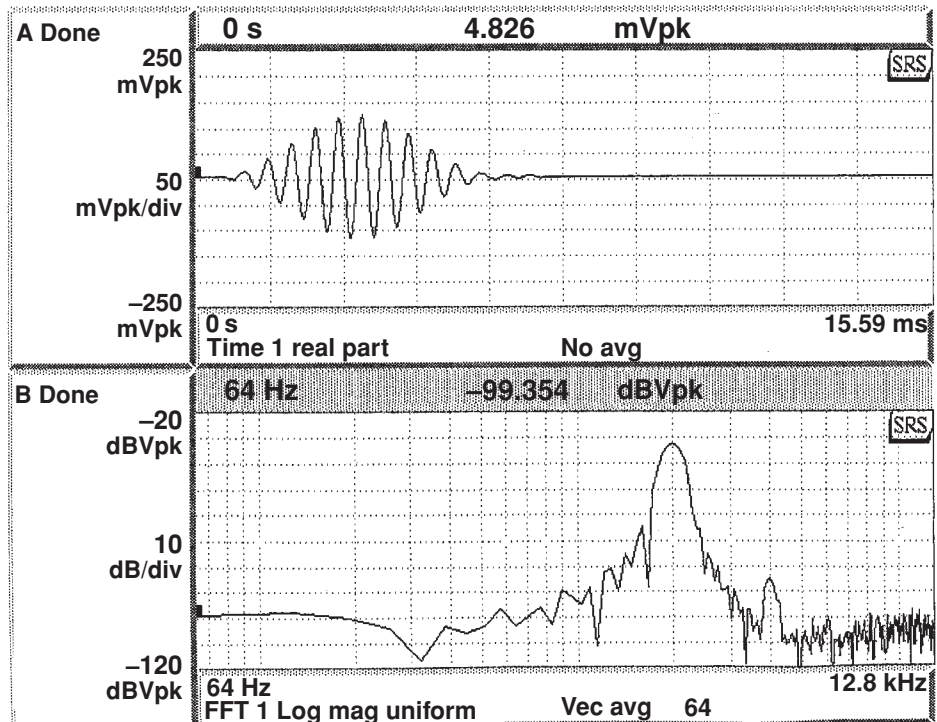

FIGURE 2.4 Time-domain waveform (upper panel) and spectrum (lower panel) of an electrical pulse with a duration of 100 μ s. [Reprinted from Burkard R, Secor C. [2002] Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. Baltimore, MD: Lippincott Williams & Wilkins; pp 233–248, with the permission of Lippincott Williams & Wilkins.]

decrease from its maximal amplitude to zero amplitude is called its fall time. Figure 2.5 (lower panel) shows the amplitude spectrum (i.e., frequency-domain representation—amplitude across frequency) of this toneburst. A tone that is infinitely long in duration only has energy at the carrier

frequency (i.e., the frequency of the sine wave). For the toneburst, there is significant energy over a range of frequencies centered at 2,000 Hz. This spread of energy to frequencies above and below the carrier frequency is referred to as spectral splatter. Acoustic transients are used to elicit

FIGURE 2.5 Upper panel: The time-domain representation of a toneburst. Lower panel: The frequency-domain representation of the same toneburst. [Reprinted from Burkard R, Secor C. [2002] Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. AEPs, because many of these AEPs, such as the ABR, are onset responses. Onset responses are elicited by the first few milliseconds of the stimulus onset, and hence are primarily affected by the stimulus rise time. When using toneburst stimuli, it is intended to serve as a compromise between an audiometric tone (long duration, long rise/fall times, and a very narrow spectrum) and a click (short duration, very fast rise/fall times, and very broad spectrum). To add even more complexity to this topic, there are many unique gating functions that can be used to shape the onset and offset of the toneburst, including linear, Blackman, and Hanning (cosine²) functions. As mentioned previously, methods for the calibration of acoustic transients can be found in IEC 60645-3:2007, and RETSPLs for clicks and select toneburst stimuli can be found in ISO 389-6:2007.

OTOACOUSTIC EMISSION DEVICES

There are currently no ANSI standards for otoacoustic emission (OAE) devices. IEC 60645-6 is an international standard that can be used to specify the stimuli used to obtain OAEs. If using a click to obtain transient-evoked otoacoustic emissions (TEOAEs), reporting the level in pSPL or peSPL is appropriate. For distortion product otoacoustic emissions (DPOAEs), verification that the primary signals (as measured in an appropriate coupler/microphone/SLM and frequency counter or spectrum analyzer) are close to the levels and frequencies as specified by the OAE device is desirable. Because the DPOAE response is an intermodulation distortion product (typically the cubic difference tone), it is critical to measure the amplitude of the distortion at this frequency in a hard-walled cavity to know when measured distortion in fact represents distortion in the instrumentation itself, rather than representing nonlinearities generated by the inner ear.

ACOUSTIC IMMITTANCE DEVICES

The standard for acoustic immittance (impedance/admittance) devices is ANSI S3.39-1987. Note that there is also an IEC standard, IEC 60645-5:2004, for measurement of aural acoustic impedance/admittance. ANSI S3.39-1987 describes four types of units for measuring acoustic immittance (listed simply as Types 1, 2, 3, and 4). The specific minimum mandatory requirements are given for Types 1, 2, and 3. There are no minimum requirements for the Type 4 device. Types 1, 2, and 3 must have at least a 226-Hz probe signal, a pneumatic system (manual or automatic), and a way of measuring static acoustic immittance, tympanometry, and the acoustic reflex. Thus, to check the acoustic immittance device, one may begin by using a frequency counter to determine the frequency of the probe signal(s). The frequency should be within 3% of the nominal value. The total harmonic distortion shall not exceed 5% of the

fundamental frequency level when measured in an HA-1-type coupler. The probe signal shall not exceed 90 dB SPL as measured in that coupler, in an attempt to minimize the possibility that the probe signal will elicit an acoustic reflex. The range of acoustic admittance and acoustic impedance values that should be measurable varies by instrument type. The accuracy of the acoustic immittance measurements should be within 5% of the indicated value or $\pm 10^{-9}$ cm³/Pa (0.1 acoustic mmho), whichever is greater. The accuracy of the acoustic immittance measurement can be determined by connecting the probe to the test cavities and checking the accuracy of the output at specified temperatures and ambient barometric pressures. A procedure for checking the temporal characteristics of the acoustic immittance instrument is described by Popelka and Dubno (1978) and by Lilly (1984).

Air pressure may be measured by connecting the probe to a “U tube” manometer and then determining the water displacement as the immittance device air pressure dial is rotated. If the SI unit of decapascals (daPa) is used, then an appropriate manometer or pressure gauge must also be used. The air pressure should not differ from that stated on the device (i.e., 200 daPa) by more than ± 10 daPa or $\pm 15\%$ of the reading, whichever is greater. The standard states that the air pressure should be measured in cavities with volumes of 0.5 to 2 cm³.

Finally, the reflex-activating system should be checked. In checking the activation of a contralateral or ipsilateral reflex, normally an insert receiver will be used that may be measured on a standard HA-1 coupler. The frequency of the activator can be measured electrically directly from the acoustic immittance device. In this case, one uses a frequency counter as described earlier for checking the frequency of puretones in audiometers. Frequency should be $\pm 3\%$ of the stated value, and harmonic distortion should be less than 3% at specified frequencies for earphones and 5% or less for the probe tube transducer or insert receiver. Noise bands should also be checked if they are to be used as activating stimuli. Broadband noises should be uniform within ± 5 dB for the range between 250 and 6,000 Hz for supra-aural earphones. This can be checked by sending the output through the transducer connected to a coupler, a microphone, and a graphic level recorder or spectrum analyzer. The SPL of tonal activators should be within ± 3 dB of the stated value for frequencies from 250 to 4,000 Hz and within ± 5 dB for frequencies of 6,000 to 8,000 Hz and for noise. The rise and fall times should be the same as those described for audiometers and may be measured in the same way. Daily listening checks as well as periodic tests of one or two persons with known acoustic immittance to check tympanograms and acoustic reflex thresholds should be performed to catch any gross problems.

In summary, acoustic immittance devices should be checked as carefully as one's puretone audiometer. Failure

to do so can lead to variability in measurement, which may invalidate the immittance measurement.

TEST ROOM STANDARDS

It is insufficient to limit the periodic calibration checks to the audiometric equipment. The environment in which the test is to be carried out must also be evaluated. ANSI S3.1-1999 provides criteria for permissible ambient noise during audiometric testing. Section 11 of ISO 8253-1:2010 also specifies appropriate ambient noise levels. The ambient level in the test room is checked by using an SLM that is sensitive enough to allow testing to levels as low as 8 dB SPL. Many modern SLMs can measure to levels of 5 dB SPL or less. One should place the SLM (preferably using a free-field microphone) in the place where the subject is to be seated. The doors of the test room should be closed when making the measurements. If one plans to use monitored live voice testing, the ambient levels in the examiner's room should also be checked. However, there are no standards concerning acceptable noise levels in the examiner's room. ANSI S3.1-1999 provides acceptable ambient noise values for threshold estimation at 0 dB HL, for one- and third-octave bandwidths, for use with supra-aural and insert earphones, and for free-field (or bone conduction) testing. These values vary with the range of audiometric frequencies investigated. If the level reported by ANSI S3.1-1999 is exceeded, then the minimum dB HL value that can be recorded is increased from 0 dB HL. This is (more or less) a linear function, so if the accepted ambient noise level in a given band is exceeded by 5 dB, then the minimum dB HL value that you can measure is increased to 5 dB HL.

CONCLUSIONS

This chapter has emphasized that the audiologist must, on a daily basis, listen to the output of the equipment. There are many problems that can be detected by a trained human ear. However, the listener is simply not good enough to check the auditory equipment with the precision that is needed to ensure that it is working properly. Thus, it has also been stressed that, to determine the precise characteristics of the equipment, routine electroacoustic checks must be carried out. Even when there are no current standards (i.e., there is, at the time this chapter is being written, no ANSI standard specifying the RETSPL of transients), one should at least check the stability of one's equipment. Because the test results that one obtains are no more accurate than the equipment on which they are performed, both clinical and calibration equipment must be chosen and maintained with care. The ultimate responsibility for the accuracy of the test results lies with the audiologist. Therefore, the audiologist must make sure that the equipment is working properly by carrying out routine calibration checks.

FOOD FOR THOUGHT

1. Do you think it is more important for standards to tell us (a) how to *optimally* characterize our stimuli or (b) how to *be consistent* in how we characterize our stimuli? What are your reasons? If you believe that they are equally important, please state your reasons for that point of view.
2. Describe the advantages and disadvantages of having a formal electroacoustic characterization of your audiometric equipment every 3 months versus annually.
3. State why you agree or disagree with the following statement: All Au.D. students should learn (both in lecture and in hands-on laboratories) how to calibrate all audiometric equipment that they use in the clinic.

Puretone Evaluation

Robert S. Schlauch and Peggy Nelson

INTRODUCTION

Most people who attend primary school in the United States and in other industrialized nations experience puretone* testing firsthand as a method to screen for hearing loss. Puretone threshold testing is seen in films, such as Woody Allen's award-winning movie *Hannah and Her Sisters* or the film *Wind Talkers*. These casual experiences with audiology may give lay people the false impression that audiology is a narrow profession.

Most audiologists would likely agree that puretone (PT) thresholds represent a key component of the assessment battery. Proper administration and interpretation of PT threshold tests require considerable knowledge, as it is not always simple and straightforward. The goal of this chapter is to introduce readers to the complexity of PT threshold testing, as well as to provide clinicians with a reference for clinical applications.

WHAT ARE PURETONES AND HOW ARE THEY SPECIFIED?

PT thresholds represent the lowest level of response to a tonal stimulus. Puretones are the simplest of sounds described by their frequency, amplitude, phase, and duration. The most important of these characteristics for puretone audiometry are frequency and amplitude (or intensity level).

Puretone frequency is perceived as pitch, the characteristic of sound that determines its position on a musical scale. Young people with normal hearing are able to perceive frequencies between 20 and 20,000 Hz. Human hearing is more sensitive (better) in the range of frequencies between 500 and 8,000 Hz than it is at either extreme of the audible range of frequencies. Conventional puretone audiometry typically assesses thresholds for frequencies between 250 (or 125) and 8,000 Hz. The frequency range for conventional audiometry is very similar to the range of frequencies (100

to 6,000 Hz) that is important for speech understanding (French and Steinberg, 1947).

Puretone amplitude or level is usually quantified in decibels. Decibels (dB) represent the logarithm of a ratio of two values; the term is meaningless without a reference. Two commonly used decibel scales are sound pressure level (SPL) and hearing level (HL). The reference level for dB SPL is 20 μ Pa, a pressure value. This reference value for SPL was selected to correspond to the faintest pressure that is audible in the frequency region where hearing is most sensitive. The frequency is not specified in the reference level for dB SPL; all sounds expressed in units of dB SPL share the same reference of 20 μ Pa. The SPL scale is frequently used in audiology to compare the level of speech or other sounds at different frequencies. Such comparisons are critical for prescribing and evaluating hearing aids. HL, a second decibel scale, is used to plot an audiogram, the accepted clinical representation of puretone thresholds as a function of frequency. The reference for dB HL is the median threshold for a particular frequency for young adults with no history of ear problems. Unlike dB SPL, the zero reference level for dB HL varies with frequency, because humans have more sensitive hearing at some frequencies than others. Because the reference is normal human hearing, thresholds that deviate from 0 dB HL at any frequency show how much one's hearing deviates from this normal value.

Figure 3.1 illustrates thresholds displayed in dB SPL and dB HL. The left panel shows hearing thresholds plotted in dB SPL as a function of frequency. Thresholds plotted in this way constitute a minimum audibility curve. The right panel shows a conventional audiogram plotted in dB HL. Note that on the dB SPL scale, larger decibel values are plotted higher on the graph. By contrast, larger values in dB HL are plotted lower on the audiogram. To illustrate the relationship between dB SPL and dB HL, the reference values for 0 dB HL (average normal hearing) for a specific earphone are plotted in dB SPL as a solid line. Illustrated with a dashed line on these same two figures are the thresholds for a person with a high-frequency hearing loss. Note in the figure on the left that the separation between the solid line and the dashed line represents values for dB HL on the audiogram.

*The use of the compound noun "puretone" is the editor's choice for consistency purposes.

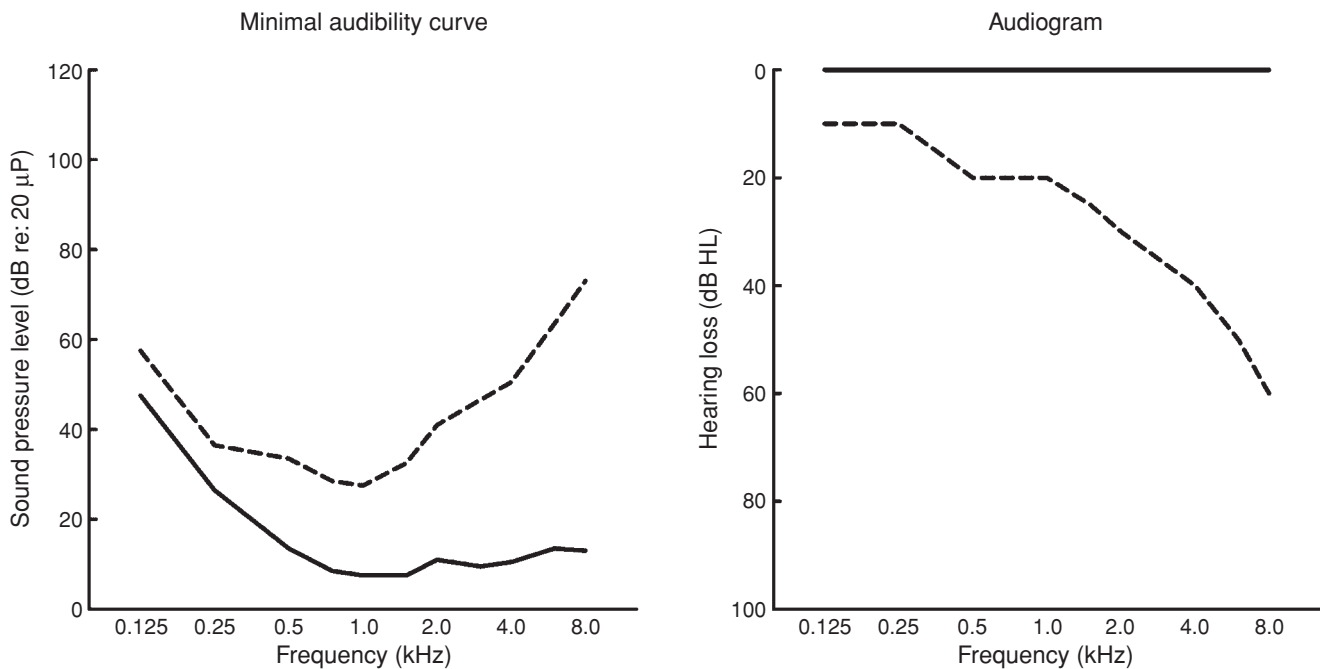

FIGURE 3.1 Thresholds in dB sound pressure level [SPL; **left panel**] and dB hearing level [HL; **right panel**] as a function of frequency. The *solid line* represents average normal hearing; the *dashed line* represents a person's threshold who has a high-frequency hearing loss.

WHY PURETONE THRESHOLDS?

The reader might be wondering why audiologists use puretones at specific frequencies when the most meaningful stimulus is speech. Two important reasons are that PT thresholds provide information about the type of hearing loss, as well as quantify frequency-specific threshold elevations that result from damage to the auditory system.

PT thresholds provide quantification of amount of loss due to problems with the outer and middle ear (the conductive system) separately from the cochlea and the auditory nerve (the sensory/neural system). This distinction helps in the diagnosis and guides audiologists and physicians with important details for providing treatment strategies.

Damage to the auditory system often results in a loss of sensitivity that is frequency specific. For instance, changes in the stiffness and mass properties of the middle ear affect the relative amount of loss in the low and high frequencies (Johanson, 1948). For air-conduction thresholds, an increase in stiffness results in a greater low-frequency loss, whereas an increase in mass results in a greater loss in the high frequencies. Thresholds for puretones (or other narrowband sounds) also provide us with diagnostic information about the integrity of different channels in the sensory/neural pathway. The auditory system is organized tonotopically (i.e., a frequency-to-place mapping) from the cochlea to the cortex. The tonotopic organization of the cochlea is a result of the frequency tuning of the basilar membrane, with high frequencies represented at the basal end and low

frequencies at the apical end. Damage to sensory cells of the cochlea at a specific place along the basilar membrane can result in a loss of hearing that corresponds to the frequencies coded by that place. For this reason, PT threshold tests provide details that would otherwise remain unknown if a broadband stimulus such as speech were used.

In addition to providing audiologists with critical diagnostic information about the amount and type of loss, PT thresholds find applications (1) for estimating the degree of handicap, (2) as a baseline measure for hearing conservation programs, (3) for monitoring changes in hearing following treatment or progression of a disease process, (4) for screening for hearing loss, (5) for determining candidacy for a hearing aid or a cochlear implant, and (6) for selecting the frequency-gain characteristics of a hearing aid. PT thresholds also provide a reference level for presentation of suprathreshold speech testing and for the meaningful interpretation of other audiologic tests, such as evoked otoacoustic emissions and acoustic reflex thresholds. PT thresholds are also used to assess the functional attenuation of hearing protection devices.

TUNING FORK TESTS

A struck tuning fork produces a sustained puretone that decays in level over time. Unlike an audiometer, tuning forks cannot present a calibrated signal level to a listener's ear. Despite this shortcoming, tuning fork tests provide qualitative information that can help determine whether a

hearing loss is conductive or sensory/neural. Tuning fork tests are promoted by some as an important supplement to puretone audiometry. In a recently published book, otologists are advised to include tuning fork tests as an integral part of the physical examination for conductive hearing loss (Torres and Backous, 2010).

The two best known tuning fork tests are the Weber and Rinne. Judgments about the type of hearing loss are made by comparing the pattern of results on both tests. Air conduction (AC) is tested by holding the tuning fork at the opening of the ear canal, and bone conduction (BC) is tested by placing the tuning fork on the mastoid process (the bony area behind the pinna) or on the forehead or incisors (British Society of Audiology, 1987). For the Weber test, a client judges whether sound is perceived in one or both ears when the tuning fork is placed on the forehead. For the Rinne test, the client judges whether sound is louder when presented by AC or by BC. Ideally, conductive hearing losses produce a pattern of responses that is uniquely different from the one for sensory/neural hearing losses. In the Weber, the sound is lateralized to the poorer ear with a conductive loss and to the better ear for a sensory/neural loss. In the Rinne, the sound is louder by BC in a conductive loss and by AC with a sensory/neural loss.

Some recommend tuning fork tests to check the validity of audiograms (Gabbard and Uhler, 2005) or to confirm the audiogram before conducting ear surgery (Sheehy et al., 1971). However, it is important to recognize that tuning fork tests administered to people with known conductive losses have shown that these procedures are often inaccurate (Browning, 1987; Snyder, 1989). Although only about 5% of people with normal hearing or sensory/neural losses are

falsely identified as having conductive losses with the Rinne test, this test misses many people with significant conductive losses (Browning, 1987), including 50% of losses that have 20-dB air–bone gaps. The Weber test fares equally poorly. Browning (1987) reports that a majority of children with conductive losses give inappropriate responses on the Weber test. From these and other studies, one must conclude that tuning fork tests are not a replacement or even a supplement to audiometry. Audiometry is capable of identifying nearly 100% of air–bone gaps, as small as 15 dB.

PURETONE AUDIOMETRY

Audiometers are used to make quantitative measures of AC and BC PT thresholds. AC thresholds assess the entire auditory pathway and are usually measured using earphones. When sound is delivered by an earphone, the hearing sensitivity can be assessed in each ear separately. BC thresholds are measured by placing a vibrator on the skull, with each ear assessed separately, usually by applying masking noise to the nontest ear. The goal of BC testing is to stimulate the cochlea directly, thus bypassing the outer and middle ears. A comparison of AC and BC thresholds provides separate estimates of the status of the conductive and sensory/neural systems. If thresholds are elevated equally for sounds presented by AC and BC, then the outer and middle ear are not contributing to a hearing loss. By contrast, if thresholds are poorer by AC than by BC, then the source of at least some of the loss is the outer or middle ear. Figure 3.2 illustrates the AC and BC pathways and how hearing thresholds are typically affected by damage to these structures. See Chapter 4 for a complete review of BC assessment.

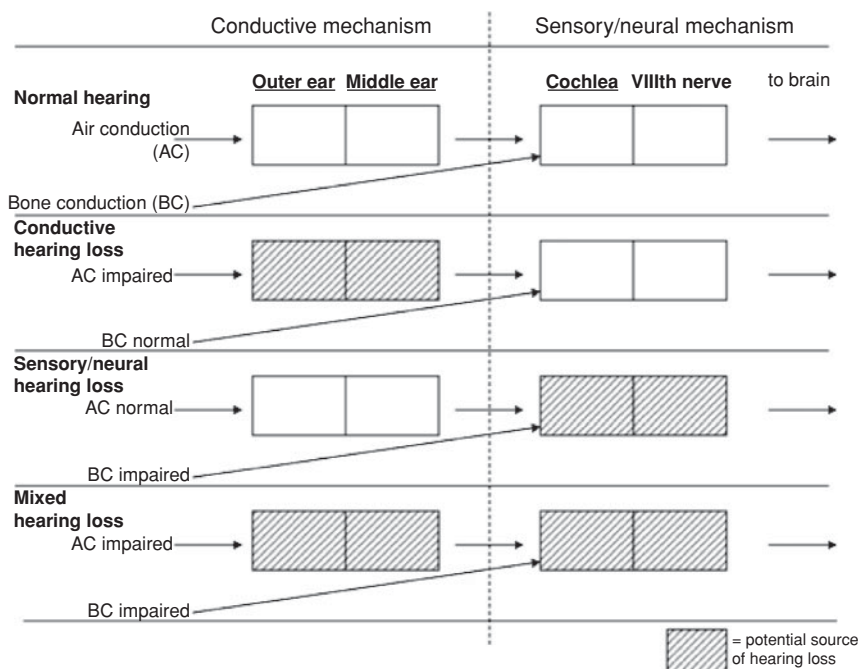

FIGURE 3.2 Conductive and sensory/neural pathways. [Adapted from Martin (1994)]

Equipment

AUDIOMETERS

Puretones are generated within an audiometer. Audiometers have the ability to select tonal frequency and intensity level and to route tones to the left or right earphone. All audiometers also have an interrupter switch that presents the stimulus to the examinee. The American National Standards Institute (ANSI) Specification for Audiometers (ANSI, 2010) describes four types of audiometers, with Type 1 having the most features and Type 4 having the fewest features. A Type 1 audiometer is a full-featured diagnostic audiometer. A Type 1 audiometer has earphones, bone vibrator, loud speakers, masking noise, and other features. A Type 4 audiometer is simply a screening device with earphones, but none of the other special features.

Type 1 (full-featured, diagnostic audiometer) has the ability to assess puretone AC thresholds for frequencies ranging from 125 to 8,000 Hz and BC thresholds for frequencies ranging from 250 to 6,000 Hz. If an audiometer has extended high-frequency capability, air-conduction thresholds can be extended to 16,000 Hz. Maximum output levels for AC testing are as high as 120 dB HL for frequencies where hearing thresholds are most sensitive. By contrast, distortion produced by bone oscillators at high intensities limits maximum output levels for BC thresholds to values nearly 50 dB lower than those for AC thresholds for the same frequency.

TRANSDUCERS

Earphones

Earphones are generally used to test puretone AC thresholds. A pair of supra-aural earphones is illustrated in Figure 3.3. For decades, supra-aural earphones, ones in which the cushion rests on the pinna, were the only choice for clinical audiology. The popularity of supra-aural phones was mainly

FIGURE 3.3 Telephonics model TDH-49, an example of supra-aural earphones.

FIGURE 3.4 Etymotic model ER-3A insert earphones.

due to their ease of calibration and the lack of other types of commercially available earphones. In the past few years, insert earphones and circumaural earphones have become available and provide some useful applications for puretone assessment.

Insert earphones are coupled to the ear by placing a probe tip, typically a foam plug, into the ear canal. The commercially available model that has a standardized calibration method for audiology is the Etymotic model ER-3A, which is illustrated in Figure 3.4. These earphones have gained popularity in the past few years because they offer distinct advantages over supra-aural earphones. One major advantage is that insert earphones yield higher levels of interaural attenuation than supra-aural earphones (Killion and Villchur, 1989). Interaural attenuation represents the decibel reduction of a sound as it crosses the head from the test ear to the nontest ear. The average increase in interaural attenuation is roughly 20 dB. This reduces the need for masking the nontest ear and decreases the number of masking dilemmas, situations for which thresholds cannot be assessed, because the presentation level of the masking noise is possibly too high. (See Chapter 6 for a comprehensive review of masking.) Another important advantage of insert earphones over supra-aural earphones is lower test-retest variability for thresholds obtained at 6 and 8 kHz; variability for other frequencies is comparable. Given that thresholds for 6 and 8 kHz are important for documenting changes in hearing due to noise exposure and for identifying acoustic tumors, lower variability should increase the diagnostic precision. A third advantage that insert earphones offer is elimination of collapsed ear canals (Killion and Villchur, 1989). In about 4% of clients, supra-aural earphones cause the ear canal to narrow or be closed off entirely when the cushion presses against the pinna, collapsing the ear canal (Lynne, 1969), resulting in false hearing thresholds, usually in the high frequencies (Figure 3.5) (Ventry et al., 1961). Because insert earphones keep the ear canal open, collapsed canals are eliminated. A fourth advantage of insert earphones is that they can be easily used with infants and toddlers who

FIGURE 3.5 Air-conduction [AC] thresholds [in dB hearing level [HL]] for different percentages of ear canal occlusion. One hundred percent indicates that the ear canal is completely occluded. Deviations from 0 dB HL represent the loss due to occlusion. [Adapted from Chandler (1964)]

cannot or will not tolerate supra-aural earphones. A fifth advantage of insert earphones is the option of conducting middle-ear testing and otoacoustic emission testing without changing the earphones; some recently introduced diagnostic instruments use this approach. Although insert earphones offer a hygienic advantage over supra-aural earphones, because the foam tips that are placed into a client's ear canal are disposable, the replacement cost of those tips is prohibitive for many applications. In addition to higher costs, insert earphones also yield errant thresholds in persons with eardrum perforations, including pressure-equalization tubes (Voss et al., 2000). (See Figure 3.12 for additional information about perforations.) Insert earphones also have maximum output levels that are lower than those produced by supra-aural earphones for some frequencies. Because of these differences, many diagnostic clinics keep both earphone types on hand and switch between them depending on the application.

Circumaural earphones, a third type, have cushions that encircle the pinna. ANSI (2010) describes reference equivalent threshold SPL values (SPL values corresponding to 0 dB HL) for Sennheiser model HDA200 and Koss model HV/1A earphones. These earphones and the Etymotic ER-2 insert earphones are the only ones in the current standard that have reference values covering the extended high frequencies (8 to 20 kHz).

Current standards for earphone calibration specify the level based on measures obtained with the earphone attached to an acoustic coupler or artificial ear. These couplers are designed to approximate the ear canal volume of an average person. Given that some clients (e.g., infants) have very small or very large ear canals (e.g., some postsurgical clients and persons with perforated eardrums), coupler measures may produce erroneous results, regardless of the

earphone type (Voss et al., 2000; Voss and Herman, 2005). For these cases, measuring the SPL at the eardrum to specify the level presented to an individual patient would improve the accuracy of hearing thresholds. The probe-tube microphones necessary for these types of measures already exist, and hopefully, this technology will become routinely available for use in diagnostic audiometers (see Scheperle et al., 2011 for a discussion of calibration in the ear canal).

Speakers

AC thresholds can be measured using speakers as the transducer. Thresholds so obtained are known as sound-field thresholds. Sound-field thresholds are unable to provide ear-specific sensitivity estimates. In cases of unilateral hearing losses, the listener's better ear determines threshold. This limitation and others dealing with control over stimulus level greatly limit clinical applications involving sound-field thresholds. Applications for sound-field thresholds are screening infant hearing or demonstrating to the parents their child's hearing ability. Sound-field thresholds may also be desirable for a person wearing a hearing aid or cochlear implant.

In sound-field threshold measures, the orientation of the listener to the speaker has a large effect on stimulus level presented at the eardrum. A person's head and torso as well as the external ear (e.g., pinna, ear canal, concha) affect sound levels (Shaw, 1974). Differences in SPL at the eardrum are substantial for speaker locations at different distances and different angles relative to the listener. For this reason, sound-field calibration takes into consideration these factors. A mark is usually made on the ceiling (or floor) of the room to indicate the location of the listener during testing. Even at the desired location, stimulus level at the eardrum

for some frequencies can vary as much as 20 dB or more by simply having the listener move his or her head (Shaw, 1974). Calibration assumes the listener will always be facing the same direction relative to the sound source (ANSI, 2010). Furniture and other persons in the sound field also affect the stimulus level at a listener's eardrum (Morgan et al., 1979). All of these factors add to the challenge of obtaining accurate sound-field thresholds.

Another important consideration in sound-field threshold measures is the stimulus type. Thresholds corresponding to different frequencies are desired for plotting an audiogram, but puretones can exhibit large differences in level at different positions in a testing suite as a result of standing waves. Standing waves occur when direct sound from the speaker interacts with reflections, resulting in regions of cancellation and summation. Differences in stimulus level due to standing waves are minimized by using narrowband noise or frequency-modulated (FM) tones as the stimulus (Morgan et al., 1979). FM tones, also known as warbled tones, are tones that vary in frequency over a range that is within a few percent of the nominal frequency. This variation occurs several times per second. Under earphones, thresholds obtained with these narrowband stimuli are nearly identical to thresholds obtained with puretones, with some exceptions in persons with steeply sloping hearing loss configurations. FM tones and narrowband noise are the preferred stimuli for sound-field threshold measures.

Bone Vibrators

A bone vibrator is a transducer that is designed to apply force to the skull when placed in contact with the head. Puretone BC thresholds are measured with a bone vibrator like the one illustrated in Figure 3.6. A separation of 15 dB or more between masked AC and BC thresholds, with BC thresholds being lower than AC thresholds, is often evidence of a conductive hearing loss. Other possible explanations for

FIGURE 3.6 A clinical bone-conduction vibrator [Radioear Model B-72].

air–bone gaps and bone–air gaps are equipment miscalibration, test–retest variability, and individual differences in anatomy that cause thresholds to deviate from the group-mean data used to derive normative values for relating AC and BC thresholds.

For threshold measurements bone vibrators are typically placed behind the pinna on the mastoid process or on the forehead. Although forehead placement produces slightly lower intrasubject and intersubject threshold differences (Dirks, 1994), placement on the mastoid process is preferred by 92% of audiologists (Martin et al., 1998). Mastoid placement is preferred mainly because it produces between 8 and 14 dB lower thresholds than forehead placement for the same power applied to the vibrator, depending on the frequency (ANSI, 2010). The median difference is 11.5 dB. Given that the maximum output limits for bone vibrators with mastoid placement are as much as 50 dB lower than that for AC thresholds, forehead placement yields an even larger difference. The inability to measure BC thresholds for higher levels means that a comparison of AC and BC thresholds is ambiguous in some cases. That is, when BC thresholds indicate no response at the limits of the equipment (e.g., 70 dB HL) and AC thresholds are poorer than the levels where no response was obtained (e.g., 100 dB HL), the audiologist cannot establish from these thresholds whether the loss is purely sensory/neural or whether it has a conductive component.

Test Environment

Hearing tests ideally are performed in specially constructed sound-treated chambers with very low background noise. A sound-treated room is not a sound-proof room. High-level external sounds can penetrate the walls of a sound-treated room and may interfere with test results. Because test tones near threshold can be easily masked by extraneous, external noise, test chambers have strict guidelines for maximum permissible ambient noise levels. Low background noise levels are particularly important for BC testing, when the ears remain uncovered. When testing is done in a room that meets the ANSI guidelines, the audiogram reflects that by citing ANSI S3.1 (1999), the standard governing permissible ambient noise levels. Table 3.1 shows the minimum levels of ambient noise measured in octave bands encompassing the test frequency that enable valid hearing threshold measurements at 0 dB HL.

At times, audiologists must estimate hearing thresholds in rooms that do not meet the guidelines for minimal ambient noise. Some patients in hospital rooms or nursing homes must be tested at bedside. In those cases, test results should be clearly marked so that others know the conditions under which the test was done. When possible, these bedside tests should be performed using insert earphones, which provide a greater amount of attenuation in low frequencies where ambient noise is typically more of a problem. In these

TABLE 3.1

Maximum Permissible Ambient Noise Levels for Puretone Threshold Testing

Octave Band Center Frequency [Hz]	Max dB SPL with Ears Covered	Max dB SPL with Ears Uncovered
125	39	35
250	25	21
500	21	16
1,000	26	13
2,000	34	14
4,000	37	11
8,000	37	14

environments, BC testing, particularly in the low frequencies, may not be valid.

Measuring Puretone Thresholds

Psychophysics is the field of study that relates the physical world with perception. PT thresholds are an example of a psychophysical measure relating the physical characteristics of a tone to a behavioral threshold.

A psychophysical procedure describes the specific method used to obtain behavioral thresholds. The most common one used in puretone audiometry is a modified method of limits. In the method of limits, the tester has control over the stimulus. A threshold search begins with the presentation of a tone at a particular frequency and intensity that is often specified by the procedure. After each presentation of the tone (or a short sequence of pulsed tones), the tester judges whether or not the listener heard it based upon the listener's response or lack of response. Each response determines the subsequent dB-level presentation. If a tone on a given presentation is not heard, the tone level is raised. If a tone is heard, the level is lowered. The rules of the psychophysical procedure govern the amount of the level change following each response, when to stop the threshold search, and the definition of threshold. The procedure, which is described in detail in subsequent sections, may be modified slightly based on the clinical population (e.g., the age of the listener).

COOPERATIVE LISTENERS AGE 5 YEARS TO ADULT (EARPHONES)

Guidelines for Manual Pure Tone Audiometry is a publication that describes a uniform method for measuring thresholds

(American Speech-Language-Hearing Association [ASHA], 2005). The goal of the guideline is to minimize differences across clinics by standardizing procedures. The committee that drafted this consensus document understood that its recommendations represent general guidelines and that clinical populations may require variations of the procedure.

Instructions

Puretone audiometry begins with instructing the individual being tested. The instructions are a critical part of the puretone test, because thresholds measured using this clinical procedure are biased by the willingness of a person to respond. Some listeners wait for a tone to be distinct before they respond, which leads to higher thresholds than for someone who responds whenever they hear any sound that could be the tone. This bias is controlled in the instructions by informing listeners to respond any time they hear the tone no matter how faint it may be. A study by Marshall and Jesteadt (1986) shows that response bias controlled for in this manner plays only a small role (a few dB at most) in PT thresholds obtained using the ASHA guideline. Marshall and Jesteadt (1986) also reported that the response bias of elderly listeners was not different than that of a group of younger persons. Before the study by these authors, it was believed that elderly persons might adopt an extremely conservative response criterion, resulting in artificially elevated thresholds compared to those of younger persons.

According to the ASHA (2005) guideline, the instructions should also include the response task (e.g., raise your hand or finger, or press a button), the need to respond when the tone begins and to stop responding when it ends, and that the two ears are tested separately. Although not in the ASHA guideline, instructions asking the examinee to indicate which ear the sound is heard in may be useful. This is especially important in cases of unilateral or asymmetrical hearing losses where cross-hearing is possible.

The examiner should present the instructions prior to placement of earphones. Earphones attenuate external sounds making speech understanding more difficult, particularly for persons with hearing loss. Listeners should also be queried after the instructions are presented to determine if they understood what was said. Sample instructions are given below:

You are going to hear a series of beeps, first, in one ear and then in the other ear. Respond to the beeps by pressing the button [switch] when one comes on and release it as soon as it goes off. Some of the beeps will be very faint, so listen carefully and respond each time you hear one. Do you have any questions?

Earphone Placement

The earphones should be placed by the examiner. For convenience, earphones are color coded; red and blue

correspond to the right and left ears, respectively. Prior to placement of earphones, clients are asked to remove jewelry such as earrings and glasses if they will interfere with the placement of the earphone. This is particularly relevant for supra-aural earphones.

For circumaural and supra-aural earphones, the diaphragm of the earphone should be centered over the ear canal. The examiner should view each ear while the phone is being placed. Immediately after placement, the headband is tightened enough to make the earphone perpendicular to the floor when the examinee is sitting upright.

The first step in placement of insert earphones is to attach a spring-loaded clip that holds the transducer in place to the examinee's clothing. The clip can be attached to clothing near the shoulder (or behind a child's neck) to keep the plug from being pulled out of the ear. In some newer implementations that combine middle-ear and otoacoustic emission measurements, the earphone is attached to a headband. For both types of support, the audiologist compresses the foam plug and inserts it into the ear canal so that its outer edge lines up with the tragus.

Placement of the Bone-conduction Vibrator

Although some recommend forehead placement (Dirks, 1994), typically audiologists place the BC oscillator on the most prominent part of the mastoid process. While holding the oscillator against the mastoid process with one hand, the headband is fit over the head to hold the oscillator in place using the other hand. The oscillator surface should be set directly against the skin, not touching the pinna, and with no hair or as little hair as possible between the oscillator and the skin. Some audiologists play a continuous low-frequency tone while moving the oscillator slightly side to side, asking the listener to report the location at which the tone is the strongest.

Audiometric Procedure for Threshold Measurement

The ASHA Guideline (2005) recommends starting a threshold search from either well below threshold or using a supra-threshold tone that familiarizes the participant with the stimulus. Most clinicians prefer the familiarization method. For the familiarization approach, testing usually begins at 1,000 Hz at 30 dB HL unless prior knowledge of the examinee's hearing suggests otherwise (ASHA, 2005). At 1,000 Hz, an examinee is more likely to have residual hearing than at a higher frequency, and test-retest reliability is excellent. Testing begins with an examinee's self-reported better ear. If the examinee believes both ears are identical, testing begins by convention with the right ear. The better ear is tested first to provide a reference to know whether masking needs to be delivered to obtain a valid estimate of threshold for the poorer ear.

Tonal duration is an important factor in a puretone test. On most audiometers, the option exists to select either pulsed or manual presentation. A 1- to 2-second

duration tone is recommended for manual presentation (ASHA, 2005). The duration is determined by the amount of time the interrupter switch is held down. Pulsed tones are achieved by selecting this option on the audiometer's front panel. If pulsed tones are selected, then the audiometer alternately presents the tone followed by a short silent interval (typically 225 ms on followed by 225 ms off) for as long as the interrupter switch is depressed. The minimum duration for a single pulse of the tone is critical. Numerous psychoacoustic studies have shown that tonal durations between roughly 200 ms and 1 second or more yield nearly identical thresholds (Watson and Gengel, 1969). By contrast, the same studies show that durations less than 200 ms result in higher thresholds. For this reason, audiometers are designed to have a nominal pulse duration of 225 ms (ANSI, 2010). Pulsed and manually presented tones presented from audiometers that maintain tonal durations between 200 ms and 2 seconds yield nearly identical thresholds, as the psychoacoustic studies suggest. However, pulsed tones are preferred for two reasons. Most patients prefer pulsed tones (Burk and Wiley, 2004), and pulsed tones also reduce the number of presentations required to find threshold in persons with cochlear hearing loss who have tinnitus (Mineau and Schlauch, 1997). Apparently, pulsed tones help patients to distinguish the puretone signal from the continuous or slowly fluctuating noises generated from within their auditory system (tinnitus), thereby reducing false-positive responses. False-positive responses can lengthen test time (Mineau and Schlauch, 1997), which is costly to an audiology practice.

Thresholds typically are obtained using a modified Hughson-Westlake down-up procedure, which is a specific implementation of a method-of-limits procedure (Carhart and Jerger, 1959; Hughson and Westlake, 1944). The examiner begins the threshold-finding procedure by presenting a tone at 30 dB HL (ASHA, 2005). If the listener responds, the level of the tone is decreased in 10-dB steps until the listener no longer responds. If the listener does not respond to this initial 30-dB tone, the examiner raises the tone in 20-dB steps until a response is obtained. After every response to a tone, the level of the tone is decreased in 10-dB steps until there is no response. For subsequent presentations when there is no response, the examiner raises the level of the tone in 5-dB steps until a response is obtained. Following this "down-10/up-5" rule, the tester continues until the threshold is bracketed a few times, and a threshold estimate is obtained. ASHA (2005) recommends that threshold should correspond to the level at which responses were obtained for two ascending runs, which is what most clinicians based their thresholds on even when the ASHA (1978) Guideline recommended that thresholds be based on three ascending runs. Research based on computer simulations of clinical procedures (Marshall and Hanna, 1989) supports the clinician's position and that of the ASHA (2005) guideline. The computer simulations of thresholds based on three

ascending runs showed only a minimal reduction of the variability when compared to thresholds based on two ascending runs. Listeners who produce inconsistent responses are an exception, and for these listeners, additional measurements can be made to confirm the threshold estimate.

After a threshold is measured at 1,000 Hz, the next frequencies that are examined depend on the goal, but the higher frequencies are typically tested prior to the lower frequencies. For diagnostic audiometry, thresholds are measured at octave intervals between 250 and 8,000 Hz, along with 3,000 and 6,000 Hz. Intra-octave thresholds between 500 and 2,000 Hz should be measured when thresholds differ by 20 dB or more between two adjacent octaves. ASHA (2005) also recommends that 1,000 Hz be tested twice as a reliability check. Refer to the ASHA (2005) guidelines for specifics about the recommended protocol and Chapter 6 for details about the use of masking noise to eliminate the participation of the nontest ear. Masking noise is needed whenever the threshold difference between ears is equal to or exceeds the lowest possible values for interaural attenuation. For BC testing, masking is needed to verify results anytime an air–bone gap in the test ear of greater than 10 dB is observed. For AC testing, masking is needed when the difference between the AC threshold in the test ear and the BC threshold of the nontest ear is greater than or equal to 40 dB for supra-aural earphones, and considerably more for insert earphones, especially in the low frequencies (Killion and Villchur, 1989). Specific recommendations for insert earphones cannot be made until a study with a larger sample size is completed.

TESTING CHILDREN YOUNGER THAN AGE 5 YEARS AND PERSONS WITH SPECIAL NEEDS

For most children younger than age 5 years, audiologists have special procedures that they employ to measure PT thresholds. Some of these same procedures are also appropriate for persons older than 5 years who have cognitive deficits. Chapter 24 on pediatric hearing assessment describes these procedures and their interpretation.

Audiometric Interpretation

PT thresholds are displayed in tabular or graphical formats. The tabular format is useful for recording the results of serial monitoring of thresholds, as in a hearing conservation program, but in many applications, thresholds are plotted on an audiogram. ASHA (1990), in a publication entitled *Guidelines for Audiometric Symbols*, suggests a standardized form for the audiogram. Although other formats for plotting audiograms are acceptable, it is helpful to use a standardized format for ease of interpretation across clinics. The audiogram consistent with that recommended in the ASHA guidelines (1990) is shown in Figure 3.7 along with recommended symbols. This audiogram only covers the conventional frequencies. Thresholds for extended high frequencies are plotted often in units of dB SPL, because average extended high-frequency thresholds vary over a wide range with the age of the listener, making dB SPL a better reference than dB HL for comparing thresholds to norms for listeners of different ages. Conversion between

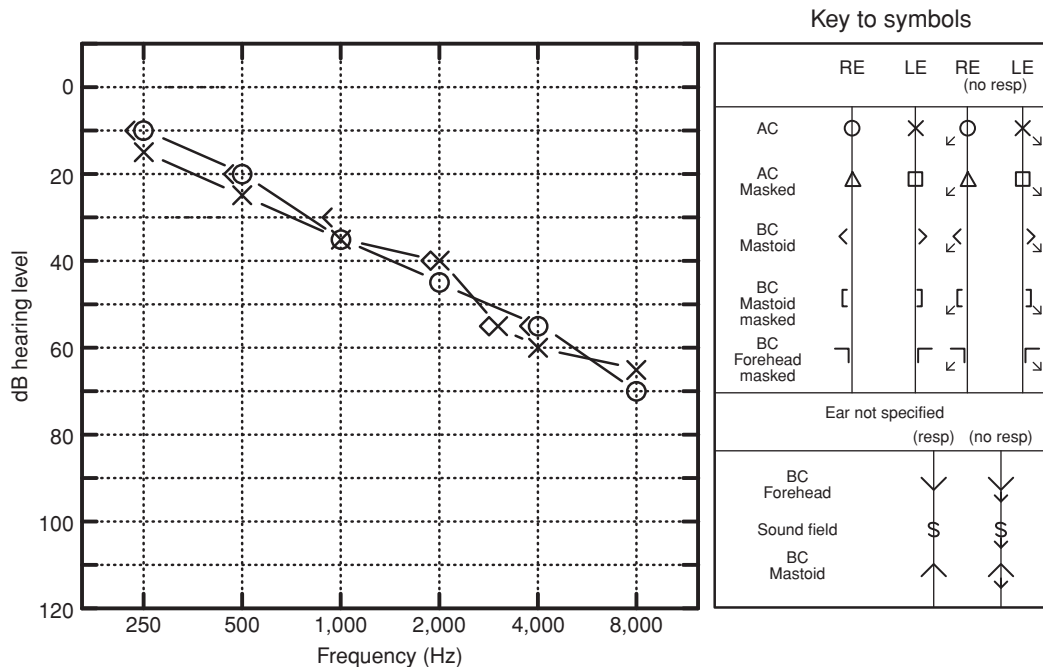

FIGURE 3.7 Recommended audiogram and symbols [ASHA, 1990] with a sensory/neural hearing loss. RE and LE represent the right ear and left ear, respectively. The word “response” is abbreviated “resp.”

TABLE 3.2

Classification of Degree of Hearing Loss Calculated from the Average of Thresholds for 500, 1,000, and 2,000 Hz^a

Degree of Loss	Northern and Downs (2002)	Goodman (1965)	Jerger and Jerger (1980)
None	<16	<26	<21
Slight	16–25		
Mild	26–30	26–40	21–40
Moderate	30–50	41–55	41–60
Moderately severe		56–70	
Severe	51–70	71–90	61–80
Profound	>70	>90	>80

^aAlthough all three references cited differ in the value accepted as a profound loss, a loss of 90 dB HL or more is widely accepted as representing a qualitative as well as a quantitative boundary between hearing and deafness.

units of dB SPL and dB HL can be accomplished for three different earphone models by consulting reference levels published in ANSI (2010).

Audiograms are often classified by categories based on the degree of hearing loss. A number of authors have published systems for classifying hearing loss based on the average AC thresholds for three frequencies. The frequencies used for this purpose are usually 500, 1,000, and 2,000 Hz, often referred to as the three-frequency puretone average (PTA). Table 3.2 shows the categories for the degree of loss based on this PTA for three different authors (Goodman, 1965; Jerger and Jerger, 1980; Northern and Downs, 2002). The first category is normal hearing. Note that none of the three authors agree on the upper limit for normal, which ranges from 15 to 25 dB HL. Northern and Downs (2002) suggest using 15 dB HL as the upper limit for normal hearing for the three-frequency PTA for children between 2 and 18 years of age and a higher limit for adults. A 15 dB HL upper limit for normal hearing may produce a significant number of false positives when applied to thresholds for individual audiometric frequencies, even in children (Schlauch and Carney, 2012). Regardless of the value used as an upper limit for normal hearing, keep in mind that an ear-related medical problem can still exist even though all thresholds fall within the defined normal range. For example, the presence of a significant air–bone gap might indicate the presence of middle-ear pathology even though all AC thresholds fall within normal limits.

The original intent of classification system for severity of loss based on a three-frequency PTA was to express, in a general way, the degree of handicap associated with the magnitude of the loss. These categories are only somewhat

FIGURE 3.8 A bilateral conductive hearing loss. The plotted values represent the average loss reported by Fria et al. (1985) in a group of children with otitis media.

successful at achieving this goal, because (1) handicap is dependent on many factors related to an individual's needs and abilities, (2) only some of the speech frequencies are assessed using this three-frequency average (speech frequencies range from 125 to 6,000 Hz), and (3) identical amounts of hearing loss sometimes result in large differences in the ability to understand speech and, as a consequence, the degree of disability associated with the loss. Despite these limitations, many audiologists use these categories routinely to summarize the amount of loss in different frequency regions of an audiogram when describing results to other professionals or to a client during counseling.

Another factor in audiometric classification is the type of hearing loss. The type of hearing loss is determined by comparing the amount of hearing loss for AC and BC thresholds at the same frequency. A sensory/neural hearing loss has an equal amount of loss for AC and BC thresholds (as shown in Figure 3.7). By contrast, a conductive loss has lower BC thresholds than AC thresholds (as shown in Figure 3.8). Conductive-loss magnitude is described by the decibel difference between AC and BC thresholds. This difference is known as the air–bone gap, a value that has a maximum of about 65 dB[†] (Rosowski and Relkin, 2001). Due to test–retest differences, an air–bone gap needs to exceed 10 dB before it is considered significant. A mixed hearing loss shows a conductive component and a sensory/neural component. In other words, a mixed loss has an air–bone

[†]Physiologic models suggest that the maximum air–bone gap occurs when there is an intact tympanic membrane and a disarticulated ossicular chain (Rosowski and Relkin, 2001).

FIGURE 3.9 A mixed hearing loss.

gap, and the thresholds for BC fall outside the range of normal hearing (Figure 3.9).

Yet another way that audiograms are described is by the hearing-loss configuration. The configuration takes into account the shape of the hearing loss. A description of the configuration of the loss helps in summarizing the loss to patients and to other professionals and often provides insight into the etiology or cause of the loss. Some typical shapes and the criteria used to describe them are shown in Table 3.3.

An audiogram is summarized verbally by the degree, type, and configuration of the hearing loss for both ears. If a person has normal thresholds in one ear and a hearing loss in the other ear, this is known as a unilateral hearing loss. A loss in both ears is described as a bilateral hearing loss. Bilateral losses are described as symmetric (nearly equal thresholds in both ears) or asymmetric.

Some Limitations of Puretone Testing

TEST-RETEST RELIABILITY

PT thresholds are not entirely precise. Consider a cooperative adult whose AC thresholds are measured twice at octave intervals between 250 and 8,000 Hz. For these two measures, assume too that the earphones are removed and replaced between tests. For this situation, the probability of obtaining identical thresholds at each frequency is small. This is due to test-retest variability. Test-retest variability is also responsible for BC thresholds not always lining up with AC thresholds in persons with pure sensory/neural losses. As reported by Studebaker (1967), test-retest variability causes false air-bone gaps and false bone-air gaps (BC thresholds poorer than AC

TABLE 3.3

Criteria for Classifying Audiometric Configurations

Term	Description
Flat	<5 dB rise or fall per octave
Gradually falling	5–12 dB increase per octave
Sharply falling	15–20 dB increase per octave
Precipitously falling	Flat or gradually sloping, then threshold increasing at 25 dB or more per octave
Rising	>5 dB decrease in threshold per octave
Peaked or saucer	20 dB or greater loss at the extreme frequencies, but not at the mid frequencies
Trough	20 dB or greater loss in the mid frequencies [1,000–2,000 Hz], but not at the extreme frequencies [500 or 4,000 Hz]
Notched	20 dB or greater loss at one frequency with complete or near-complete recovery at adjacent octave frequencies

Modified from Carhart R. [1945] An improved method of classifying audiograms. *Laryngoscope*. 5, 1–15 and Lloyd LL, Kaplan H. [1978] *Audiometric Interpretation: A Manual for Basic Audiometry*. Baltimore, MD: University Park Press.

thresholds). The source of this variability is a combination of variations in the person's decision process, physiologic or bodily noise, a shift in the response criterion, and differences in transducer placement. It is assumed that the equipment is calibrated correctly for successive tests and that the standard is not in error (Margolis et al., 2013).

The inherent variability of PT thresholds poses a problem for audiologists who are faced with making clinical decisions based on these responses. Audiologists frequently need to assess whether hearing has changed significantly since the last test, whether hearing is significantly better in one ear than the other, and whether an air-bone gap is significant.

A good place to begin with understanding test-retest variability is to consider the standard deviation (SD) of test-retest differences at a single frequency. When a 5-dB SD is assumed, threshold differences on retest of 15 dB or more are rarely expected if only a single threshold measurement is retested. By contrast, when complete audiograms are assessed, the likelihood of obtaining a large threshold difference at one frequency on retest increases. For example, 15 dB or greater differences on retest are expected only 1.24% of the time when the threshold for a single frequency is assessed. When thresholds for six frequencies are assessed in each ear (octave intervals between 0.25 and 8 kHz), 14%

of the persons tested would be expected to have at least one threshold differing by 15 dB or more (Schlauch and Carney, 2007). Thus, differences of 15 dB or more in these applications would be much more commonplace than those predicted by the SD of inter-test differences for a single frequency.

Several methods have been proposed to assess the significance of threshold differences on retest for complete audiograms (Schlauch and Carney, 2007). These methods usually require that thresholds for more than one frequency contribute to the decision process, although some accept a large change for a single frequency, such as 20 dB or more, as a significant difference. One of these methods defines a significant threshold shift by a minimal change in a PTA. For instance, the Occupational Safety and Health Administration (1983) defines a notable threshold shift (in their terminology, a standard threshold shift) as a 10-dB or greater change in the PTA based on thresholds for 2, 3, and 4 kHz in either ear. These frequencies were selected because they include those that are susceptible to damage by occupational noise and have stable test–retest reliability. A second commonly used approach requires threshold differences to occur at adjacent frequencies. One rule that is applicable to many situations defines a significant threshold shift as one for which two adjacent thresholds differ by 10 dB or more on retest. This criterion has been applied widely in audiometric studies and is sometimes combined with other criteria to arrive at a decision (ASHA, 1994). A third approach recommends repeating threshold measurements during a single session to improve audiometric reliability (National Institute for Occupational Safety and Health, 1998). This method is paired with a rule or rules defining the criterion for a significant threshold shift. The notable difference between this method and the others described earlier is that the criterion defining a threshold shift must be repeatable to be accepted as significant.

The examples in this section on the variability of PT thresholds have assumed a fixed SD of test–retest differences of ± 5 dB for all audiometric frequencies. Although 5 dB is a reasonable average value for many situations, studies show that the SD varies with type of earphone, the time between tests, and even with audiometric frequency (Schlauch and Carney, 2007).

VIBROTACTILE THRESHOLDS

In persons with significant hearing losses, sound vibrations produced by earphones and bone vibrators may be perceived through the sense of touch. Such thresholds are known as vibrotactile thresholds.

Figure 3.10 illustrates the range of levels found to yield vibrotactile thresholds for a supra-aural earphone and a bone vibrator. A threshold occurring within the range of possible vibrotactile thresholds is ambiguous; it could be a hearing threshold or a vibrotactile threshold. Because

FIGURE 3.10 Mean vibrotactile thresholds for bone conduction [*dashed line*] and air conduction [*solid line*]. The range of responses is indicated by the *shaded region*. [Adapted from Boothroyd and Cawkwell (1970)].

relatively low vibrotactile thresholds are observed for BC at 250 and 500 Hz, a false air–bone gap is likely to occur in persons with significant sensory/neural losses at these frequencies.

Boothroyd and Cawkwell (1970) recommend asking the client if they “feel” the stimulus or “hear” the stimulus as a means to differentiate between these two outcomes. Persons with experience with auditory sensations can usually make this distinction.

The values for vibrotactile thresholds illustrated in Figure 3.10 are based on only nine listeners. A more detailed study needs to be conducted to specify these ranges more precisely for the transducers in current use.

BONE-CONDUCTION THRESHOLDS: NOT A PURE ESTIMATE OF SENSORY/NEURAL RESERVE

The goal of BC testing is to obtain an estimate of sensory/neural reserve, but BC thresholds sometimes are influenced by the physiologic properties of the external, middle, and inner ears. The BC vibrator sets the skull into vibration, which stimulates the cochlea, but this does not happen in isolation. When the skull is vibrated, the middle-ear ossicles are also set into motion, and this inertial response of the ossicular chain contributes to BC thresholds. Changes in the external and middle ear can modify the contribution of the inertial response, which may result in significant changes in BC thresholds (Dirks, 1994).

A classic example of a middle-ear problem that influences BC thresholds is otosclerosis. Otosclerosis frequently

causes the footplate of the stapes to become ankylosed or fixed in the oval window. This disease process and some other types of conductive losses (e.g., glue ear) (Kumar et al., 2003) reduce the normal inertial response of the ossicles to BC hearing. The result is poorer thresholds that form a depressed region of BC hearing known as Carhart's notch (Carhart, 1950). This notch, which typically shows poorer BC thresholds between 500 and 4,000 Hz with a maximum usually at 2,000 Hz of 15 dB, disappears following successful middle-ear surgery. The finding that BC thresholds improve following middle-ear surgery is strong evidence that these poorer BC thresholds observed in stapes immobilization are due to a middle-ear phenomenon rather than a change in the integrity of the cochlea.

A frequently observed example of middle-ear problems affecting BC thresholds occurs in persons with otitis media with effusion. In this group, falsely enhanced BC thresholds in the low frequencies (1,000 Hz and below) are seen often. The magnitude of the enhancement can be as much as 25 dB (Snyder, 1989). Upon resolution of the middle-ear problem, these previously enhanced BC thresholds become poorer and return to their premorbid values.

Similarly, enhancement in BC thresholds occurs for low frequencies with occlusion of the external ear canal by a supra-aural ear phone. This low-frequency BC enhancement, known as the occlusion effect, must be considered when occluding the nontest ear to present masking noise during BC testing. However, when the masking noise is presented using an insert earphone with the foam plug inserted deeply into the ear canal, the amount of the low-frequency enhancement is smaller than it is when supra-aural earphones are used to deliver the masking noise (Dean and Martin, 2000). Further, apparent enhancement of BC thresholds can occur in cases of superior canal dehiscence (see Chapter 4).

Special Populations

TINNITUS

Many people who come for hearing testing experience tinnitus, the sensation of hearing internal sounds when no sound is present (see Chapter 35). Tinnitus can interfere with the perception of test tones, which can lead to a large number of false-positive responses, and false-positive responses can produce an inaccurate (too sensitive) threshold estimation. Some listeners simply require additional instruction and encouragement to wait until they are more certain they have heard a test tone. In some cases, the audiologist can present a clearly audible tone at the test frequency to remind the listener of the test tone. For more intractable cases, the examiner can present a series of pulsed tones and ask the listener to count the number of tones. It is important with listeners who are giving false-positive responses to avoid a fixed presentation rhythm and to provide irregular intervals

of “no trial” silence to confirm that their responses are, in fact, responses to test tones.

In rare cases, patients have tinnitus resulting from blood flowing nearby auditory structures. Blood flowing through a vein or artery sometimes produces masking noise or “bruit” that can elevate thresholds for low-frequency tones (Champlin et al., 1990). On the audiogram, this form of tinnitus may produce an apparent sensory/neural loss. The loss occurs because the tinnitus masks AC and BC thresholds. Bruit, a recordable form of tinnitus resulting from vibrations in the head or neck, is documented by audiologists by measuring sound levels in the ear canal (Champlin et al., 1990). This problem is treatable when the problem is caused by a vein. In a case study reported by Champlin et al. (1990), the patient received some reduction in tinnitus loudness before surgery by applying pressure to her neck. Surgical ligation of the vein responsible for the tinnitus was shown to be an effective treatment. Surgery reduced tinnitus loudness, SPLs of the bruit measured in the ear canal were lower, and the audiogram showed significantly improved thresholds.

PSEUDOHYPACUSIS

Pseudohypacusis, also known as functional hearing loss and nonorganic hearing loss, is the name applied to intra-test and inter-test inconsistencies that cannot be explained by medical examinations or a known physiologic condition (Ventry and Chaiklin, 1965). Most persons who present with this condition are feigning a hearing loss for monetary or psychological gain, but a very small percentage of persons have subconscious motivations related to psychological problems (see Chapter 33).

Persons presenting with pseudohypacusis are often identified from inconsistencies in their responses to the puretones. In addition to general poor reliability during threshold searches, there is a tendency for the threshold to become poorer as more presentations are made (Green, 1978). Methods of identifying the pseudohypacusis by comparing PT thresholds with other measures and the use of special tests are covered in Chapter 33.

AUDITORY NEUROPATHY

Auditory neuropathy (or auditory dys-synchrony) is a condition that may account for 11% of hearing losses found in children at risk for hearing loss (Rance et al., 1999). Information about this disorder may be found in Chapters 13 and 19. Many of these children appear to be severely hard of hearing because of very poor speech recognition; however, PT thresholds do not follow any specific pattern. Puretone hearing thresholds for these children range from minimal to profound losses. Individuals with auditory neuropathy classically show very inconsistent audiometric responses during a test and between tests.

FIGURE 3.11 Average audiograms for adult males for different decades of life. Data from National Institute on Deafness and Other Communication Disorders [2005].

AGING

Presbycusis is a term that describes the gradual loss of hearing sensitivity that occurs in most individuals as they grow older. Studies suggest (Schuknecht, 1974; Dubno et al., 2013) that several different types of damage can occur to the auditory system because of aging. Hearing loss due to aging typically causes a gently sloping, high-frequency sensory/neural hearing loss that tends to be slightly greater in men than in women. Figure 3.11 shows the average amount of threshold elevation expected based on aging in men who have had limited exposure to intense sounds. Even among this select group of participants, large individual differences are often observed.

ACOUSTIC TUMORS

An acoustic tumor (acoustic neuroma/neurinoma or vestibular schwannoma) is a rare disorder. Once identified, these tumors are usually removed surgically, because they can compress the brainstem and threaten life. Early diagnosis and removal lessen the risk of complications during surgery and increase the opportunity to preserve hearing if that approach is pursued.

Magnetic resonance imaging (MRI) is the definitive test for acoustic tumors. Unfortunately, it is expensive and only becomes cost effective when a screening test is used to assess which patients should receive an MRI. Puretone audiometry should be considered as part of that screening procedure. When the auditory nerve is compressed by the tumor, it often, but not always (Magdziarz et al., 2000), results in a unilateral or asymmetrical hearing loss. Because the fibers

on the outside of the auditory nerve code high frequencies, the hearing loss is associated with the high frequencies (Schlauch et al., 1995). Studies have shown that a screening test that compares the average threshold difference between ears for 1, 2, 4, and 8 kHz is most effective (Schlauch et al., 1995). Threshold differences between ears for this PTA that exceed 15 dB or 20 dB maximize identification of persons with these tumors while minimizing false-positive diagnoses of persons with cochlear losses. The pass-fail criterion (e.g., requiring a 20-dB difference between ears) may differ depending on the money available for follow-up tests. A pass-fail criterion requiring 15-dB or greater differences between ears identifies more tumors than one requiring 20-dB or larger differences, but the smaller difference also yields more false-positive responses. False-positive responses (in this case, persons with cochlear losses identified incorrectly as having tumors) place a burden on the healthcare system, because follow-up tests such as MRI or auditory-evoked potentials are expensive.

The effectiveness of a screening test based on the threshold asymmetries between ears is dependent on the clinical population. This test was found to be ineffective in a Veterans Administration hospital where many patients are males who have presbycusis and noise-induced hearing loss (NIHL) (Schlauch et al., 1995). By contrast, preliminary data from young women with normal hearing in their better ear suggest that true-positive rates and false-positive rates for this test are comparable to those for auditory brainstem response (Schlauch et al., 1995). It should also be noted that a small percentage of persons (<3%) with acoustic tumors have no hearing loss or hearing threshold asymmetry (Magdziarz et al., 2000).

MÉNIÈRE'S DISEASE

Ménière's disease is diagnosed based on the symptoms of sensory/neural hearing loss, vertigo, tinnitus, and aural fullness (Committee on Hearing and Equilibrium, 1995) as well as the exclusion of other known diseases. Adding to the diagnostic challenge, the four symptoms do not occur all at once, and some of them may occur only during the intermittent attacks that characterize this disease. It takes, on average, 1 year after the first symptom occurs before all of the symptoms are experienced by a person stricken with this disease. Ménière's disease rarely occurs before age 20 and is most likely to begin between the fourth and sixth decades (Pfaltz and Matefi, 1981).

Ménière's disease usually begins as a unilateral sensory/neural hearing loss, but the frequency of bilateral involvement increases with disease duration (Stahle and Klockhoff, 1986). Although audiometric configuration is not too helpful in diagnosing Ménière's disease, a peaked audiogram (described in Table 3.3) is most common (roughly 60% of involved ears), and a rising audiogram is also seen quite frequently, especially in the earliest stages of the disease.

However, the peaked audiogram is also seen in 13% of ears with acoustic tumors (Ries et al., 1998).

NOISE-INDUCED HEARING LOSS AND ACOUSTIC TRAUMA

Exposure to intense sound levels can cause permanent or temporary hearing loss due to hair cell damage. When a narrowband sound is presented at a level high enough to result in damage, a loss occurs at a frequency roughly one-half octave above the frequency of exposure (Henderson and Hamernik, 1995). Most people who are exposed to damaging noise levels in their work or recreational endeavors are exposed to broadband sounds, but their losses, especially during early stages of NIHL, are characterized by a “notch” (a drop in hearing) on the audiogram. The greatest hearing loss typically occurs in the region of 3,000 to 6,000 Hz. The susceptibility of these frequencies is a result of sound amplification by the external ear (Gerhardt et al., 1987). The amplification is mainly a result of the ear canal resonance, which increases the level of sound by 20 dB or more. Temporary hearing loss is referred to as temporary threshold shift (TTS), and permanent changes are referred to as permanent threshold shifts (PTS).

The greater variability of thresholds at 6 and 8 kHz than at other frequencies makes small noise notches associated with early NIHL difficult to identify. Some frequently used rules for quantifying noise notches can produce high false-positive rates when decisions are based on a single audiogram (Schlauch and Carney, 2011). Averaging multiple audiograms improves diagnostic accuracy as does clearing the ear canals of all earwax, which can result in the appearance of a high-frequency loss (Jin et al., 2013; Schlauch and Carney, 2012). NIHL can be slowly progressive, as listeners are exposed to high sound levels over months and years (Ward et al., 2000), or it can rapidly change, such as noise trauma after a sudden explosion or impulsive sound (Kerr and Byrne, 1975; Orchik et al., 1987). The shooting of a rifle can result in a greater loss in the ear closest to the muzzle of the gun. In right-handed persons, the left ear is exposed directly to the muzzle, and the right ear is protected from the direct blast by the head. New evidence (Kujawa and Liberman, 2009) suggests that PT thresholds may return to near normal following noise exposure, whereas functional auditory abilities may remain compromised due to the noise exposure. (See Chapter 32 for NIHL.)

OTOTOXICITY

Regular monitoring of PT thresholds is particularly important for patients who take drugs known to be ototoxic. For example, certain powerful antibiotics and cancer-fighting drugs are known to cause cochlear and vestibular damage in many patients. Monitoring hearing sensitivity during treatment could allow a physician to consider alternative treat-

ments that might preserve hearing. Ototoxic drugs typically cause reduction in high-frequency hearing before having any adverse effect on hearing for the speech range. For this reason, extended high-frequency hearing testing is recommended for ototoxic monitoring test protocols. Several studies have demonstrated the effectiveness of early identification of ototoxic hearing loss by monitoring thresholds for frequencies higher than 8,000 Hz (Fausti et al., 1992). However, for ototoxic drugs that selectively damage inner hair cells in the cochlea (e.g., carboplatin), PT thresholds may be unaffected even though extensive damage has occurred (Lobaranis et al., 2013).

OTITIS MEDIA

Young children are susceptible to temporary, recurring middle-ear inflammations (otitis media) that are often accompanied by fluid in the middle ear (effusion). Otitis media, often referred to as a middle-ear “infection,” may be viral or bacterial but is most often serous (noninfected fluid). Otitis media is the most common medical diagnosis for children, accounting for 6 million office visits in 1990 for children between the ages of 5 and 15 years (Stoll and Fink, 1996). Adults, too, may have otitis media with effusion, although the prevalence decreases significantly with age (Fria et al., 1985). During the active infection, often lasting a month or more, a patient’s hearing loss may fluctuate, usually varying between 0 and 40 dB. The average degree of hearing loss is approximately 25 dB. Figure 3.8, which was used earlier in this chapter to illustrate an audiogram for a conductive loss, shows an audiogram derived from the average thresholds from a group of children diagnosed with otitis media.

TYPANIC MEMBRANE PERFORATIONS

Tympanic membrane perforations are caused by trauma, disease, or surgery. The diameter and location of perforation and the involvement of other middle-ear structures determine the amount of conductive hearing loss, if any. For instance, a myringotomy and the placement of pressure-equalization tubes represent a physician-induced perforation that results in a minimal air–bone gap in successful surgeries.

The measurement of AC thresholds in the presence of tympanic membrane perforations requires special consideration. Figure 3.12 shows an audiogram obtained in a single session from a school-age child who has a tympanic membrane perforation in the left ear and a pressure-equalization tube in the right ear. Thresholds were measured twice in each ear, once with supra-aural earphones and again with insert earphones. Note that the low-frequency thresholds obtained from insert earphones were as much as 15 to 25 dB poorer than the ones obtained with supra-aural earphones. This outcome is typical and is predicted because insert earphones are more susceptible to calibration problems

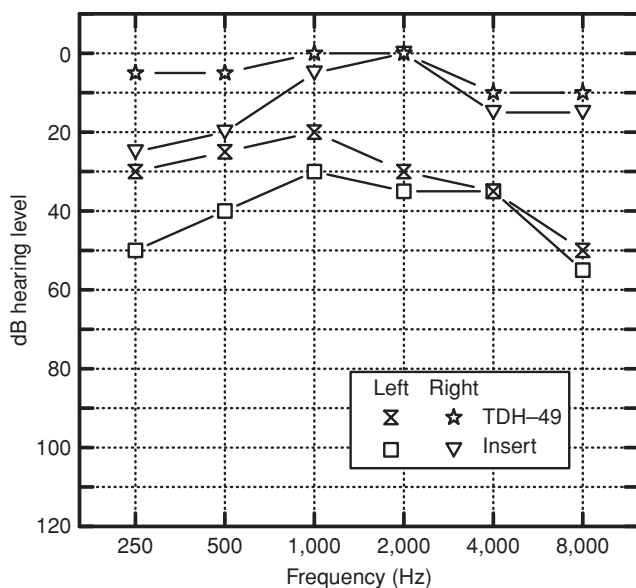

FIGURE 3.12 Audiograms obtained with two types of earphones from the same child who had bilateral perforations.

in the presence of perforations than are supra-aural earphones when calibration is based on coupler rather than real ear measurements (Voss et al., 2000). The thresholds obtained using the supra-aural earphones are more accurate in this instance and in any situations in which the effective volume of the ear canal is significantly larger than is typical.

Relation between Puretone Thresholds and Speech Measures

PT thresholds are often compared with speech audiometric test results. The two most common comparisons are with speech reception thresholds (SRT) and suprathreshold word-recognition scores (WRSs). (See Chapter 5 for a comprehensive review of speech audiometry.)

SRTs obtained using spondaic words (or spondees) agree well with PT thresholds for low frequencies. Spondees are easily recognized; listeners only need to recognize the vowels to identify these words correctly. Because of the importance of the vowels at low intensities, spondee thresholds are found to agree closely with the average of PT thresholds for 500 and 1,000 Hz (Carhart and Porter, 1971). In the event of a rising audiogram, better agreement between the spondee and PT thresholds is the average for 1,000 and 2,000 Hz. Spondee thresholds and a two-frequency PTA, as noted earlier, nearly always agree within ± 10 dB in cooperative examinees. This agreement makes the threshold for spondaic words an excellent check on the validity and reliability of the audiogram. This comparison is important for most children. It is also a valuable tool for assessing the reliability of PT thresholds in adults who demonstrate

inconsistent puretone responses or who may present with pseudohypacusis (Schlauch et al., 1996).

Suprathreshold word-recognition performance is assessed in most clinical settings by scoring a client's ability to repeat back a list of monosyllabic words. WRSs provide a valid estimate of speech understanding ability (Wilson and Margolis, 1983) and quantification of the distortion, if any, caused by sensory/neural hearing loss. WRSs are correlated with puretone audiometric thresholds in persons with cochlear losses (Pavlovic et al., 1986), but individuals' scores vary considerably depending on the type of damage to the auditory system. If the words are presented at a level high enough to make the speech sounds audible (overcoming the attenuation caused by the loss), persons with mild cochlear hearing loss are expected to have high WRSs, and those with severe to profound losses are likely to have fairly low scores. Dubno et al. (1995) and Yellin et al. (1989) have published tables relating WRSs and the average of PT thresholds for 500, 1,000, and 2,000 Hz for groups of persons with typical cochlear losses. WRSs that are abnormally low for a given PTA are associated with a variety of conditions including an acoustic tumor, multiple sclerosis, Ménière's disease, auditory neuropathy, and cochlear dead regions (Moore, 2004), to name a few. When there are dead regions (areas of missing inner hair cells in the cochlea), PT thresholds may appear artificially better than expected because of the spread of energy along the cochlea. Healthier cochlear cells adjacent to the missing cells will elicit a response to puretones presented at the dead region frequency.

Automated Audiometry

Clinical researchers automated the measurement of routine hearing thresholds to increase clinical efficiency (Rudmose, 1963). Devices were developed for this purpose, and several machines were manufactured and sold commercially. Some of these automated audiometers had the ability to vary intensity and frequency during a hearing test.

The Bekesy audiometer is an automated audiometer that was a common piece of equipment in major clinical and research settings in the 1960s. In its routine application, AC thresholds were assessed for interrupted tones and sustained tones for frequencies ranging from 100 to 10 kHz. Frequencies were swept through the range over time, typically at a rate of one octave per minute. The examinee controlled the level of the sound by depressing a handheld switch for as long as he or she heard a tone and released it when none was heard. The resulting brackets around threshold were recorded on an audiogram. Patterns of responses for sustained tones and interrupted tones were found to distinguish between different etiologies of hearing loss (see Chapter 33 on pseudohypacusis). In recent years, the use of Bekesy audiometry has decreased in medical settings, but it still has important applications in research, the military, and in hearing conservation programs.

Within the past few years, a new generation of automated audiometers has been developed (Margolis et al., 2010). The new automated audiometers are capable of measuring masked AC and BC thresholds, as well as WRSs, with only a single placement of the earphones and BC oscillator. Bekesy audiometry is still used along with some other automated methods (Laroche and Hetu, 1997), including ones that implement the threshold-finding procedure used in manual puretone audiometry (Margolis et al., 2010). Computer-based rules control the presentation of stimuli, examinee responses, and the plotting of thresholds. The goal is to automate threshold collection for routine cases, which will free audiologists to perform more complex measures or to work with difficult-to-test populations.

Calibration

Clinical data require accurate stimulus specification, or the results are meaningless. When most persons think of calibration of audiometers, the obvious examples include the accuracy of puretone frequency and level. However, puretone calibration involves much more, including an assessment of attenuator linearity, harmonic distortion, rise and fall times, and more. Consult ANSI (2010) and Chapter 2 on calibration in this book to learn more about this topic.

Puretone Thresholds and the Audiologic Test Battery

PT thresholds are measured on nearly everyone entering a diagnostic audiology clinic, but the test sequence and the extent of the measurements often differ across clinics. Most of these differences in protocol are implemented to save testing time, which contributes to the cost of running a clinic. ASHA's guide to manual PT threshold audiometry (2005) makes no recommendation concerning the puretone test sequence. In 2000, the Joint Audiology Committee on Practice Algorithms and Standards recommended an algorithm that listed puretone AC testing (with appropriate masking applied) followed by puretone BC testing with appropriate masking. They acknowledged that the assessment process may vary "based on patient need and the assessment setting." Furthermore, they stated that "decision-making . . . occurs(s) throughout this process."

Based on informal surveys of clinicians in a variety of settings, it seems that there is considerable variability in test protocols among clinics. In many clinics, BC thresholds are not usually obtained from persons with normal AC thresholds (near 0 dB HL) unless the case history or risk of middle-ear problems suggests otherwise. BC threshold testing is also omitted in some clinics for returning patients with pure sensory/neural losses if their AC thresholds match those of the prior visit. A common alternative test sequence is to begin with puretone AC thresholds followed by supra-threshold word-recognition testing. After word-recognition

testing, BC thresholds are measured. Although it would be useful to have puretone BC thresholds prior to AC thresholds to know how much masking noise can be presented safely, this advantage is outweighed by the inconvenience of having to enter the booth multiple times to reposition the BC vibrator and earphones. Valid, masked AC thresholds can be obtained successfully from most clients before obtaining BC thresholds.

A few clinics begin with immittance testing, which usually includes a tympanogram and acoustic reflex thresholds. If the case history does not indicate a middle-ear problem and these tests of middle-ear function are normal, then BC thresholds may not be performed, and the loss, if present, is assumed to be a sensory/neural loss. A possible risk of this strategy is that, in rare instances, persons with middle-ear problems have normal immittance measures. In this situation, a conductive loss would be missed. This approach also adds the expense of immittance testing for each client. Studies should be done using an evidence-based practice model to determine whether the assessment of middle-ear status of each client using immittance or wideband reflectance (see Chapter 9) is justified. Another time-saving strategy might be to measure BC thresholds at two frequencies, a low and a high frequency, and if an air–bone gap is not observed, BC thresholds are not measured for other frequencies. A low frequency, such as 500 Hz, would assess stiffness-related middle-ear pathologies. A high frequency, such as 4,000 Hz, would identify mass-related middle-ear pathologies and collapsed canals. Since this method requires placement of the BC vibrator, the amount of time actually saved would be limited.

Despite the observed variability, it seems that it is possible for audiologists to obtain important diagnostic information about the degree, type, and configuration of hearing losses using a variety of valid, evidence-based puretone audiometric methods. Although at first glance, the puretone test procedure may appear elementary, it is clear that well-informed test procedures using appropriate and calibrated test equipment provide a necessary part of the complete audiologic test battery and form the basis for clinical decision making.

FOOD FOR THOUGHT

1. Given the known test–retest variability of PT thresholds, what is the threat to the quality of a hearing conservation program if the tester chooses not to make multiple estimates of baseline audiograms?
2. Think about examples of auditory pathology where the PT threshold might be misleading, when it might not reflect the full nature of the underlying cochlear injury.
3. Consider several cases where the ear canal volume (the volume under the earphone) might significantly affect the resulting PT threshold. Consider the client's total volume of the outer ear, perforations of the eardrum, and possible occlusions in the ear canal. What effect will these have on the resulting thresholds?

Bone Conduction Evaluation

James R. Steiger

INTRODUCTION

Puretone threshold measurements are routinely carried out in audiologic evaluations. By comparing air-conducted and bone-conducted thresholds, site-of-lesion information can be obtained. Disorders of the outer or middle ears disrupt the flow of energy from the earphone to the inner ear. However, much of the energy that is conducted by a bone vibrator on the skull bypasses the outer and middle ears and stimulates the inner ear essentially unimpeded. Therefore, this discrepancy favoring the bone-conducted threshold (called the air–bone gap) indicates a mechanical or conductive hearing loss (CHL). On the other hand when the inner ear is impaired, both pathways from the earphone and the bone vibrator are impacted. This bioelectrical disturbance is referred to as a sensory/neural hearing loss (SNHL). A hearing loss that has both sensory/neural and conductive elements is called a mixed hearing loss (MHL).

However, bone-conducted energy does not entirely bypass the outer ear and middle ear. Site-of-lesion diagnoses will be more accurate with an understanding that occlusion or disorder of the outer ear, middle ear, and/or inner ear components may affect bone conduction thresholds too. An understanding of bone conduction hearing is essential for audiologists to accurately apportion hearing loss among the possible sites of lesion and to identify the etiologies of hearing losses.

CHAPTER OVERVIEW

In this chapter, a historical context and a few basic principles in bone conduction as tested with tuning fork techniques are first introduced. Then highlights of the apparatus and evaluation procedures used in routine bone conduction evaluation today are considered. An overview is provided of the outer ear, middle ear, and inner ear components of bone conduction hearing, which lead to the main purpose of this chapter: a review of site-of-lesion diagnoses based on an understanding of air and bone conduction hearing. Of course, not all possible diagnoses can be covered in one chapter; rather, examples were selected of outer ear, middle ear, and inner ear disorders to highlight their role in the bone conduction

components. The diagnoses reviewed include, in order of presentation:

- normal-hearing sensitivity,
- CHL from outer ear disorder (cerumen and osteoma examples),
- CHL from middle ear disorder (ossicular fixation and otitis media examples),
- MHL,
- SNHL from hair cell and/or neuron damage (presbycusis example),
- SNHL and pseudoSNHL from third-window disorders (superior semicircular canal dehiscence [SSCD] and large vestibular aqueduct examples), and
- pseudoSNHL from intracranial hypertension (syringomyelia example).

This chapter concludes with a review of a few important technical issues including vibrotactile responses, interaural attenuation, mastoid and forehead bone vibrator placement, and air and bone conduction threshold variability. Throughout, readers should be aware that the chapter's main focus is on persons with fully matured anatomy. Infants' bone conduction hearing may differ from adults because of immature temporal bones, outer ears, middle ears, and/or neurons (Hulecki and Small, 2011).

EARLY WRITINGS ON BONE CONDUCTION HEARING

In the 1500s Italian physicians Giovanni Filippo Ingrassia, Girolamo Cardano, and Hieronymus Capivacci were among the earliest known writers to describe bone conduction hearing (Feldmann, 1970). For instance, Capivacci recognized the diagnostic significance of bone conduction hearing to, as he described it, differentially diagnose disorders of the tympanic membrane (what we know today as CHL) from disorders of the cochlear nerve (what we know today as SNHL). For a test signal, Capivacci used the vibrations from a stringed musical instrument called a zither. He attached a metal rod to the zither strings, and his hearing-impaired listeners held the other end of the metal rod with their teeth. If the tone was heard by bone conduction, he concluded that the cochlear nerve was intact

and the hearing loss was caused by a tympanic membrane disorder blocking the pathway of air-conducted sound. In contrast, if the tone was not heard by bone conduction, he concluded that the listener's hearing loss was caused by a cochlear nerve disorder.

The Rinne Tuning Fork Test

In 1855, Heinrich Adolf Rinne (1819 to 1868) described the tuning fork test that bears his name (Feldmann, 1970). Rinne noted that the intensity of air-conducted tones was greater than that of bone-conducted tones, owing to the relatively lesser density of air in contrast to the greater density of bone. Most people, including normally hearing listeners and listeners with SNHL, therefore hear air-conducted tones louder than bone-conducted tones. In contrast, listeners with CHL hear bone-conducted tones louder than air-conducted tones for two reasons. First, listeners with CHL have outer ear occlusions or middle ear disorders that attenuate air-conducted tones. And second, outer or middle ear disorder can effectively trap bone-conducted tones that would otherwise radiate out of the ear canal; thus occlusions effectively intensify bone-conducted tones. This is the so-called occlusion effect.

Rinne's procedure was straightforward; listeners held the tuning fork with their teeth (dense bone conduction transmission) allowing vibrations to attenuate until no longer audible. Then the still vibrating tuning fork was moved in front of the ear canal (less dense air conduction transmission). If the tuning fork was audible by air conduction, the listener had normal hearing or an SNHL. If not audible by air conduction, the listener had a CHL. Today the bone conduction tuning fork placement is more likely to be on the mastoid rather than the teeth.

Audiologists to this day diagnose site of lesion by comparing the air and bone conduction thresholds of their patients. Audiometers, however, are calibrated so that 0 dB HL is a normal threshold referent for both air and bone conduction; air and bone conduction thresholds are therefore similar for normally hearing listeners as well as listeners with SNHL. For listeners with CHL, bone conduction thresholds are better than air conduction thresholds for the reasons stated above.

Weber Tuning Fork Test

In 1827, both the German physician C.T. Tourtual and the English physicist Charles Wheatstone described lateralization of bone-conducted stimuli to an occluded ear due to the occlusion effect (Feldmann, 1970). Wheatstone experienced the occlusion effect when manually occluding an ear while listening to a vibrating tuning fork in contact with his skull. Tourtual used as his stimulus a pocket watch held in his mouth. In the 1800s Heinrich Weber observed

the phenomenon in hearing-impaired listeners, and his work was carried on by both Bonafant and Schmalz in the 1840s. It was Schmalz who first wrote extensively on the diagnostic implications of what would become known as the Weber tuning fork test. Listeners with unilateral CHL hear bone-conducted tones *louder* in the impaired ear because of the occlusion effect, whereas listeners with unilateral SNHL hear bone-conducted tones *softer* in the impaired ear because of sensory/neural disorder. The Weber test is used to this day, with bone-conducted tones typically applied to the forehead by either tuning forks or bone vibrators.

APPARATUS

Bone vibrators are transducers composed of diaphragms encased in plastic. During bone conduction evaluation the circular vibrating plastic surface of the bone vibrator is held in contact with the patient's skull by the tension of a metal band. The American National Standards Institute (ANSI, 2004) specifies bone vibrator surface diameter, metal band tension, and the output characteristics of audiometers and transducers including bone vibrators. As stated above, the clinical apparatus is calibrated so that patients' air and bone conduction thresholds may be compared to the same 0 dB HL normal-hearing threshold referent. Figure 4.1 shows a common B-71 bone vibrator and also that same bone vibrator properly placed on the mastoid of a KEMAR manikin. Audiometric evaluations are conducted in test rooms compliant with ANSI S3.1-1999 (ANSI, 2003). The standard specifies maximum permissible ambient noise levels allowable for audiometric threshold testing as low as 0 dB HL, including when the ears are uncovered as during bone conduction threshold evaluations. A full discussion of calibration can be found in Chapter 2 of this book.

EVALUATION PROCEDURES

Common practice is to begin with the bone vibrator on the better hearing ear mastoid or the right mastoid if a better hearing ear is not known or suspected. Evaluation guidelines were published by the American Speech-Language-Hearing Association (ASHA) (2005), including a protocol for tone presentation, patient response modes, and the definition of threshold. Bone conduction thresholds should be tested at several frequencies and traditionally in this order: 1,000, 2,000, 3,000, and 4,000 Hz, a retest of 1,000, 500, and 250 Hz (ASHA, 1990). Because bone-conducted signals may reach either mastoid at similar intensities, contralateral ear masking may be necessary to obtain ear-specific bone conduction thresholds. A full discussion of threshold evaluation, masking procedures, and the symbols used for recording thresholds on an audiogram can be found in Chapters 3 and 6 of this book.

[2009] Assessing bone conduction thresholds in clinical practice. In: Katz J, Medwetsky L, Burkard R, Hood L, eds. *Handbook of Clinical Audiology*. Philadelphia, PA: Lippincott Williams and Wilkins, <http://www.com> by permission.]

Outer, Middle, and Inner Ear Components of Bone Conduction

Bone-conducted stimuli cause complex skull vibrations in several directions and with several resonances and antiresonances (Stenfelt and Goode, 2005), the details of which are beyond the scope of this chapter. Bone-conducted energy ultimately arrives at the cochlea by various transmission routes, which in turn cause basilar membrane-traveling waves to propagate from the stiffer basilar membrane base toward the more compliant basilar membrane apex as occurs for air conduction (Bekesy, 1960). Bone conduction transmission routes can be discussed in terms of outer ear, middle ear, and inner ear components.

OUTER EAR COMPONENT OF BONE CONDUCTION

The outer ear bone conduction component arises from vibration of the bony and especially the cartilaginous walls of the outer ear canal that, in turn, causes sound waves to radiate into the outer ear canal (Stenfelt and Goode, 2005;

Tonndorf, 1968). Vibration of the mandible may also add to the sound wave radiation into the ear canal (Stenfelt and Goode, 2005). These sound waves propagate through the middle ear and finally to the inner ear; thus, the complex phenomenon of bone conduction hearing includes exploitation of the air conduction pathway.

The outer ear component may play little role in the normal unoccluded ear canal, but its role is magnified by the occlusion effect (Stenfelt and Goode, 2005). Normally the outer ear canal acts as a high-pass filter (Tonndorf, 1968), that is, high-frequency energy is passed into the middle ear whereas low-frequency energy escapes through the ear canal opening. Outer ear canal occlusion traps this low-frequency energy and thereby enhances bone conduction hearing up to 20 dB in the lower audiometric test frequencies (Stenfelt and Goode, 2005).

MIDDLE EAR COMPONENT OF BONE CONDUCTION

The middle ear component of bone conduction is the inertial lag of the ossicles (Barany, 1938). Middle ear ossicles are not directly attached to the skull, but are instead suspended

by ligaments and tendons and attached at either end to the elastic tympanic and oval window membranes. The ossicles are free to move out of phase with skull vibrations and will do so because of inertia, much as coffee would lag and spill from a cup moved precipitously. Middle ear ossicles vibrate relative to the skull in a like manner as during air conduction hearing, and thus energy is propagated into the inner ear. The middle ear component occurs mainly at and above 1,500 Hz and is especially significant near 2,000 Hz, the approximate resonant frequency of the middle ear (Stenfelt et al., 2003). Finally, some have proposed that bone conduction energy radiates from the walls of the middle ear into the middle ear space and sets the tympanic membrane into vibration, but that hypothesis has been challenged (Stenfelt and Goode, 2005).

INNER EAR COMPONENT OF BONE CONDUCTION

The inner ear component of bone conduction involves several contributing factors, including cochlear compression or distortion, cochlear fluid inertia, osseous spiral lamina inertia, and sound pressure transmission through skull contents (brain, membranes, and fluid). Inner ear bone conduction has been described as resulting from alternate compressions and expansions (Herzog and Krainz, 1926) or distortions (Tonndorf, 1968) of the bony cochlear capsule. In turn, cochlear fluids are displaced and basilar membrane-traveling waves are initiated. One factor making cochlear fluid displacement possible is the out-of-phase and disproportionate yielding of the round and oval cochlear windows, which creates alternating spaces for fluid displacement. Cochlear fluid movement, in turn, displaces the basilar membrane and initiates traveling waves. Also, the cochlear and vestibular aqueducts may serve as outlets for fluid displacement allowing for bone conduction hearing when the oval window is fixed as in otosclerosis (Stenfelt and Goode, 2005; Tonndorf, 1968). Fluid displacement is further enabled by a fluid volume differential between the scala tympani on

one side of the scala media and the greater fluid volume of the scala vestibuli, vestibule, and semicircular canals on the other side of the scala media (Stenfelt and Goode, 2005; Tonndorf, 1968).

Inertia of the inner ear fluids contributes to inner ear bone conduction hearing, especially below 1,000 Hz (Stenfelt and Goode, 2005). Cochlear fluids and windows are free to vibrate out of phase with skull vibrations and will do so because of inertia, compared earlier to coffee that will lag and spill from a moving cup. Cochlear fluid movement, in turn, displaces the basilar membrane and initiates traveling waves. The spiral lamina may also be flexible and lag skull vibrations, thereby contributing to bone conduction hearing, especially at higher frequencies (Stenfelt et al., 2003).

Finally, bone conduction energy can travel in nonosseous skull contents, such as the brain, membranes, and fluids, and reach the cochlea through the cochlear and/or vestibular aqueducts (de Jong et al., 2011; Stenfelt and Goode, 2005). The nonosseous skull contents route may contribute little to normal bone conduction hearing, but it plays a role in some inner ear disorders as discussed below.

TRANSMISSION ROUTE MODEL

Figure 4.2 illustrates the air and bone conduction transmission routes. Note the orderly air conduction route through the outer, middle, and inner ear in contrast with more complex bone conduction hearing involving concomitant outer, middle, and inner ear components bilaterally.

EXAMPLES OF DIAGNOSES

Normal-hearing Sensitivity

Normally hearing patients are without disorder that would hinder energy from reaching the inner ear by the air conduction route. Owing to calibration, air conduction thresholds will be near 0 dB HL. Similarly, normally hearing patients

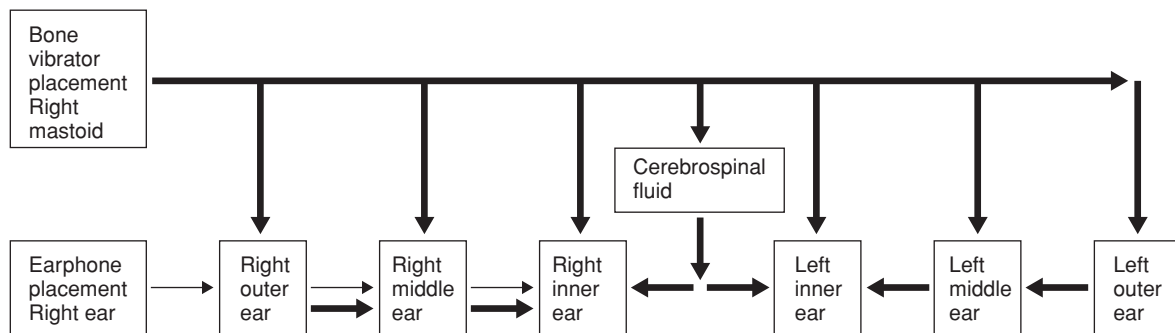

FIGURE 4.2 Transmission routes for air conduction, right ear example [*narrow arrows*] and bone conduction, right mastoid example [*bold arrows*]. Note: Higher intensity air-conducted signals can activate the bone conduction transmission route.

FIGURE 4.3 Audiogram depicting normal-hearing sensitivity.

are without disorder that would hinder any of the bone conduction components. Again owing to calibration, bone conduction thresholds will be near 0 dB HL and be similar to air conduction thresholds (± 10 dB). Figure 4.3 shows an example audiogram of a patient with normal-hearing sensitivity.

CHL with Air–Bone Gaps of Outer Ear Origin

Outer ear occlusive disorder may hinder air conduction energy from reaching the inner ear. In such cases, air conduction thresholds would be poorer than 0 dB HL, at least at some frequencies, to a degree dictated by the occlusive disorder. Bone conduction thresholds, in contrast, may be unaffected if the outer ear bone conduction component is not hindered. Bone conduction thresholds would be near 0 dB HL and accurately reflect sensory/neural hearing (sensory/neural reserve or true sensory/neural capability). The result is a hallmark of CHL: air conduction thresholds >10 dB HL lower (poorer) than normal bone conduction thresholds. The maximum air–bone gap is approximately 60 dB; higher intensity air-conducted sound waves set the skull into vibration and induce bone conduction hearing thus limiting the maximum difference between air and bone conduction thresholds (Bekesy, 1960).

However, bone conduction thresholds are often improved by occlusive disorders due to the occlusion effect. In such cases, bone conduction thresholds overestimate sensory/neural reserve. In rarer cases, outer ear occlusive disorder may interfere with the outer or middle ear bone conduction components and thus lower bone conduction thresholds, a so-called pseudoSNHL because

FIGURE 4.4 Audiogram depicting CHL from osteomas. Air conduction: presurgery thresholds represented with filled circles and postsurgery thresholds represented with open circles. Bone conduction: presurgery thresholds connected with a dotted line, postsurgery thresholds not connected. [Modified from Pinsker OT. [1972] Otological correlates of audiology. In: Katz J, ed. *Handbook of Clinical Audiology*. Baltimore, MD: Williams and Wilkins, <http://lww.com> by permission.]

neither hair cell nor neuron damage is the cause (Hall and Croutch, 2008). In such cases, bone conduction thresholds underestimate sensory/neural reserve. Figure 4.4 shows an audiogram example involving occlusive osteomas; the presurgery audiogram shows CHL, but with bone conduction thresholds that underestimated the true sensory/neural reserve revealed by postsurgery bone conduction thresholds. Cerumen impaction that loads (adds mass to) the tympanic membrane can cause pseudoSNHL (Hall and Croutch, 2008; Tonndorf, 1968). Anderson and Barr (1971) reported pseudoSNHL with partial cerumen occlusion of the outer ear canal, though they attributed it to earphone artifact.

CHL with Air–Bone Gaps of Middle Ear Origin

Middle ear disorder may hinder air conduction energy from reaching the inner ear. In such cases, air conduction thresholds would be poorer than 0 dB HL, at least at some frequencies, to a degree dictated by the middle ear disorder. Bone conduction thresholds, in contrast, may be unaffected if the middle ear bone conduction component is not significantly hindered. Bone conduction thresholds would therefore be near 0 dB HL and accurately reflect sensory/neural reserve or be improved due to the occlusion effect.

FIGURE 4.5 Audiogram representing the mean CHL from a group of children. [Modified from Schlauch RS, Nelson P. [2009] Puretone evaluation. In: Katz J, Medwetsky L, Burkard R, Hood L, eds. *Handbook of Clinical Audiology*. Philadelphia, PA: Lippincott Williams and Wilkins, <http://lww.com> by permission.]

The resulting air–bone gaps can be as great as approximately 60 dB. Air–bone gaps can be seen with many middle ear disorders; an example of a CHL audiogram is shown in Figure 4.5.

However, middle ear disorder often hinders the middle ear contribution to bone conduction and thus lowers (makes poorer) bone conduction thresholds. The result is a pseudoSNHL in addition to the CHL, with bone conduction thresholds underestimating sensory/neural reserve. For example, ossicular fixation caused by otosclerosis predictably manifests as lower (poorer) than normal bone conduction thresholds at the approximate middle ear resonant frequency of 2,000 Hz (Carhart, 1950). The air–bone gaps one expects with CHL may therefore be reduced or obliterated at and near 2,000 Hz. For stapedial fixation caused by otosclerosis, this pseudoSNHL is known as the Carhart notch. An audiogram example is shown in Figure 4.6; note the Carhart notch and CHL presurgery and the restoration of normal air and bone conduction thresholds postsurgery consistent with restoration to more normal middle ear resonance.

The middle ear bone conduction component can be affected by other disorders as well. For example, Dirks and Malmquist (1969) reported pseudoSNHL in addition to CHL in a case of malleal fixation. Similarly, pseudoSNHL in addition to CHL has been reported for subjects with otitis media (Carhart, 1950; Hall and Crouch, 2008). Yasan (2007) reported 1,000 Hz and in some cases 2,000 Hz bone conduction notches in patients with otitis

FIGURE 4.6 Audiogram depicting CHL from otosclerosis. Air conduction: presurgery thresholds represented with *filled circles* and postsurgery thresholds represented with *open circles*. Bone conduction: presurgery thresholds connected with a *dotted line*, postsurgery thresholds not connected. [Modified from Dirks D. [1985]. Bone-conduction testing. In: Katz J, ed. *Handbook of Clinical Audiology*. Baltimore, MD: Williams and Wilkins, <http://lww.com> by permission.]

media, and Kumar et al. (2003) reported 2,000 Hz bone conduction notches in patients with glue ear. Apparently, effusion may produce stiffening or loading effects, thus hindering the middle ear bone conduction component (Tonndorf, 1968). An example of CHL caused by otitis media is shown in Figure 4.7; note the pretreatment pseudoSNHL and CHL, and the resolution of the same post-treatment.

It should be noted here that true SNHL with otitis media has also been proposed. Pathogens in middle ear effusion may pass through the round window and cause damage to cochlear hair cells, and because of the round window proximity to the basal turn of the cochlea, high-frequency SNHL might result (Paparella et al., 1984).

SNHL

Neither sensory nor neural disorders hinder energy from reaching the inner ear by the air conduction route or by any of the bone conduction routes. Changes in air and bone conduction thresholds are affected only by the damage to sensory/neural structures which will lower (make poorer) air and bone conduction thresholds similarly. Air and bone conduction thresholds will therefore be similar (± 10 dB). Figure 4.8 shows an example audiogram of a patient with SNHL from presbycusis.

FIGURE 4.7 Audiograms depicting CHL from otitis media. Air conduction: pretreatment thresholds represented with *filled circles* and post-treatment thresholds represented with *open circles*. Bone conduction: pretreatment thresholds connected with a *dotted line*, post-treatment thresholds not connected. [Modified from Hall CM, Crouch C. [2008] Pseudosensory-neural hearing loss. *Hear Rev.* 16(1), 18–22, by permission.]

FIGURE 4.8 Audiogram depicting a sensory/neural hearing loss from presbycusis. [Modified from Harrell RW, Dirks D. [1994] In: Katz J, ed. *Handbook of Clinical Audiology*. Philadelphia, PA: Lippincott, Williams and Wilkins, <http://lww.com> by permission.]

MHL with Air–Bone Gaps of Outer or Middle Ear Origin

Patients may have an MHL. An MHL audiogram will therefore show evidence of both the SNHL (affected air and bone conduction thresholds) and the CHL (air–bone gaps >10 dB). Bone conduction thresholds may accurately reflect sensory/neural reserve or a pseudoSNHL may underestimate sensory/neural reserve. An MHL audiogram example is shown in Figure 4.9.

Superior Semicircular Canal Dehiscence with PseudoSNHL and Air–Bone Gaps of Inner Ear Origin

SSCD is a thinning or absence of the temporal bone over the membranous labyrinth of the superior semicircular canal. This condition opens a third elastic membranous inner ear window at the dehiscence, the other two windows of course being the oval and round windows of the cochlea (Merchant et al., 2007). The audiogram manifestation of SSCD may mimic CHL or MHL, with air–bone gaps that could approach 60 dB (Chien et al., 2012). Air conduction thresholds may be adversely affected because energy reaching the inner ear by the air conduction route is shunted away from the cochlea through the dehiscence,

typically manifesting in the lower test frequencies consistent with a mathematical model analysis based on the anatomical dimensions of the inner ear (Merchant et al., 2007). Bone conduction thresholds, in contrast, may be improved by skull content sound pressure transmissions

FIGURE 4.9 Audiogram depicting an MHL. [Modified from Schlauch RS, Nelson P. [2009] Puretone evaluation. In Katz J, Medwetsky L, Burkard R, Hood L, eds. *Handbook of Clinical Audiology*. Philadelphia, PA: Lippincott Williams and Wilkins, <http://lww.com> by permission.]

FIGURE 4.10 Audiogram depicting hearing loss from superior semicircular canal dehiscence.

through the dehiscence, that is, augmentation of the inner ear bone conduction component. The term air–bone gap of inner ear origin has been used to describe these findings (Attias et al., 2012). This is a useful term as it emphasizes that the air–bone gaps do not reflect either a CHL or MHL. Figure 4.10 shows an example audiogram from a patient with SSCD.

Large Vestibular Aqueducts with SNHL and Air–Bone Gaps of Inner Ear Origin

Large vestibular aqueducts (LVA) cause SNHL with air–bone gaps of inner ear origin (Attias et al., 2012; Jackler and De La Cruz, 1989). The cause of SNHL with LVA is unclear; it may result from traumatic endolymph pressure from the endolymphatic duct and sac that damages hair cells, or by endolymph electrolyte content that is harmful to the hair cells or stria vascularis (Campbell et al., 2011; Jackler and De La Cruz, 1989; Levinson et al., 1989). The audiometric findings for LVA may also be influenced by the third-window effect similar to SSCD. Air–bone gaps of inner ear origin are possible: Air conduction thresholds may be lowered (made poorer) because some energy is shunted away from the cochlea through the LVA, whereas bone conduction thresholds may be unaffected or improved by sound pressure transmissions through the skull contents to the LVA, (Attias et al., 2012; Merchant et al., 2007). Therefore, as with SSCD, the air–bone gaps seen with LVA do not reflect outer ear occlusion or middle ear disorder as in CHL or MHL. Figure 4.11 shows an example audiogram from a patient with LVA.

FIGURE 4.11 Audiogram depicting hearing loss from a large vestibular aqueduct.

Intracranial Hypertension with PseudoSNHL

Intracranial hypertension with abnormal cerebrospinal fluid flow has been associated with a number of neurologic conditions including syringohydromyelia, Chiari malformations, trauma, tumors, arachnoiditis, subarachnoid hemorrhages, meningitis, and multiple sclerosis (Steiger et al., 2007). Resulting audiologic symptoms may include whooshing pulsatile tinnitus and low-frequency pseudoSNHL. The pulsatile tinnitus may arise from circle of Willis blood flow or pulsations of the walls of the dural sinuses (Rudnick and Sismanis, 2005), which travel through the cochlear or vestibular aqueducts to the cochlea (Marchbanks et al., 2005). The pseudoSNHL might be attributable to masking from the pulsatile tinnitus (Rudnick and Sismanis, 2005; Steiger et al., 2007) or from elevated cochlear fluid pressure stiffening the basilar, oval, and round window membranes (Sismanis, 1987). Stiffened cochlear membranes, in turn, may interfere with cochlear fluid motion and thus hinder the inner ear bone conduction component. Figure 4.12 shows an audiogram of a patient with intracranial hypertension.

TECHNICAL CLINICAL CAVEATS

Vibrotactile Responses

It is possible for a patient to feel bone conductor diaphragm vibrations during bone conduction evaluation, especially at high intensities and at lower test frequencies (Nober, 1964). When a patient responds to stimuli felt but not heard, the responses are called vibrotactile. Vibrotactile responses must not be recorded as auditory thresholds as two possible errors

FIGURE 4.12 Audiogram depicting pseudoSNHL from intracranial hypertension. [Adapted from Steiger JR, Saccone PA, Watson KN. [2007] Assessment of objective pulsatile tinnitus in a patient with syringohydromyelia. *J Am Acad Audiol.* 18[3], 197–206.] Used with permission of the American Academy of Audiology.

might result. First, bone conduction vibrotactile responses could be better than the air conduction thresholds and therefore might result in erroneous air–bone gaps and misdiagnoses. Second, recording vibrotactile responses as bone conduction thresholds might erroneously suggest hearing in patients who are deaf (Nober, 1964). Individual sensitivity to vibrotactile sounds is variable (Boothroyd and Cawkwell, 1970). Perhaps the only way to know if responses are vibrotactile is to ask patients; this is recommended, especially when bone conduction thresholds appear inconsistent with other audiometric findings or history.

Interaural Attenuation, Masking, and the Occlusion Effect

Audiologists typically target a test ear for evaluation while being vigilant for the possibility of the patient hearing in the nontest ear. This vigilance is warranted during bone-conduction threshold evaluation; transducer placement on the test ear side mastoid bone results in activation of bone conduction bilaterally. The so-called cross-over from the test ear side to the nontest ear can occur with minimal interaural attenuation, ranging from 0 dB at 250 Hz to 15 dB at 4,000 Hz (Studebaker, 1967). Caution compels most audiologists to assume the worst-case scenario of 0 dB interaural attenuation, that is, equal tone intensity at the test and nontest ears. Bone conduction thresholds are therefore not typically considered to be ear-specific unless sufficient masking noise is delivered to the nontest ear. There are many variables to consider while masking, such as when to mask, masking noise type, masker intensity, and accounting for the occlusion effect caused by the earphone on the nontest ear (see Chapter 6 for details).

Mastoid versus Forehead Placement

During bone conduction hearing evaluation, audiologists may place the bone vibrator on either the mastoids or the foreheads of their patients. Mastoid placement is preferred by most audiologists (Martin et al., 1998). Perhaps the main advantage of mastoid placement is that the resulting bone conduction thresholds are up to 14.7 dB less than bone conduction thresholds measured with forehead transducer placement (Table 4.1). This allows for a greater testing range from threshold to equipment intensity limits or vibrotactile sensation. Moreover, vibrations from mastoid bone vibrator placement are in the same plane as middle ear ossicular motion, therefore engaging the middle ear bone conduction mechanism. This allows the audiologist

to record evidence of changes in the middle ear bone conduction component, for example, the middle ear resonance changes that are likely to occur with otosclerosis. Not surprisingly, audiometers in most clinics are calibrated for mastoid placement.

Forehead placement can be used if correction factors from Table 4.1 are applied or if the audiometer is calibrated for forehead transducer placement. Audiologists who prefer forehead transducer placement should consider purchasing a specifically designed bone vibrator and headband. Forehead placement has advantages, including low intra-subject and intersubject variability because of the less variable forehead placement surface and more uniform non-pneumatized forehead bone (Dirks, 1964). Also, vibrations from forehead placement are perpendicular to middle ear ossicular motion and may not engage the middle ear bone conduction mechanism as with mastoid placement. The resulting forehead bone conduction thresholds should be relatively unaffected by the changes in middle ear resonance and, in cases of ossicular fixation, reflect a truer measure of cochlear reserve than bone conduction thresholds obtained during mastoid transducer placement. Figure 4.13 shows an example audiogram with forehead and mastoid bone vibrator placement for a patient with ossicular fixation.

Threshold Accuracy and the Air–Bone Gap

Throughout this chapter significant air–bone gaps were defined as >10 dB. However, patient response variability can result in underestimated or exaggerated air–bone gaps and even bone–air threshold gaps. Studebaker (1967), for example, calculated the standard deviation of air–bone gaps at 5 dB and noted that air–bone threshold gaps of ≥ 15 dB can sometimes be seen in the absence of CHL. Similarly, Margolis (2008) calculated a hypothetical air–bone threshold gap distribution based on the independent variability of air and bone conduction thresholds. Significant air–bone and even bone–air threshold gaps were predicted, of course, with greater threshold gaps occurring less frequently. Moreover, Margolis reported apparent tester bias; when testing patients with SNHL an expert audiologist measured more air–bone threshold gaps ≤ 5 dB than the distribution predicted. Audiologists should not rigidly adhere to untenable expectations regarding air–bone threshold gaps.

CONCLUSION

Bone conduction threshold evaluation is an integral component of the basic audiologic examination. When bone conduction thresholds are interpreted with an understanding of air and bone conduction hearing, more accurate site-of-lesion and etiology diagnoses can be made. It is hoped that with this chapter the author has informed and motivated readers to that end.

FOOD FOR THOUGHT

1. How might the air–bone gaps of patients with outer ear occlusion differ from the air–bone gaps of patients with middle ear disorder?
2. Why are air–bone gaps usually but not always indicative of CHL?
3. Why is worsening bone conduction hearing not always indicative of hair cell and/or neural disorder?

Speech Audiometry

Rachel McArdle and Theresa Hnath-Chisolm

INTRODUCTION

Auditory assessment using speech stimuli has a long history in the evaluation of hearing. As early as 1804, there were scientific attempts to study hearing sensitivity for speech by assessing which classes of speech sounds an individual could hear: (1) vowels; (2) voiced consonants; or (3) voiceless consonants. In 1821, Itard, who is well known for his contributions to deaf education, differentiated individuals who were hard of hearing from those who were deaf by whether a person could understand some or none of a spoken message (Feldmann, 1970). This early focus on hearing for speech continued through the 19th century, and by the mid-1920s, the first speech audiometer, the Western Electric 4 A, which incorporated a phonograph with recorded digit speech stimuli, was employed in large-scale hearing screenings (Feldmann, 1970).

Hearing and understanding speech have unique importance in our lives. For children, the ability to hear and understand speech is fundamental to the development of oral language. For adults, difficulty in detecting and understanding speech limits the ability to participate in the communication interactions that are the foundation of numerous activities of daily living. Measures of sensitivity and understanding form the basis of speech audiometry. This chapter focuses on providing information that can lead to the implementation of evidence-based best practices in speech audiometry.

WHAT IS SPEECH AUDIOMETRY?

Speech audiometry refers to procedures that use speech stimuli to assess auditory function (Konkle and Rintelmann, 1983). Since the classic work of Carhart (1951), speech audiometry has involved the assessment of sensitivity for speech as well as assessment of clarity when speech is heard. These concepts were described by Plomp (1978), in his framework of hearing loss, as an audibility component (i.e., loss of sensitivity) and a distortion component (i.e., loss of clarity). The audibility component is quantified through assessment of speech recognition abilities in quiet. The distortion component is a reduction in the ability to understand speech, especially in a background of noise, regardless of the presentation level. Quantifying the distortion component typically involves percent correct recognition at suprathreshold levels for the

speech recognition score (SRS). More recently, the signal-to-noise ratio (S/N) at which 50% correct recognition is achieved has been recommended instead of the traditional SRS (Killion et al., 2004; Wilson, 2003). Before discussing measurement of speech thresholds and speech recognition in quiet and noise, general considerations in speech audiometry related to terminology, stimulus calibration, presentation methods, response modes, and presentation levels are discussed.

SPEECH AUDIOMETRY TERMINOLOGY

There are two types of threshold measures using speech stimuli: speech detection threshold (SDT) and speech recognition threshold (SRT). SDT, as defined by the American Speech-Language-Hearing Association (ASHA, 1988), is an estimate of the level at which an individual perceives speech to be present 50% of the time and should be reported in decibels hearing level (dB HL). SDTs are commonly used to establish the level for awareness of speech stimuli by infants, young children, or adults who cannot respond verbally or whose speech recognition ability is so poor that they are unable to recognize spondaic (i.e., compound) words to obtain an SRT. SDT is sometimes called a speech awareness threshold (SAT), although SDT is the term preferred by ASHA (1988).

The SRT is an estimate of the level at which an individual can repeat back spondaic words (e.g., hotdog, baseball) 50% of the time; it is most commonly reported in dB HL or decibels sound pressure level (dB SPL). The most common suprathreshold measure in quiet is the SRS or word recognition score and is generally measured in percent correct at a level (dB HL) relative to either the SRT or an average of puretone thresholds. Word recognition has been referred to as speech discrimination; however, discrimination infers that an individual is judging between two or more specific stimuli, which is not the task in most suprathreshold speech recognition measures.

GENERAL CONSIDERATIONS FOR SPEECH AUDIOMETRY

Audiometers have to meet calibration standards set forth by the American National Standards Institute (ANSI, 2004). In

addition, recorded materials used as stimuli for speech audiometry must meet the ANSI standards (ANSI, 2004, Annex B). To reduce error of measurement and increase consistency from clinic to clinic, speech measures should employ accepted calibration procedures, methods and modes of presentation, test instructions, and response modes.

Method of Presentation

Historically, VU meters were used for the tester to “monitor” the energy of his or her voice while presenting speech stimuli via the speech audiometer. The development of analog audiotape followed by compact disc technology was instrumental in facilitating standardization of word lists used in speech audiometry (Wilson et al., 1990). ASHA guidelines (1988) for speech thresholds indicate that the use of recorded stimuli is preferred. The majority of audiologists, however, who responded to a survey of audiometric practices (Martin et al., 1998), still report using monitored live speech to determine thresholds for speech. Of the 218 audiologists who completed the survey, 94% reported using monitored live voice test methods.

We feel that it is even more important to use recorded speech for SRSs. Digitized speech recordings improve both the intrasubject and intersubject precision of threshold and suprathreshold measures by providing a consistent level for all test items and consistent speech patterns between patients. The reliability of a given set of speech stimuli can vary across speakers and across test time for a single speaker. Hood and Poole (1980) found that a speaker had a significant impact on the difficulty of particular monosyllabic word lists. Similarly, Roeser and Clark (2008) found significant differences in performance when the same subjects were tested via recorded materials and monitored live voice with the latter showing better performance. Other studies have found variability in recognition performance as a function of speaker–list interactions (Asher, 1958; Hirsh et al., 1954) such that the acoustic waveforms of two speakers can cause differences in recognition performance even when the word lists are the same. The reported contribution of the speaker to the recognition performance of each listener reinforces previous reports by Krueger et al. (1969), who stated that word lists should be thought of as a group of utterances and not as a written list of words because speaker differences may affect a person’s performance on a particular list.

Presentation Level

PSYCHOMETRIC FUNCTION

Understanding the influence of presentation level on performance is best described by psychometric functions. In simple terms, a function is when you measure a change in a dependent variable (y -axis; e.g., number or percent correct,

FIGURE 5.1 Psychometric functions of word recognition performance measured in percent correct (ordinate) for a listener with hearing loss as a function of presentation level (abscissa). The dashed line indicates the 50% point. The function to the left is the SRT function whereas the function to the right is the SRS function.

which is a psychological variable) based on changes of an independent variable (x -axis; e.g., presentation level in HL or SNR, which is a physical variable). Figure 5.1 is a graphic display of two psychometric functions. The function to the left is an SRT function whereas the function to the right is an SRS function. The characteristic audiogram thought to accompany this type of performance can be seen in the lower right quadrant. Presentation level is on the x -axis (dB HL), whereas percent correct performance is on the y -axis. As can be seen for both functions, the percent correct is low when the level is low, and as the level is increased, the percent correct increases. The dashed line in Figure 5.1 highlights the 50% point on the functions and indicates that an SRT was obtained about 40 dB HL. Also illustrated in Figure 5.1 is that the maximum point of performance (100%) was reached at approximately 75 dB HL for the SRS function. As the level is increased above 75 dB HL, no change in performance is observed. The highest percent correct score obtained by an individual is often referred to as PB_{max} , because historically SRSs were obtained using phonetically balanced (PB) word lists. Further discussion of PB word lists can be found later in this chapter under the section titled “Speech Recognition in Quiet.”

Because listeners with normal hearing, on average, achieve maximal performance on a speech recognition task at 30 to 40 dB sensation level (SL) re: SRT, clinicians will often test their patients at one of these levels, assuming this will result in maximal performance for the listener. Assessing only a single level may provide limited diagnostic or rehabilitative information. Conversely, assessing performance at multiple presentation levels for individuals with sensory/neural hearing loss provides greater diagnostic information

FIGURE 5.2 Psychometric functions of word recognition performance illustrating various types of hearing loss can be seen in both panels as a function of percent correct [ordinate] and presentation level [abscissa]. The top panel illustrates a sample psychometric function for a listener with normal hearing [open circles], conductive hearing loss [curve #1], and cochlear hearing loss [curves #2 and #3]. The bottom panel shows possible psychometric functions for retrocochlear hearing loss [curves #4, #5, and #6]. [Adapted from Department of Veterans Affairs [1997].]

as demonstrated by the example functions drawn in Figure 5.2. In the top panel of Figure 5.2, curve #2 shows a function that reaches maximum performance (88%) at 80 dB HL and plateaus through 100 dB HL. In the bottom panel of Figure 5.2, curve #4 shows a function that reaches maximum performance (85%) at approximately 60 dB HL, and then performance decreases as level is increased, which is depicted by a rollover in the shape of the function.

Also of importance when describing performance in terms of the psychometric function is the slope of the function. The slope of the function is typically calculated from the dynamic portion of the function that ranges between 20% and 80%. Scores below 20% are often affected by floor

effects because the task difficulty is too great to show subtle changes in performance, whereas scores above 80% are often affected by ceiling effects because the task difficulty is too easy to be sensitive to performance changes. For an individual with a steep slope, the measurements should be made in small (dB) steps to obtain valid results, whereas a shallow function allows for larger step sizes to obtain valid results. When selecting test material, it is best to choose stimuli that produce a steep function, which suggests the materials are homogeneous with respect to the task (Wilson and Margolis, 1983).

Response Mode

The response mode for speech audiometry is generally verbal. However, for SDT the response mode can be similar to that of puretone thresholds, where patients can push a button or raise their hand when they hear the speech stimuli. A written response is generally avoided because of the increased test time and reliance on the patient's ability to write and spell. For testing children or nonverbal individuals, see Chapters 24 and 31.

SPEECH RECOGNITION THRESHOLD

Stimuli

Spondaic words are generally used for obtaining SDTs and SRTs and are recommended by ASHA (1988). Spondaic (adjective) words or spondees (noun) are two-syllable words with equal stress on both syllables. Lists of spondaic words for assessing hearing loss for speech were first developed at the Harvard Psychoacoustic Laboratories (PAL) by Hudgins et al. (1947). Criteria for selection of words included a high level of word familiarity, phonetic dissimilarity, and homogeneity with respect to audibility. Of the original 42 spondees identified by Hudgins et al. (1947), 36 of the most familiar were used in the development of the Central Institute for the Deaf (CID) W-1 and W-2 tests (Hirsh et al., 1952). Currently, ASHA (1988) recommends the use of 15 of the original 36 spondees used in the CID W-1 and W-2 tests for obtaining SRTs. These 15 words, shown in Table 5.1, are the most homogeneous with respect to audibility (Young et al., 1982), as is the list of 20 easily pictured spondees for use with children (Frank, 1980).

Recommended SRT Testing Protocol

The SRT measurement involves four steps: (1) instructions; (2) familiarization; (3) initial and test phase for the descending technique; and (4) calculation of threshold. Wilson et al. (1973) described these steps, which were subsequently set forth by ASHA (1988) as a guideline for determining an SRT.

TABLE 5.1

Spondaic Words Recommended by ASHA (1988)

15 Most Homogeneous Re: Audibility (Young et al., 1982)	20 Most Easy to Picture (Frank, 1980)
Toothbrush	Toothbrush
Inkwell	Hotdog
Playground	Baseball
Sidewalk	Airplane
Railroad	Cupcake
Woodwork	Popcorn
Baseball	Bathtub

Doormat	Football
Grandson	Mailman
Eardrum	Snowman
Northwest	Ice cream
Mousetrap	Sailboat
Drawbridge	Flashlight
Padlock	Bluebird
	Toothpaste
	Reindeer
	Shoelace
	Seesaw

STEP 1: INSTRUCTIONS

Patients need to be instructed regarding what stimuli will be used (i.e., spondaic words from the list) and how to respond during the testing procedure (i.e., written or verbal response). Also, it is important to make patients aware that the level of the stimulus will become quite soft and to encourage them to guess throughout the testing procedure.

STEP 2: FAMILIARIZATION

Each patient should be familiarized with the word list to be used during the testing procedure by listening to the list of test words at a level that is easily audible and repeating back each word as a demonstration of word recognition. If a patient is unable to repeat back a particular spondaic word from the test list, then that word should be removed from the test list. Another method of familiarization is to give the patient a written list of the test words to read.

Previous research has shown differences in SRT values obtained with and without familiarization (Conn et al., 1975; Tillman and Jerger, 1959). Specifically, Tillman and Jerger (1959) found poorer SRTs of almost 5 dB HL when individuals were not familiarized with the test list. The ASHA guideline strongly suggests that familiarization should not be eliminated from the test protocol.

STEP 3: DETERMINATION OF THRESHOLD

- Initial starting level—Present one spondaic word at a level 30 to 40 dB HL above the anticipated SRT. If a correct response is received, drop the level in 10-dB steps until an incorrect response occurs. Once an incorrect response is received, present a second spondaic word at the same level. If the second word is repeated correctly, drop down by 10-dB steps until two words are missed at the same level. Once you reach the level where two spondees are missed, increase the level by 10 dB. This is the starting level.
- Threshold estimation—Thresholds have been estimated using 2- or 5-dB steps since most audiometers are equipped with those step sizes. Previous studies have shown that threshold differences as a function of step size are too small to be clinically significant (Wilson et al., 1973).

2-dB step size—Present two spondaic words at the starting level. Drop the level by 2 dB and present two spondaic words. An individual should get the first five out of six words correct or else the starting level needs to be increased by 4 to 10 dB. If at least five of the first six words are correct, continue dropping the level by 2 dB until the individual misses five of six presentations.

5-dB step size—Present five spondaic words at the starting level. An individual should get the first five spondaic words correct at the starting level. Drop the level by 5 dB and present five spondaic words. Continue dropping the level by 5 dB until the individual misses all five spondaic words at the same level.

STEP 4: CALCULATION OF THRESHOLD

Calculation of an SRT is based on the Spearman-Kärber equation (Finney, 1952). An SRT is calculated by subtracting the number of words repeated correctly from the starting level and adding a correction factor of 1 dB when using the 2-dB step size and a correction factor of 2 dB when using the 5-dB step size. For a 5-dB step example, with a starting level of 40 dB, the patient got all five words; at 35 dB, three of the words were correct; and at 30 dB, none were correct. Eight of the 15 words were correct. Therefore, the SRT calculation would be $40 - 8 = 32$, + 2 for the correction, equals 34 dB HL.

Clinical Functions of SRT

The most recent surveys of audiometric practices in the United States reported that 99.5% (Martin et al., 1998) and 83% (ASHA, 2000) use SRT as part of their basic audiologic assessment. The reasons stated for using SRT were (1) cross validation for puretone thresholds; (2) measurement of communication disability; and (3) reference for supra-threshold measures. Unfortunately, most of the historical purposes lack scientific evidence to support routine clinical

use of an SRT (Wilson and Margolis, 1983). In addition, only 58% of audiologists complete the familiarization step of the test protocol, and 60% do not follow the recommended ASHA (1988) protocol but, instead, determine an SRT using a modified Hughson–Westlake procedure with two out of three criteria (Martin et al., 1998). These observations are of concern because the SRT is a valid and reliable procedure when standardized recorded materials are used with a specified testing procedure. The SRT is also particularly useful when assessing response reliability in an individual who appears to be malingering (see Chapter 33).

SPEECH RECOGNITION IN QUIET

The purpose of speech recognition testing in quiet is to assess how well a person can understand speech in a quiet environment when the level of the speech is loud enough to obtain a maximum SRS (PB_{max}). The level necessary for a person with hearing loss to perform maximally is highly variable from person to person and is dependent on the materials used to obtain the SRS (Jerger and Hayes, 1977). We feel that it is unfortunate that, in most audiology clinics, speech recognition testing is assessed only at one presentation level (Wiley et al., 1995). The majority of audiologists select a single presentation level 30 to 40 dB SL re: SRT, meaning that the materials are presented 30 to 40 dB above the SRT (Martin et al., 1998; Wiley et al., 1995). Kamm et al. (1983) found that speech recognition testing at 40 dB SL re: SRT did not approximate maximal performance for 40% of their 25 subjects with hearing loss. Evidence suggests that evaluating speech recognition abilities at more than one level captures a portion of the psychometric function and allows a better estimation of performance at PB_{max} . A procedure suggested by Wilson (2005, Personal communication) suggests the use of at least two levels with 25 words presented at each level. For persons with normal hearing or mild hearing loss as evidenced by a puretone average (PTA) of ≤ 35 dB HL for 500, 1,000, and 2,000 Hz, the first level should be 50 dB HL followed by the second level of 70 dB HL. For persons with greater hearing loss, the first level should be 10 dB greater than their PTA of 500, 1,000, and 2,000 Hz, and the second level should be 20 dB greater than the first level. If you are unable to raise the second level 20 dB greater than the first level because of loudness discomfort issues, raise the second level as high as possible over the first level.

Several types of materials are used to assess speech recognition ability in quiet such as sentences, nonsense syllables, and the most commonly used stimuli, monosyllabic words. Previous research has shown that nonsense syllables are the most difficult of the three materials mentioned above for individuals to recognize, whereas sentences are the easiest. Recognition performance of monosyllabic words falls on the performance continuum somewhere between nonsense syllables and sentences. Although monosyllables are the most commonly used stimuli in clinical settings for measuring speech

recognition performance in quiet, it is important to note that empirical data (Bilger, 1984) support that speech recognition performance is a single construct and performance at one level of linguistic complexity (e.g., sentences) can be predicted by performance at another level (e.g., monosyllabic words).

The systematic relationship between recognition performances at various levels of linguistic complexity by adults with acquired hearing losses was demonstrated by Olsen et al. (1997). Performance for phonemes, words in isolation, and words in sentences was measured for 875 listeners with sensory/neural hearing loss. They found that the scores for words in isolation and in sentences were predictable from the phoneme recognition scores, with mean prediction errors of only 6% and 12%, respectively. Thus, for example, a person scoring 60% correct on a phoneme recognition task would be predicted to score 22% ($\pm 6\%$) for the recognition of words in isolation and 42% ($\pm 12\%$) for the recognition of words in sentences.

Monosyllabic Words

Historically, word lists such as the Northwestern University Auditory Test Number 6 (NU No. 6; Tillman and Carhart, 1966), the CID Auditory Test W-22 (CID W-22; Hirsh et al., 1952), and the Phonetically Balanced 50 (PB-50; Egan, 1948) have been used to assess word recognition performance in a quiet background during audiologic evaluations.

The initial work of Egan (1944) outlined six principal criteria that the Psychoacoustics Lab at Harvard used to develop the PB-50 word lists. The six criteria were (1) monosyllabic structure, (2) equal average difficulty of lists, (3) equal range of difficulty of lists, (4) equal phonetic composition of lists, (5) representative sample of American English, and (6) familiar words. According to Hood and Poole (1980), it was assumed by Egan that meeting criteria 1, 4, 5, and 6 would ensure criteria 2 and 3. Further work to revise the PB-50 word lists by Hirsh et al. (1952) and Tillman et al. (1963) utilized the six criteria to create the W-22 word lists and the NU No. 6 word lists, respectively.

PB-50

The initial use of monosyllabic words for speech recognition testing is attributed to Egan (1948) who worked in the PAL at Harvard University. His original pool of 1,000 words was divided into 20 lists of 50 words, which collectively are known as the PAL PB-50 word lists. Each list was considered to be phonetically balanced such that the 50 words that composed a list were a proportionally correct representation of the phonetic elements in English discourse.

CID W-22

Hirsh et al. (1952) had five judges rate the familiarity of the 1,000 monosyllabic words selected by Egan for the PB-50

word lists, and 120 of the PB-50s were selected along with 80 other words to compose the new word lists. These 200 very common words were selected and phonetically balanced into four 50-word lists known as the CID W-22 word lists. The CID W-22 word lists were recorded onto magnetic tape as spoken by Ira Hirsh who monitored his voice on a VU meter stating the carrier phrase “You will say” and letting each target word fall naturally at the end of the phrase. The CID W-22 word lists are some of the most popular word lists used by audiologists for measuring suprathreshold word recognition ability in quiet.

NU NO. 6

Lehiste and Peterson (1959) devised lists of CNCs (consonant-syllable nucleus [vowel]-consonant) that were phonemically balanced versus phonetically balanced. That is, lists that were developed to be phonetically balanced did not take into account the position of the sound in a word and how the acoustic realization of the sound would be affected by coarticulatory factors. Lehiste and Peterson argued that phonemic balancing could be accomplished by allowing for the frequency of occurrence of each initial consonant, vowel nucleus, and final consonant to be similar across CNC word lists. The Lehiste and Peterson lists were condensed into four lists of 50 words known today as the NU No. 6.

Historically, 50 words were included in each test list to facilitate phonetic balancing and to allow for a simple conversion from number correct to percent correct following testing. Studies have examined the benefits of abbreviating the number of words used per list from 50 to 25 with mixed results in terms of test-retest reliability (Beattie et al., 1978; Elpern, 1961). The most important work regarding this issue of half versus full lists was the examination of speech recognition data as a binomial variable by Thornton and Raffin (1978). As discussed in the earlier section on psychometric functions, performance ability between 20% and 80% is the most variable, whereas performance ability is least variable at either extreme of the function (Egan, 1948). The results of Thornton and Raffin (1978) support these early views on performance using the binomial distribution to mathematically model word recognition performance. It indicates that the accuracy between scores for the same listener depends on the number of words used per list and the listener's level of performance. In addition, Thornton and Raffin created a table of the lower and upper limits of the 95% critical differences for percentage scores as a function of test items. Table 5.2 shows the critical differences a retest score would need to exceed to be considered statistically different for the original test score. As seen in Table 5.2, as the number of items increases, the range decreases, suggesting that as the set size increases, the variability in the scores decreases, allowing for the detection of more subtle differences in performance. One way to increase set size without increasing test time is to move from whole-word scoring to

TABLE 5.2

Critical Difference Ranges (95%) for Select Percent Correct Scores as a Function of Number of Test Items

% Correct	10 Words	25 Words	50 Words
0	0–20	0–8	0–4
10	0–50		2–24
20	0–60	4–44	8–36
30	10–70		14–48
40	10–80	16–64	22–58
50	10–90		32–68
60	20–90	36–84	42–78
70	30–90		52–86
80	40–100	56–96	64–92
90	50–100		76–98
100	80–100	92–100	96–100

From Thornton and Raffin (1978).

phoneme scoring (Boothroyd, 1968). In a 25-word list of monosyllables, you have 25 items to score using whole-word scoring, whereas you would have 50 to 75 possible items to score using phoneme scoring.

Sentence Tests

Sentence-level tests were developed at Bell Laboratories (Fletcher and Steinberg, 1929) and were used during World War II to evaluate military communication equipment (Hudgins et al., 1947). Until the development of the CID Everyday Sentences (Silverman and Hirsh, 1955), no sentence test had received clinical acceptance. The CID sentences consist of 10 lists of 10 sentences each with 50 key words in each list. Interrogative, imperative, and declarative sentences are included. Responses can be spoken or written and are scored as the percentage of key words correctly recognized.

The basis for the use of sentences in the clinical assessment of speech recognition abilities is that sentences provide a more “realistic” listening condition for everyday communication than does the use of isolated words or nonsense syllables (Bess, 1983; Silverman and Hirsh, 1955). Although sentences may have greater face validity than other stimuli, they also provide semantic, syntactic, and lexical clues (i.e., extrinsic redundancies). Thus it is difficult to distinguish individuals who do well on a speech recognition task because they have good speech recognition skills or because they make good use of top-down (linguistic, cognitive) processing skills. Another complication of the use of sentence materials is that, as length exceeds seven to nine syllables, memory constraints, particularly in the elderly, may impact performance (Miller, 1956). Despite these potential limitations, several clinically useful sentence tests have been developed. Because the ability to use context is preserved even in older adults with hearing loss, for most patient populations,

sentence tests are typically too easy (ceiling effect) and, therefore, fail to distinguish among levels of difficulty. However, they are well suited as adaptive noise procedures (see “Speech Recognition in Noise” section) instead of supra-threshold quiet procedures. An exception to this trend is the use of sentence tests in quiet for individuals with severe-to-profound hearing losses.

For the profoundly impaired patient population, the City University of New York (CUNY) Sentences (Boothroyd et al., 1988), which consist of 72 sets of topic-related sentences, were designed to assess the use of cochlear implants and tactile aids as supplements to speech reading. Each sentence in a set is about one of 12 topics: food, family, work, clothes, animals, homes, sports/hobbies, weather, health, seasons/holidays, money, or music. Each set contains four statements, four questions, and four commands and one sentence of each length from 3 to 12 words, for a total of 102 words per set. Performance is scored as the number of words correct. Original recordings were on laser-video disc and were presented via the Computer Assisted Speech Perception Software (CASPER; Boothroyd, 1987) program. The CUNY Sentences are being converted to DVD format with upgrades to the CASPER software as part of current work at the Rehabilitation Engineering Research Center (RERC) on Hearing Enhancement at Gallaudet University (<http://www.hearingresearch.org/>).

Nonsense Syllable Tests/Phoneme Recognition Tests

The effects of lexical context and word familiarity on test performance can be minimized by the use of nonsense syllable and/or closed-set phoneme recognition tests. Nonsense syllables were one of the first materials used to assess speech recognition ability during the development of telephone circuits at Bell Telephone Laboratories (Fletcher and Steinberg, 1929). However, clinical use of nonsense syllables for those with hearing loss did not occur until the 1970s when two carefully developed tests became available—the CUNY Nonsense Syllable Test (CUNY-NST; Levitt and Resnick, 1978) and the Nonsense Syllable Test (NST; Edgerton and Danhauer, 1979). The CUNY-NST is a closed-set test consisting of seven subtests, each of which has seven to nine consonant–vowel (CV) or vowel–consonant (VC) syllables. The CUNY-NST assesses perception of the consonants most likely to be confused by individuals with hearing loss using three vowel contexts. The Edgerton–Danhauer NST is an open-set test consisting of 25 nonsense bisyllabic CVCV items, allowing for assessment of the perception of 50 consonant and 50 vowel stimuli. More recently, Boothroyd et al. (1988) described the Three Interval Forced Choice Test of speech pattern contrast perception (THRIFT), an NST that can be used with children 7 years of age or older (Hnath-Chisolm et al., 1998). The THRIFT measures the perception of nine speech pattern contrasts presented in varying pho-

netic context. Contrasts include intonation; vowel height and place; and initial and final consonant voicing, continuance, and place. In addition to minimizing the effects of lexical context and word familiarity on performance, the use of nonsense syllables allows for detailed examination of phonetic errors. Despite these advantages, nonsense syllables lack face validity with regard to being representative of everyday speech communication.

Minimization of lexical context and word familiarity effects, while allowing for the analysis of errors and confusions, can also be accomplished through the use of closed-set tests using real word stimuli. Classic tests of phoneme recognition include the Modified Rhyme Test (MRT; House et al., 1955; Krueger et al., 1968) and its variations (e.g., Rhyming Minimal Contrasts Test (Griffiths, 1967) and the California Consonant Test (CCT; Owens and Schubert, 1977). The MRT consists of 50 test items each with six response alternatives. Twenty-five of the items differ by the initial consonant (i.e., bent, went, sent, tent, dent, and rent), and the other 25 items differ by the final consonant (i.e., peas, peak, peal, peace, peach, and peat). The CCT also consists of 100 items but uses a four-choice, rather than a six-choice, response format in assessing the perception of 36 initial consonant items and 64 final consonant items. The perception of medial vowels as well as initial and final consonants was added in the University of Oklahoma Closed Response Speech Test by Pederson and Studebaker (1972).

A closed-set format is also used in the Speech Pattern Contrast (SPAC) test (Boothroyd, 1984), which was designed to assess the ability to perceive both suprasegmental (i.e., stress and intonation) and segmental phonologically (i.e., vowel height and place, initial and final consonant voicing, continuance, and place) relevant distinctions. Test length of SPAC is minimized by combining two segmental contrasts in one subset (e.g., final consonant voicing and continuance) with four items (e.g., seat–seed–cease–sees). Although the SPAC as well as other speech feature tests and NSTs are not routinely used in clinical audiology, the information provided about the details of an individual’s speech perception ability can be quite useful when assessing the need for and the benefits of hearing aids and cochlear implants for both children and adults.

SPEECH RECOGNITION IN NOISE

The most common complaint expressed by adults with hearing loss is the inability to understand a speaker when listening in an environment of background noise. In 1970, Carhart and Tillman suggested that an audiologic evaluation should include some measure of the ability of an individual to understand speech when in a background of speech noise. Prior to the revival of the directional microphone in the late 1990s, however, the information gained from a speech-in-noise task for most rehabilitative audiologists was not pertinent to the selection of amplification because of the fact that

most hearing aids were mainly selected based on gain, slope, and output curves. Thus in the technology-driven field of audiology, speech-in-noise testing failed to gain a place in the traditional audiologic evaluation. The revolution of digital hearing aids and their multitude of features, such as directional microphones, noise reduction strategies, and digital signal processing strategies, have created an important reason for utilizing speech-in-noise tasks on a routine basis when evaluating an individual with hearing loss.

For the past 40 years, researchers have observed that listeners with hearing loss show a greater disadvantage when listening in a competing speech background compared with listeners with normal hearing, such that the S/N needed for the listener with hearing loss is 10 to 15 dB greater than that needed by listeners with normal hearing (e.g., Carhart and Tillman, 1970). Plomp (1978) reported that for every 1-dB increase in signal over the competing noise, a listener with hearing loss would receive, on average, an improvement of 3% in terms of ability to recognize the signal. Thus, a 10-dB improvement in S/N should add 30% in terms of intelligibility as measured by open-set, speech recognition tests for listeners with hearing loss.

The addition of background noise to a speech recognition task has been shown to improve the sensitivity and validity of the measurement (Beattie, 1989; Sperry et al., 1997). In terms of improving sensitivity, the addition of multiple S/Ns increases the difficulty of the task and allows

for separation between individuals with normal hearing and those with hearing loss (Beattie, 1989; McArdle et al., 2005b). Typically, individuals with sensory/neural hearing loss require the signal to be 10 to 12 dB higher than the noise to obtain 50% performance on the psychometric function, whereas individuals with normal hearing on average obtain 50% performance at an S/N of 2 to 6 dB. McArdle et al. (2005a, 2005b) found mean performance on the Words-in-Noise (WIN) test (Wilson, 2003) to be 12.5 and 6 dB S/N for 383 listeners with hearing loss and 24 listeners with normal hearing, respectively. Similarly, under similar experimental conditions, Dirks et al. (1982) and Beattie (1989) who used CID W-22 word lists in noise found 50% points of 12 and 11.3 dB S/N, respectively, for listeners with hearing loss.

Several studies have examined the possibility of predicting the ability of an individual to understand speech-in-noise using puretone audiograms and SRSs in quiet without success (Beattie, 1989; Carhart and Tillman, 1970; Cherry, 1953; Dirks et al., 1982; Killion and Niquette, 2000; Plomp, 1978; Wilson, 2003). The data in Figure 5.3 were compiled from two studies (McArdle et al., 2005a, 2005b). In the figure, performance on a word recognition in quiet task at 80 dB HL is graphed on the ordinate as a function of 50% points on the WIN test along the abscissa. The same words spoken by the same speaker were used for both the recognition task in quiet and in noise. The shaded area of the figure represents

FIGURE 5.3 A plot of word recognition performance in quiet in percent correct [y-axis] versus the 50% point of recognition performance in multitalker babble on the Words-in-Noise (WIN) test [x-axis]. The shaded area of the figure defines the range of performances [10th to 90th percentiles] obtained by listeners with normal hearing on the WIN test. The numbers represent the number of listeners who had word recognition scores in quiet $\geq 90\%$, $\geq 80\%$, and $\geq 70\%$ correct on the words in quiet. The data are combined from McArdle et al. [2005a, 2005b]. [Reprinted with permission from the *Journal of Rehabilitative Research and Development*.]

the range of performance by 24 listeners with normal hearing on the WIN.

Two main observations can be seen in the data in Figure 5.3: (1) only 5 out of 387 listeners with hearing loss performed in the normal range on both the recognition task in quiet and in noise; and (2) 45.5% of the 387 listeners with hearing loss had word recognition scores in quiet at 80 dB HL that were $\geq 90\%$ correct. Thus, it is of interest to note that although 73% of the listeners with hearing loss had word recognition scores in quiet $\geq 80\%$, the overwhelming majority of these listeners displayed abnormal performance on a word recognition task in noise. This finding suggests that speech-in-noise testing may be considered a stress test of auditory function (Wilson, 2013, Personal communication). In addition, it is clear that word recognition ability in noise is not easily predicted by word recognition in quiet for listeners with hearing loss other than to say that listeners with poor recognition ability in quiet also perform poorly on word recognition tasks in noise. Because we are unable to predict the ability of an individual to understand speech in a noisy background, audiologists should use the tests available for quantifying the S/N needed by the listener to understand speech in noise. Several materials, described in the following section, have been developed to measure speech-in-noise performance.

Materials

Initially, efforts in speech-in-noise testing were focused on sentence-level materials to make the task more of a real-world experience; however, normal everyday sentences were too easy, and further manipulation of the sentences was needed to obtain the 50% correct point of performance for a listener on a speech-in-noise task. Speaks and Jerger (1965) developed the Synthetic Sentence Identification (SSI) test to minimize the effect of contextual cues that often made it easy to understand sentence-level materials even in a background of noise. The stimuli are called synthetic sentences because they are not actual sentences, but rather they contain normal English phonemes and syntax but no semantic context. An example of a sentence is “Small boat with a picture has become.” The task of the listener is to select which one of 10 sentences displayed on a response form is perceived when presented against a competing story describing the life of Davy Crockett. The competing story can be presented either contralaterally or ipsilaterally.

Another interesting sentence-level test, the Speech Perception in Noise (SPIN) test (Kalikow et al., 1977), varies the amount of semantic context that leads to the last word of each sentence, which is a monosyllabic target word. The SPIN test has eight forms of 50 sentences each that are presented at a fixed S/N of 8 dB. The target word in 25 of the sentences has low predictability (LP) given the limited clues from the preceding context, and the other 25 have high predictability (HP) from the preceding sentence context.

Recognition performance is scored as the percentage of LP and HP words correctly perceived. By providing both LP and HP scores, the SPIN test not only allows for the assessment of the acoustic-phonetic components of speech, but also examines the ability of an individual to utilize linguistic context.

In the 1980s, two additional tests designed to assess recognition of everyday speech based on correct word recognition performance in sentence length stimuli were developed. The Connected Speech Test (CST; Cox et al., 1987), which was developed as a criterion measure in studies of hearing aid benefit, consists of 48 passages of conversationally produced connected speech. Each passage is about a familiar topic and contains 10 sentences. Sentence length varies from 7 to 10 words, and there is a total of 25 key words in each passage. Sentences are presented at an individually determined S/N, and performance is scored as the number of key words correct.

The most recent application of sentence length stimuli is in tests that are scored in terms of the decibel-to-noise ratio required to achieve 50% correct performance. The two most common tests are the Hearing in Noise Test (HINT; Nilsson et al., 1994) and the Quick Speech-in-Noise (QuickSIN) test (Killion et al., 2004). The two tests vary in the type of sentences and type of noise used. The HINT uses the Bamford–Kowal–Bench (BKB) Standard Sentence Lists (Bench et al., 1979) that were compiled from the utterances of hearing-impaired children and contain straightforward vocabulary and syntax. Sentences are presented in sets of 10 sentences, and the listener must repeat the entire sentence correctly to receive credit. The noise used is speech-spectrum noise that is held constant while the signal is varied to find the 50% correct point. The QuickSIN uses the Harvard Institute of Electrical and Electronics Engineers (IEEE, 1969) sentences, which are a collection of low-context, meaningful sentences, whose phonetic balance is similar to that of English. In the QuickSIN, there are six sentences per list, and each sentence contains five key words. All sentences are presented in multitalker babble with the five key words in each sentence scored as correct or incorrect. Recently, the BKB-SIN test (Etymotic Research, 2005) was developed for use with children (ages ≥ 5), cochlear implant patients, and adults for whom the QuickSIN test is too difficult.

More recently, monosyllabic and digit materials in multitalker babble have been developed at the Auditory Research Lab of the James H. Quillen Veterans Affairs Medical Center (Wilson, 2003; Wilson and Strouse, 2002; Wilson and Weakley, 2004). The word and digit materials have been shown to be sensitive to the different recognition abilities of normal-hearing and hearing-impaired adults in multitalker babble (Wilson et al., 2003; Wilson and Weakley, 2004). McArdle et al. (2005b) examined the effect of material type (i.e., digits, words, and sentences) on S/N loss for young listeners with normal hearing and older listeners with hearing impairment. The three speech-in-noise tests that were examined

FIGURE 5.4 Bivariate plot of the 50% points [in dB S/N] on the Words-in-Noise [WIN] test [ordinate] and on the Quick Speech-in-Noise [QuickSIN] test [abscissa]. The *diagonal line* represents equal performance, with the *larger filled symbol* indicating the mean datum point. The *dashed line* is the linear regression fit to the data. The *numbers in parentheses* are the number of performances above and below the line of equal performances. [Reprinted with permission from the *Journal of Rehabilitative Research and Development*.]

include: (1) QuickSIN (Etymotic Research, 2001); (2) WIN test (Wilson and Strouse, 2002; Wilson, 2003); and (3) digit triplets-in-multitalker babble (Wilson and Weakley, 2004). As expected, the younger listeners performed better than the older listeners on all three tasks. For the older listeners with hearing loss, the S/N required for 50% recognition of each material type presented was -4 , 12.4 , and 11.7 dB S/N for digits, words, and sentences, respectively. Figure 5.4 shows a bivariate plot of the 50% points for the older listeners with hearing loss on both the QuickSIN (abscissa) and the WIN (ordinate). The diagonal line in Figure 5.4 represents equal performance on both QuickSIN and the WIN. As can be seen, mean performance, as indicated by the bold filled circle, is close to the diagonal line, suggesting that either the use of monosyllabic words or IEEE sentences in this population provided a similar measure of performance in noise. More importantly, the performance difference at the 50% point between normal-hearing listeners and hearing-impaired listeners was 7.6 dB for both words and sentences, suggesting that words and sentences in a descending speech-in-noise task were equally sensitive to the effects of hearing loss. For a more in-depth discussion of the use of words or sentences in speech-in-noise testing, see Wilson and McArdle (2005).

A new body of literature has evolved in the area of speech-in-noise testing focused on informational masking, which is defined as nonenergetic masking that increases threshold as a result of uncertainty (Wilson et al., 2012). Although the term informational masking is more recent,

the construct was described by Carhart et al. (1969) and termed perceptual masking. Energetic masking is described in the literature as peripheral masking, such that a stimulus interferes with the perception of a second stimulus making the first stimulus a “masker.” Nonenergetic masking, or informational masking, occurs when the target stimulus is similar to the masking stimulus, creating uncertainty for the listener as to whether he or she is hearing the target or the masker. Informational masking can occur at different processing levels (e.g., phonetic, semantic) and is greater for a speech masker than noise, especially when the talker is the same gender or, even worse, the same talker for both the target and the masker (Brungart, 2001). Informational masking has a greater effect when the masker is a single speaker versus a background of multiple talkers since once you add more than a couple of speakers the background “information” in the masker becomes hard to distinguish. Most commercially available speech-in-noise tests involve multitalker babble, which decreases the effects of informational masking but future studies in this area are warranted.

CONSIDERATIONS FOR SPEECH AUDIOMETRY IN CHILDREN AND OTHER SPECIAL POPULATIONS

Speech stimuli are used for the behavioral assessment of the auditory function of a child from birth onward. With very young infants, speech stimuli might be used to elicit a startle

response, and as the infant develops, SDTs and SRTs can be obtained using a variety of behavioral techniques, such as visual response audiometry or play audiometry. The technique used will be dependent on the motor capabilities of the child. In addition to considering the motor capacity of the child for responding (e.g., head turn, picture pointing), the phonologic, receptive, and expressive language skills of the child need to be considered during speech recognition testing. For example, by the time a child can function at about a 5-year-old level, conventional SRTs can be obtained as long as the spondee words used are within the receptive vocabulary of the child (ASHA, 1988). Similarly, several suprathreshold pediatric speech recognition tests, such as the Word Intelligibility Picture Identification (WIPI) test (Ross and Lerman, 1970) and the Northwestern University Children's Perception of Speech (NU-CHIPS) test (Elliot and Katz, 1980), are comprised of words expected to be within the receptive vocabulary of a child.

A variety of speech recognition tests are available for use with children. For example, both the WIPI and NU-CHIPS use monosyllabic words presented in a closed-set format. Other test paradigms allow for the assessment of the perception of speech feature contrasts (e.g., Imitative Test of Speech Pattern Contrast Perception [IMSPAC]; Kosky and Boothroyd, 2003; Visually Reinforced Audiometry Speech Pattern Contrast Perception [VRASPAC]; Eisenberg et al., 2004), syllabic pattern and stress (e.g., Early Speech Perception [ESP] test; Moog and Geers, 1990), lexically easy versus lexically hard words (e.g., the Lexical Neighborhood Test [LNT]; Kirk et al., 1995), and words in sentences presented in quiet (e.g., BKB sentences; Bamford and Wilson, 1979) and in noise (e.g., BKB-SIN test; Etymotic Research, 2005), a task which requires word and sentence recognition in both quiet and noise (e.g., Pediatric Speech Intelligibility [PSI] test; Jerger and Jerger, 1984).

In addition to children, special consideration also needs to be given to the assessment of speech perception abilities in profoundly hearing-impaired adults, nonverbal patients, and multilingual patients (Wilson and Strouse, 1999). Profoundly hearing-impaired adults typically obtain scores of zero on standard speech recognition tests. As a result, batteries such as the Minimal Auditory Capabilities (MAC) battery have been developed (Owens et al., 1985). Tasks included in the MAC battery involve discrimination of syllabic number, noise versus voice, and statements versus questions; recognition of spondaic words and consonants and vowels in real words in closed-set tasks; and more standard open-set recognition of words in isolation and sentences.

Nonverbal patients are often encountered in medical settings where patients may have medical conditions such as laryngectomies or cerebral vascular accidents. For these patients, written responses or picture pointing tasks may be appropriate. Increases in the ethnic diversity of the US population can result in the audiologist assessing a patient who speaks little to no English. Limited knowledge of English could impact

on speech perception performance in the same way that the developing linguistic abilities of a child are important to consider in assessment. Although recorded materials are available in languages such as Spanish (Wesilender and Hodgson, 1989), unless the audiologist speaks Spanish, errors could be made in determining correct from incorrect responses. Wilson and Strouse (1999) suggest the use of a multimedia approach similar to that used by McCullough et al. (1994) with nonverbal patients. Stimulus words are presented in the patient's native language, and the person responds by selecting the perceived word from a closed set of alternatives shown on a touchscreen monitor. Scoring could be done automatically through a software program.

CLINICAL FUNCTIONS OF SPEECH RECOGNITION MEASURES

One of the historical purposes for the use of speech recognition testing in the clinical test battery was as a diagnostic tool for determining the location of peripheral auditory pathology. Figure 5.2 illustrates typical psychometric functions obtained in quiet for the recognition of monosyllabic words by listeners with normal auditory function as well as those with conductive, sensory (cochlear), and neural (retrocochlear) hearing losses. For normal-hearing listeners, regardless of word recognition materials used, when the presentation level is about 30 dB higher than the dB level needed for 50% performance (i.e., SRT), a score of 90% or better can be expected. For individuals with hearing loss, when listening at a moderate level, scores may range anywhere from 100% correct to 0% correct. Because of this wide dispersion of speech recognition performance across individuals with various types of hearing loss, speech recognition testing provides only limited diagnostic information if testing is done at only one intensity level (see, for discussion, Bess, 1983; Penrod, 1994). When testing is completed at several intensity levels, however, certain patterns of performance can be expected with certain hearing losses (Wilson and Strouse, 1999).

Individuals with conductive hearing loss tend to exhibit little difficulty on speech recognition tests, with performance typically at 90% or better when testing is conducted at moderate SLs (curve #1 of Figure 5.2). A patient with a sensory/neural hearing loss will generally have poorer SRSs than would a person with the same degree of hearing loss due to conductive pathology. Although a very wide range of scores are found across patients with cochlear as well as retrocochlear hearing losses, SRSs tend to be poorest among those with retrocochlear pathology. Although some individuals with cochlear losses will demonstrate a slight decrease in recognition performance when intensity levels are increased beyond the initial level needed for obtaining maximum performance (curve #3 of Figure 5.2), marked decreases in performance with increasing intensity after maximum performance is achieved are typically characteristic of a neural

loss (curves #4 and #5 of Figure 5.2). The phenomenon of reduced SRSs with increasing intensity that occurs with retrocochlear pathology is referred to as the “rollover” effect (Bess et al., 1979; Dirks et al., 1977). In addition to rollover, retrocochlear pathology would be suspected in the presence of a significant discrepancy in SRSs between two ears or lower than expected performance at all presentation levels (curve #6 of Figure 5.2).

Assessment of the central auditory system also uses measures of speech recognition performance. Tasks can be presented either monaurally or binaurally. Monaural tasks use distorted, degraded, or low-redundancy speech stimuli to reduce extrinsic redundancies. Methods of degradation include filtering (Bocca et al., 1955), time compression (Wilson et al., 1994), and reverberation (Nabelek and Robinson, 1982). Binaural tests were designed to assess the ability of the central auditory nervous system to integrate or resynthesize the different parts of a signal that are presented to each of the two ears. For example, in the Binaural Fusion test (Matzker, 1959), a low-pass filtered version of a word is presented to one ear, whereas a high-pass filtered version of the same word is presented to the opposite ear. A normal-functioning central auditory nervous system is able to integrate the information from each ear and respond with the correct target word. On the other hand, binaural dichotic tasks involve the presentation of different speech signals simultaneously to both ears. The patient must repeat either or both of the signals depending on the test used. Common clinical dichotic tests include Dichotic Digits (Kimura, 1961), the Staggered Spondaic Word test (Katz, 1962), and the Dichotic Sentence Identification test (Fifer et al., 1983). The interpretation of performance on tests designed to assess auditory processing abilities is beyond the scope of the present chapter and is discussed in detail in Chapters 27 and 29.

In addition to diagnostic applications, speech recognition testing has an important role in estimating the adequacy and effectiveness of communication and in the planning and evaluation of (re)habilitative efforts, including the selection and fitting of hearing aids and cochlear implants. For example, many audiologists label speech recognition performance for monosyllabic words presented in quiet performance as “excellent,” “good,” “fair,” or “poor” in an attempt to link performance to the adequacy of communication in everyday settings. However, research designed to demonstrate systematic relationships between recognition performance in quiet and actual everyday communication has been largely unsuccessful (Davis, 1948; High et al., 1964). A better estimate of the impact of a hearing loss on daily communication might be obtained with the use of speech-in-noise tests such as the WIN, QuickSIN, or HINT. As Wilson and McArdle (2005) discuss, speech-in-noise testing allows for the assessment of the most common complaint of patients—the inability to understand speech in background noise; and thus, test results provide important information for use in counseling. Furthermore, test results

can provide insight into the use of appropriate amplification and/or cochlear implant speech processing strategies.

In addition to testing in noise, Brandy (2002) points out that audiologists can gain insight into the (re)habilitative needs of patients through recording incorrect word responses, with subsequent examination of speech feature error patterns (e.g., fricatives, stops, glides). Other rehabilitative applications of speech audiometry include the use of materials that allow for the assessment of use of linguistic context (Flynn and Dowell, 1999) and auditory–visual performance (Boothroyd, 1987) and for the determination of most comfortable and uncomfortable listening levels (Punch et al., 2004). Information obtained with a variety of materials presented in a variety of paradigms can be useful in determining optimal device settings, starting points for therapeutic intervention, and directions for patient counseling.

FOOD FOR THOUGHT

1. Given the use of SRTs as a verification for puretone thresholds in every patient has been questioned since 1983, what is the cost benefit of measuring SRTs in a busy practice? Might the time be better spent gathering other information about the patient’s auditory functioning?
2. Determining the presentation level for word recognition testing in quiet historically has been 40 dB SL, re: SRT. Given the evidence for this level is based on listeners with normal hearing, what is most appropriate for determining the presentation level(s) for listeners with hearing loss? Additionally in an audiologic evaluation, what are the benefits of using 25 words at each of two or three presentation levels versus 50 words at one presentation level?
3. Speech recognition in quiet has been performed by audiologists since the 1950s. Given that the most common complaint of listeners with hearing loss is their difficulty communicating in noisy situations, should the standard comprehensive audiometric battery be modified to include speech-in-noise measures?

Clinical Masking

William S. Yacullo

In the first edition of this text, Sanders (1972) wrote the following introduction to his chapter on clinical masking:

Of all the clinical procedures used in auditory assessment, masking is probably the most often misused and the least understood. For many clinicians the approach to masking is a haphazard hit-or-miss bit of guesswork with no basis in any set of principles. (p 111)

Unfortunately, this statement may still hold true today.

The principles of clinical masking are difficult for many beginning clinicians to understand. Although the clinician can apply masking formulas and procedures appropriately in most clinical situations, a lack of understanding of the underlying theoretical constructs becomes evident during cases where modification of a standard procedure is required. A lack of understanding of the underlying concepts of masking often leads to misuse of clinical procedures.

Theoretical and empirical bases of masking provide a strong foundation for the understanding of applied clinical masking procedures. It will become evident throughout this chapter that there is not a single “correct” approach to clinical masking. Any approach to clinical masking that is based on sound theoretical constructs and verified through clinical experience is correct. One approach will not meet all clinical needs. A strong foundation in the underlying concepts of clinical masking serves three purposes. First, it allows the clinician to make correct decisions about the need for masking. Second, it allows the clinician to make a well-informed decision when selecting a specific approach to clinical masking. Finally, it allows the clinician to apply and modify a clinical masking procedure appropriately.

THE NEED FOR MASKING

A major objective of the basic audiologic evaluation is assessment of auditory function of each ear. There are situations during both air-conduction and bone-conduction testing when this may not occur. Although a puretone or speech stimulus is being presented through a transducer to the test ear, the nontest ear can contribute partially or totally to the observed response. Whenever it is suspected that the nontest ear is responsive during evaluation of the test ear,

a masking stimulus must be applied to the nontest ear to eliminate its participation.

Air-Conduction Testing

Cross hearing occurs when a stimulus presented to the test ear “crosses over” and is perceived in the nontest ear. There are two parallel pathways by which sound presented through an earphone (i.e., an air-conduction transducer) can reach the nontest ear. Specifically, there are both bone-conduction and air-conduction pathways between an air-conduction signal presented at the test ear and the sound reaching the nontest ear cochlea (Studebaker, 1979). First, the earphone can vibrate with sufficient force to cause deformations of the bones of the skull. An earphone essentially can function as a bone vibrator at higher sound pressures. Because both cochleas are housed within the same skull, the outcome is stimulation of the nontest ear cochlea through bone conduction. Second, sound from the test earphone can travel around the head to the nontest ear, enter the opposite ear canal, and finally reach the nontest ear cochlea through an air-conduction pathway. Because the opposite ear typically is covered during air-conduction testing, sound attenuation provided by the earphone will greatly minimize or eliminate the contribution of the air-conduction pathway to the process of cross hearing. Consequently, cross hearing during air-conduction testing is considered primarily a bone-conduction mechanism.

Cross hearing is the result of limited interaural attenuation (IA). IA refers to the “reduction of energy between ears.” Generally, it represents the amount of separation or the degree of isolation between ears during testing. Specifically, it is the decibel difference between the hearing level (HL) of the signal at the test ear and the HL reaching the nontest ear:

$$IA = \text{dBHL}_{\text{Test Ear}} - \text{dBHL}_{\text{Nontest Ear}}$$

Consider the following hypothetical examples presented in Figure 6.1. You are measuring puretone air-conduction threshold using traditional supra-aural earphones. A puretone signal of 90 dB HL is presented to the test ear. Because of limited IA, a portion of the test signal can

FIGURE 6.1 Interaural attenuation (IA) is calculated as the difference between the hearing level (HL) of the signal at the test ear and the HL reaching the nontest ear cochlea. A puretone signal of 90 dB HL is being presented to the test ear through traditional supra-aural earphones. **Example A:** If IA is 40 dB, then 50 dB HL is reaching the nontest ear cochlea. **Example B:** If IA is 80 dB, then 10 dB HL is reaching the nontest ear cochlea. [From Yacullo WS. [1996] *Clinical Masking Procedures*. 1st ed. Boston, MA: Allyn & Bacon, © 1996, p 3. Adapted by permission of Pearson Education, Inc., Upper Saddle River, NJ.]

reach the nontest ear cochlea. If IA is 40 dB, then 50 dB HL theoretically is reaching the nontest ear:

$$\begin{aligned} \text{IA} &= \text{dB HL}_{\text{Test Ear}} - \text{dB HL}_{\text{Nontest Ear}} \\ &= 90 \text{ dB HL} - 50 \text{ dB HL} \\ &= 40 \text{ dB} \end{aligned}$$

If IA is 80 dB, then only 10 dB HL is reaching the nontest ear. It should be apparent that a greater portion of the test signal can reach the nontest ear when IA is small. Depending on the hearing sensitivity in the nontest ear, cross hearing can occur.

IA during earphone testing is dependent on three factors: Transducer type, frequency spectrum of the test signal, and individual subject. There are three major types of earphones currently used during audiologic testing: Supra-aural, circumaural, and insert (American National Standards Institute/Acoustical Society of America [ANSI/ASA], 2010). Supra-aural earphones use a cushion that makes contact solely with the pinna. Circumaural earphones use a cushion that encircles or surrounds the pinna, making

contact with the skin covering the cranial skull. Insert earphones are coupled to the ear by insertion into the ear canal.

Generally, IA increases as the contact area of the transducer with the skull decreases (Zwislocki, 1953). More specifically, IA is greater for supra-aural than circumaural earphones. Furthermore, IA is greatest for insert earphones (Killion et al., 1985; Sklare and Denenberg, 1987), partly because of their smaller contact area with the skull. (The reader is referred to Killion and Villchur, 1989; Zwislocki et al., 1988, for a review of advantages and disadvantages of earphones in audiometry.) Because supra-aural and insert earphones are most typically used during audiologic testing, they will be the focus of this discussion.

There are different approaches to measuring IA for air-conducted sound (e.g., “masking” method, “compensation” method, method of “best beats”; the reader is referred to Zwislocki, 1953, for discussion). The most direct approach, however, involves measurement of transcranial thresholds (Berrett, 1973). Specifically, IA is measured by obtaining unmasked air-conduction (AC) thresholds in subjects with unilateral, profound sensory/neural hearing loss and then calculating the threshold difference between the normal and impaired ears:

$$\text{IA} = \text{Unmasked AC}_{\text{Impaired Ear}} - \text{Unmasked AC}_{\text{Normal Ear}}$$

For example, if unmasked air-conduction thresholds are obtained at 60 dB HL in the impaired ear and 0 dB HL in the normal ear, then IA is calculated as 60 dB:

$$\begin{aligned} \text{IA} &= 60 \text{ dB HL} - 0 \text{ dB HL} \\ &= 60 \text{ dB} \end{aligned}$$

There is the assumption that air- and bone-conduction thresholds are equal (i.e., no air-bone gaps) in the ear with normal hearing.

Figure 6.2 illustrates the expected *unmasked* puretone air-conduction thresholds in an individual with normal hearing in the left ear and a profound sensory/neural hearing loss in the right ear. Unmasked bone-conduction thresholds, regardless of bone vibrator placement, are expected at HLs consistent with normal hearing in the left ear. If appropriate contralateral masking is not used during air-conduction testing, then a shadow curve will result in the right ear. Because cross hearing is primarily a bone-conduction mechanism, unmasked air-conduction thresholds in the right ear will “shadow” the bone-conduction thresholds in the left (i.e., better) ear by the amount of IA. For example, if IA for air-conducted sound is equal to 60 dB at all frequencies, then unmasked air-conduction thresholds in the right ear theoretically will be measured 60 dB above the bone-conduction thresholds in the better ear. The shadow curve does not represent true hearing thresholds in the right ear. Rather, it reflects cross-hearing responses from the better (i.e., left) ear.

When using supra-aural earphones, IA for puretone air-conducted signals varies considerably, particularly across

FIGURE 6.2 Expected unmasked puretone air- and bone-conduction thresholds in an individual with normal hearing in the left ear and a profound sensory/neural hearing loss in the right ear. Without the use of appropriate contralateral masking, a *shadow curve* will result in the right ear. Unmasked air-conduction thresholds in the better (i.e., left) ear will shadow the bone-conduction thresholds in the better (i.e., left) ear by the amount of interaural attenuation. [From Yacullo WS. (1996) *Clinical Masking Procedures*. 1st ed. Boston, MA: Allyn & Bacon, © 1996, p 7. Adapted by permission of Pearson Education, Inc., Upper Saddle River, NJ.]

subjects, ranging from about 40 to 85 dB (Berrett, 1973; Chaiklin, 1967; Coles and Priede, 1970; Killion et al., 1985; Sklare and Denenberg, 1987; Smith and Markides, 1981; Snyder, 1973). Your assumption about IA will influence the decision about the need for contralateral masking. The use of a smaller IA value assumes that there is smaller separation between ears. Consequently, contralateral masking will be required more often. When making a decision about the need for contralateral masking during clinical practice, a single value defining the lower limit of IA is recommended (Studebaker, 1967a).

Based on currently available data, a conservative estimate of IA for supra-aural earphones is 40 dB at all frequencies.

Although this very conservative estimate will take into account the IA characteristics of all individuals, it will result in the unnecessary use of masking in some instances.

Commonly used insert earphones are the Etymotic Research ER-3A (Killion, 1984) and the E-A-RTONE 3A (E-A-R Auditory Systems, 1997). The ER-3A and the E-A-RTONE 3A insert earphones are considered functionally equivalent because they are built to identical specifications (Frank and Vavrek, 1992). Each earphone consists of a shoulder-mounted transducer, a plastic sound tube of spec-

ified length, a nipple adaptor, and a disposable foam eartip. A major advantage of the 3A insert earphone is increased IA for air-conducted sound, particularly in the lower frequencies (Hosford-Dunn et al., 1986; Killion et al., 1985; Sklare and Denenberg, 1987; Van Campen et al., 1990). This is clearly illustrated in the results of a study by Killion et al. (1985) (Figure 6.3).

Increased IA with 3A insert earphones is the result of two factors: (1) Reduced contact area of the transducer with the skull and (2) reduction of the occlusion effect (OE). Zwislocki (1953) evaluated IA for three types of earphones: circumaural, supra-aural, and insert. Results suggested that IA for air-conducted sound increased as the contact area of the earphone with the skull decreased. When an acoustic signal is delivered through an earphone, the resultant sound pressure acts over a surface area of the skull determined by the earphone cushion. The surface area associated with a small eartip will result in a smaller applied force to the skull, resulting in reduced bone-conduction transmission.

Chaiklin (1967) has also suggested that IA may be increased in the low frequencies with a deep insert because of a reduction of the OE. ANSI/ASA (2010) defines the OE as an increase in loudness for bone-conducted sound at

FIGURE 6.3 Average and range of interaural attenuation values obtained on six subjects using two earphones: TDH-39 encased in MX-41/AR supra-aural cushion (●) and ER-3A insert earphone with deeply inserted foam eartip (■). [From Killion MC, Wilber LA, Gudmundsen GI. (1985) Insert earphones for more interaural attenuation. *Hear Instrum.* 36, 34, 36. frequencies below 2,000 Hz when the outer ear is covered or occluded. There is evidence that the OE influences the measured IA for air-conducted sound (e.g., Berrett, 1973; Chaiklin, 1967; Feldman, 1963; Killion et al., 1985; Littler et al., 1952; Van Campen et al., 1990; Zwislocki, 1953). In fact, there is an inverse relationship between magnitude of the OE and the measured IA in the lower frequencies. Specifically, an earphone that reduces the OE will exhibit increased IA for air-conducted sound. Recall that cross hearing occurs primarily through the mechanism of bone conduction. When the nontest ear is covered or occluded by an air-conduction transducer, the presence of an OE will enhance hearing sensitivity for bone-conducted sound in that ear. Consequently, the separation between ears (i.e., IA) is reduced. The increased IA for air-conducted sound observed in the lower frequencies when using 3A insert earphones (with deeply inserted foam eartips) is primarily related to the significant reduction or elimination of the OE. The OE is presented in greater detail later in this chapter in the section on clinical masking procedures during bone-conduction audiometry.

If increased IA is a primary goal when selecting an insert earphone, then the 3A is the transducer of choice. Evidence suggests that the 3A insert earphone provides significantly greater IA, particularly in the lower frequencies, than

the “button” transducer (Blackwell et al., 1991; Hosford-Dunn et al., 1986). Blackwell et al. (1991) compared the IA obtained with a standard supra-aural earphone (TDH-50P) and a button transducer fitted with a standard immittance probe cuff. Although greater IA was observed with the button transducer, the difference between the insert and supra-aural earphone did not exceed 10 dB at any frequency.

There are only limited data available regarding IA of 3A insert earphones using deeply or intermediately inserted foam eartips. IA values vary across subjects and frequency, ranging from about 75 to 110 dB at frequencies of $\leq 1,000$ Hz and about 50 to 95 dB at frequencies $> 1,000$ Hz (Killion et al., 1985; Sklare and Denenberg, 1987; Van Campen et al., 1990). Based on Studebaker’s (1967a) recommendation, we will again use the smallest IA values reported when making a decision about the need for contralateral masking. To take advantage of the significantly increased IA proved by the 3A insert in the lower frequencies, a single value of IA will not be employed across the frequency range.

Based on currently available data, conservative estimates of IA for 3A insert earphones with deeply inserted foam eartips are 75 dB at $\leq 1,000$ Hz and 50 dB at frequencies $> 1,000$ Hz.

The IA values recommended clinically for 3A earphones assume that deeply inserted foam eartips are used. Maximum IA is achieved in the low frequencies when a deep eartip insertion is used (Killion et al., 1985). The recommended deep insertion depth is achieved when the outer edge of the eartip is 2 to 3 mm inside the entrance of the ear canal. Conversely, a shallow insertion is obtained when the outer edge of the eartip protrudes from the entrance of the ear canal (E-A-R Auditory Systems, 1997). An intermediate insertion is achieved when the outer edge of the eartip is flush with the opening of the ear canal (Van Campen et al., 1990). There are limited data suggesting that IA is similar for either intermediate or deep insertion of the foam eartip. However, a shallow insertion appears to significantly reduce IA (Killion et al., 1985; Sklare and Denenberg, 1987; Van Campen et al., 1990). Remember that a major factor contributing to superior IA of the 3A insert earphone is a significantly reduced OE. There is evidence that the OE is negligible when using either deeply or intermediately inserted insert earphones. In fact, the advantage of a greatly reduced OE is lost when a shallow insertion is used (Berger and Kerivan, 1983). To achieve maximum IA with 3A insert earphones, deeply inserted eartips are strongly recommended.

More recently, E-A-R Auditory Systems (2000a, 2000b) introduced a next-generation insert earphone, the E-ARTONE 5A. The lengthy plastic sound tube that conducted sound from the body-level transducer of the 3A has been eliminated in the 5A model; rather, the foam eartip is coupled directly to an ear-level transducer. Very limited data obtained with only two subjects (unpublished research by Killion, 2000, as cited in E-A-R Auditory Systems, 2000b) suggest that the average IA for puretone stimuli ranging from 250 to 4,000 Hz is equivalent (within approximately

5 dB) to the average values reported for the 3A insert earphone (Killion et al., 1985).

IA for speech is typically measured by obtaining speech recognition thresholds (SRTs) in individuals with unilateral, profound sensory/neural hearing loss. Specifically, the difference in threshold between the normal ear and impaired ear without contralateral masking is calculated:

$$IA = \text{Unmasked SRT}_{\text{Impaired Ear}} - \text{SRT}_{\text{Normal Ear}}$$

Recall that SRT represents the lowest HL at which speech is recognized 50% of the time (ANSI/ASA, 2010; American Speech-Language-Hearing Association [ASHA], 1988). IA for spondaic words presented through supra-aural earphones varies across subjects and ranges from 48 to 76 dB (Martin and Blythe, 1977; Sklare and Denenberg, 1987; Snyder, 1973). Again, a single value defining the lower limit of IA is recommended when making a decision about the need for contralateral masking (Studebaker, 1967a). A conservative estimate of IA for spondees, therefore, is 45 dB when using supra-aural earphones (Konkle and Berry, 1983). The majority of audiologists measure SRT using a 5-dB step size (Martin et al., 1998). Therefore, the IA value of 48 dB is typically rounded down to 45 dB.

There is considerable evidence that speech can be detected at a lower HL than that required to reach SRT. Speech detection threshold (SDT) is defined as the lowest HL at which speech can be detected or “discerned” 50% of the time (ASHA, 1988). The SRT typically requires an average of about 8 to 9 dB greater HL than that required for the detection threshold (Beattie et al., 1978; Chaiklin, 1959; Thurlow et al., 1948). Given this relationship between the two speech thresholds, Yacullo (1996) has suggested that a more conservative value of IA may be appropriate when considering the need for contralateral masking during measurement of SDT.

Consider the following hypothetical example. You are measuring speech thresholds in a patient with normal hearing in the right ear and a profound, sensory/neural hearing loss in the left ear. If the patient exhibits the minimum reported IA value for speech of 48 dB, then an SRT of 0 dB HL would be measured in the right ear and an *unmasked* SRT of 48 dB HL would be measured in the left ear. If an unmasked SDT is subsequently measured in the left ear, it is predicted that the threshold would occur at an HL of about 8 to 9 dB lower than the unmasked SRT. An unmasked SDT would be expected to occur at about 39 to 40 dB HL. Comparison of the unmasked SDT in the impaired ear with the SRT in the normal ear theoretically would result in measured IA of approximately 39 to 40 dB. When an unmasked SDT is measured and the response is compared to the SRT in the nontest ear, a more conservative estimate of IA for speech may be appropriate.

It should be noted that the actual IA for speech does not change during measurement of speech detection and rec-

ognition thresholds. Rather, a different response task when measuring *different* speech thresholds in each ear (i.e., SDT in one ear and SRT in the other) can affect the measured IA for speech. Comparison of SRTs between ears or SDTs between ears generally should result in the same measured IA. Smith and Markides (1981) measured IA for speech in 11 subjects with unilateral, profound hearing loss. IA was calculated as the difference between the SDT in the better ear and the unmasked SDT in the poorer ear. The range of IA values was 50 to 65 dB. It is interesting to note that the lowest IA value reported for speech using a detection task in each ear was 50 dB, a value comparable to the lowest minimum reported IA value (i.e., 48 dB) for spondaic words (e.g., Martin and Blythe, 1977; Snyder, 1973).

There is also some evidence that it may be appropriate to use a more conservative estimate of IA when making a decision about the need for contralateral masking during assessment of suprathreshold speech recognition. Although IA for the speech signal remains constant during measurement of threshold or suprathreshold measures of speech recognition (i.e., the decibel difference between the level of the speech signal at the test ear and the level at the nontest ear cochlea), differences in the performance criterion for each measure must be taken into account when selecting an appropriate IA value for clinical use. SRT is defined relative to a 50% response criterion. However, suprathreshold speech recognition performance can range from 0% to 100%.

Konkle and Berry (1983) provide an excellent rationale for the use of a more conservative estimate of IA when measuring suprathreshold speech recognition. They suggest that the fundamental difference in percent correct criterion requires the specification of nontest ear cochlear sensitivity in a different way than that used for threshold measurement. If suprathreshold speech recognition materials are presented at an HL equal to the SRT, then a small percentage of the test items can be recognized. It should be noted that the percentage of test words that can be recognized at an HL equal to SRT is dependent on the type of speech stimuli, as well as on the talker and/or recorded version of a speech recognition test. Regardless of the type of speech stimulus (e.g., meaningful monosyllabic words, nonsense syllables, or sentences) and the specific version (i.e., talker/recording) of a speech recognition test, 0% performance may not be established until an HL of about -10 dB relative to the SRT. Konkle and Berry (1983) recommend that the value of IA used for measurement of suprathreshold speech recognition should be estimated as 35 dB. That is, the IA value of 45 dB (rounded down from 48 dB) based on SRT measurement is adjusted by subtracting 10 dB. This adjustment in the estimate of IA reflects differences in percent correct criterion used for speech threshold and suprathreshold measurements.

The majority of audiologists use an IA value of 40 dB for all air-conduction measurements, both puretone and

speech, when making a decision about the need for contralateral masking (Martin et al., 1998). The use of a single IA value of 40 dB for both threshold and suprathreshold speech audiometric measurements can be supported. Given the smallest reported IA value of 48 dB for spondaic words, a value of 40 dB is somewhat too conservative during measurement of SRT. However, it should prove adequate during measurement of SDT and suprathreshold speech recognition when a more conservative estimate of IA (by approximately 10 dB) may be appropriate.

Unfortunately, there are only very limited data available about IA for speech when using insert earphones. Sklare and Denenberg (1987) reported IA for speech (i.e., SRT using spondaic words) in seven adults with unilateral, profound sensory/neural hearing loss using ER-3A insert earphones. IA ranged from 68 to 84 dB. It should be noted that the smallest reported value of IA for spondaic words (i.e., 68 dB) is 20 dB greater when using 3A insert earphones with deeply inserted foam eartips (Sklare and Denenberg, 1987) than when using supra-aural earphones (i.e., 48 dB) (Martin and Blythe, 1977; Snyder, 1973). Therefore, a value of 60 dB represents a very conservative estimate of IA for speech when using 3A insert earphones. This value is derived by adding a correction factor of 20 dB to the conservative IA value used with supra-aural earphones (i.e., 40 dB) for all threshold and suprathreshold measures of speech.

Based on currently available data, conservative estimates of IA for all threshold and suprathreshold measures of speech are 40 dB for supra-aural earphones and 60 dB for 3A insert earphones with deeply inserted foam eartips.

Bone-Conduction Testing

There are two possible locations for placement of a bone vibrator (typically, the Radioear B-71) during puretone threshold audiometry: The mastoid process of the temporal bone and the frontal bone (i.e., the forehead). Although there is some evidence that a forehead placement produces more reliable and valid thresholds than a mastoid placement (see Dirks, 1994, for further discussion), the majority (92%) of audiologists in the United States continue to place a bone-conduction transducer on the mastoid process (Martin et al., 1998).

IA is greatly reduced during bone-conduction audiometry. IA for bone-conducted sound when using a bone vibrator placed at the forehead is essentially 0 dB at all frequencies; IA when using a mastoid placement is approximately 0 dB at 250 Hz and increases to about 15 dB at 4,000 Hz (Studebaker, 1967a). Regardless of the placement of a bone vibrator (i.e., mastoid vs. forehead), it is generally agreed that IA for bone-conducted sound at all frequencies is negligible and should be considered 0 dB (e.g., Dirks, 1994; Hood, 1960; Sanders and Rintelmann, 1964; Studebaker, 1967a). When a bone vibrator, regardless of its location, sets the bones of the skull

into vibration, both cochleas can be potentially stimulated. Consequently, an unmasked bone-conduction threshold can reflect a response from either cochlea or perhaps both. Although a bone vibrator may be placed at the side of the test ear, it cannot be assumed that the observed response is in fact from that ear.

Consider the following example. You have placed a bone vibrator at the right mastoid process. A puretone signal of 50 dB HL is presented. If IA is considered to be 0 dB, then it should be assumed that a signal of 50 dB HL is potentially reaching both cochleas. It should be apparent that there is essentially no separation between the two cochleas during unmasked bone-conduction audiometry.

Based on currently available data, a conservative estimate of IA for bone-conducted sound is 0 dB at all frequencies.

WHEN TO MASK

Contralateral masking is required whenever there is the possibility that the test signal can be perceived in the nontest ear. IA is one of the major factors that will be considered when evaluating the need for masking. The basic principles underlying the decision-making processes of when to mask during puretone and speech audiometry will now be addressed.

Puretone Audiometry: Air Conduction

When making a decision about the need for masking during puretone air-conduction testing, three factors need to be considered: (1) IA, (2) unmasked air-conduction threshold in the test ear (i.e., HL at the test ear), and (3) bone-conduction hearing sensitivity (i.e., threshold) in the nontest ear. Recall that when cross hearing occurs, the nontest ear is stimulated primarily through the bone-conduction mechanism. When a decision is made about the need for contralateral masking, the unmasked air-conduction threshold in the test ear ($AC_{\text{Test Ear}}$) is compared to the bone-conduction threshold in the nontest ear ($BC_{\text{Nontest Ear}}$). If the difference between ears equals or exceeds IA, then air-conduction threshold in the test ear must be remeasured using contralateral masking. The rule for when to mask during puretone air-conduction testing can be stated as follows:

Contralateral masking is required during puretone air-conduction audiometry when the unmasked air-conduction threshold in the test ear equals or exceeds the apparent bone-conduction threshold (i.e., the unmasked bone-conduction threshold) in the nontest ear by a conservative estimate of IA:

$$AC_{\text{Test Ear}} - BC_{\text{Nontest Ear}} \geq IA$$

This rule is consistent with the guidelines for manual puretone threshold audiometry recommended by ASHA (2005).

FIGURE 6.4 Audiogram illustrating the need for contralateral masking during puretone air-conduction audiometry. See text for discussion.

Note that the term “apparent” bone-conduction threshold is considered when making a decision about the need for masking. Remember that an unmasked bone-conduction threshold does not convey ear-specific information. It is assumed that the bone-conduction response can originate from either or both ears. Therefore, the unmasked bone-conduction response is considered the apparent or possible threshold for either ear.

Consider the unmasked puretone audiogram* presented in Figure 6.4. Because IA for bone-conducted sound is considered 0 dB, unmasked bone-conduction thresholds are traditionally obtained at only one mastoid process. During air-conduction threshold testing, the potential for cross hearing is greatest when there is a substantial difference in hearing sensitivity between the two ears and when a stimulus is presented at higher HLs to the poorer ear. Consequently, there is greater potential for cross hearing when measuring puretone thresholds in the right ear.

*The puretone audiogram and audiometric symbols used throughout this chapter are those recommended in ASHA’s (1990) most recent guidelines for audiometric symbols (see Chapter 3).

First consider the need for contralateral masking assuming that air-conduction thresholds were measured using supra-aural earphones. A conservative estimate of IA is 40 dB. We will use the following equation when making a decision about the need for contralateral masking:

$$AC_{\text{Test Ear}} - BC_{\text{Nontest Ear}} \geq IA$$

Because it is not possible to measure bone-conduction threshold at 8,000 Hz, it is necessary to predict an unmasked threshold given the findings at other test frequencies. In this particular example, unmasked bone-conduction threshold at 8,000 Hz will probably have a similar relationship with the air-conduction thresholds in the better (i.e., left) ear. Because there is no evidence of air-bone gaps at the adjacent high frequencies, we will assume that a similar relationship exists at 8,000 Hz. Therefore, our estimate of unmasked bone-conduction threshold is 45 dB HL.

It will be necessary to remeasure puretone thresholds at all test frequencies in the right ear using contralateral masking because the difference between ears equals or exceeds our estimate of IA.

Right Ear (Test Ear)		Masking Needed?
250 Hz	55-0 ≥40?	Yes
500 Hz	60-5 ≥40?	Yes
1,000 Hz	80-25 ≥40?	Yes
2,000 Hz	90-30 ≥40?	Yes
4,000 Hz	95-40 ≥40?	Yes
8,000 Hz	100-45 ≥40?	Yes

However, contralateral masking is not required when testing the left ear. The difference between ears does not equal or exceed the estimate of IA.

Left Ear (Test Ear)		Masking Needed?
250 Hz	20-0 ≥40?	No
500 Hz	25-5 ≥40?	No
1,000 Hz	30-25 ≥40?	No
2,000 Hz	35-30 ≥40?	No
4,000 Hz	40-40 ≥40?	No
8,000 Hz	45-45 ≥40?	No

Many audiologists will obtain air-conduction thresholds prior to measurement of bone-conduction thresholds. A preliminary decision about the need for contralateral masking can be made by comparing the air-conduction thresholds of the two ears.

Contralateral masking is required during puretone air-conduction audiometry when the unmasked air-conduction threshold in the test ear ($AC_{Test Ear}$) equals or exceeds the air-conduction threshold in the nontest ear ($AC_{Nontest Ear}$) by a conservative estimate of IA:

$$AC_{Test Ear} - AC_{Nontest Ear} \geq IA$$

It is important to remember, however, that cross hearing for air-conducted sound occurs primarily through the mechanism of bone conduction. Consequently, it will be necessary to re-evaluate the need for contralateral masking during air-conduction testing following the measurement of unmasked bone-conduction thresholds.

Consider again the audiogram presented in Figure 6.4. Let us assume that we have not yet measured unmasked bone-conduction thresholds. We can make a preliminary decision about the need for contralateral masking by considering the difference between air-conduction thresholds in the two ears. Based on the air-conduction responses only, it appears that contralateral masking is needed only when testing the right ear at octave frequencies from 1,000 through 8,000 Hz. Yet, once unmasked bone-conduction thresholds are measured, it becomes apparent that contralateral masking will also be required when testing the right ear at 250 and 500 Hz.

It is conventional to obtain air-conduction thresholds prior to bone-conduction thresholds. However, an alternative (and recommended) approach involves obtaining

unmasked bone-conduction thresholds before obtaining unmasked air-conduction thresholds. Decisions about the need for masking during air-conduction testing then can be made using the important bone-conduction responses.

3A insert earphones are often substituted for the supra-aural configuration during audiometric testing. We now will take a second look at the audiogram in Figure 6.4 and assume that air-conduction thresholds were obtained with 3A insert earphones. Recall that conservative estimates of IA for 3A insert earphones with deeply inserted foam eartips are 75 dB at ≤1,000 Hz and 50 dB at frequencies >1,000 Hz. Previously, we determined that contralateral masking was not required when testing the better (i.e., left) ear using supra-aural earphones. Given the greater IA offered by 3A insert earphones, it is easy to understand that contralateral masking again should not be required when testing the left ear. However, a different picture results when considering the need for contralateral masking when testing the right ear.

Right Ear (Test Ear)		Masking Needed?
250 Hz	55-0 ≥75?	No
500 Hz	60-5 ≥75?	No
1,000 Hz	80-25 ≥75?	No
2,000 Hz	90-30 ≥50?	Yes
4,000 Hz	95-40 ≥50?	Yes
8,000 Hz	100-45 ≥50?	Yes

Because of the greater IA provided by 3A insert earphones in the lower frequencies, the need for contralateral masking is eliminated at 250, 500, and 1,000 Hz. It should be apparent that the process of evaluating the need for contralateral masking when using either supra-aural or insert earphones is the same. The only difference is the substitution of different values of IA in our equations.

Puretone Audiometry: Bone Conduction

Remember that a conservative estimate of IA for bone-conducted sound is 0 dB. Theoretically, masked bone-conduction measurements are always required if ear-specific information is needed. However, given the goal of bone-conduction audiometry, contralateral masking is not always required. Generally, bone-conduction thresholds are primarily useful for determining gross site of lesion (i.e., conductive, sensory/neural, or mixed). The presence of air-bone gaps suggests a conductive component to a hearing loss.

The major factor to consider when making a decision about the need for contralateral masking during bone-conduction audiometry is whether the unmasked bone-conduction threshold (Unmasked BC) suggests the presence of a significant conductive component in the test ear.

The use of contralateral masking is indicated whenever the results of unmasked bone-conduction audiometry suggest

the presence of an air-bone gap in the test ear (*Air-Bone Gap_{Test Ear}*) of 15 dB or greater:

$$\text{Air-Bone Gap}_{\text{Test Ear}} \geq 15 \text{ dB}$$

where

$$\text{Air-Bone Gap} = \text{AC}_{\text{Test Ear}} - \text{Unmasked BC}$$

ASHA (2005) recommends that contralateral masking should be used whenever a potential air-bone gap of 10 dB or greater exists. When taking into account the variability inherent in bone-conduction measurements (Studebaker, 1967b), however, a criterion of 10 dB may be too stringent. There is a certain degree of variability between air- and bone-conduction threshold, even in individuals without conductive hearing loss. If we assume that there is a nor-

mal distribution of the relationship between air- and bone-conduction thresholds in individuals without significant air-bone gaps, then an air-bone difference of ± 10 dB is not unexpected.

If unmasked bone-conduction thresholds suggest air-bone gaps of 10 dB or less, then contralateral masking is not required. Although unmasked bone-conduction thresholds do not provide ear-specific information, we have accomplished our goal for bone-conduction testing. If unmasked bone-conduction thresholds suggest no evidence of significant air-bone gaps, then we have ruled out the presence of a significant conductive component. Consequently, our assumption is that the hearing loss is sensory/neural in nature.

Figure 6.5 provides three examples of the need for contralateral masking during bone-conduction audiometry.

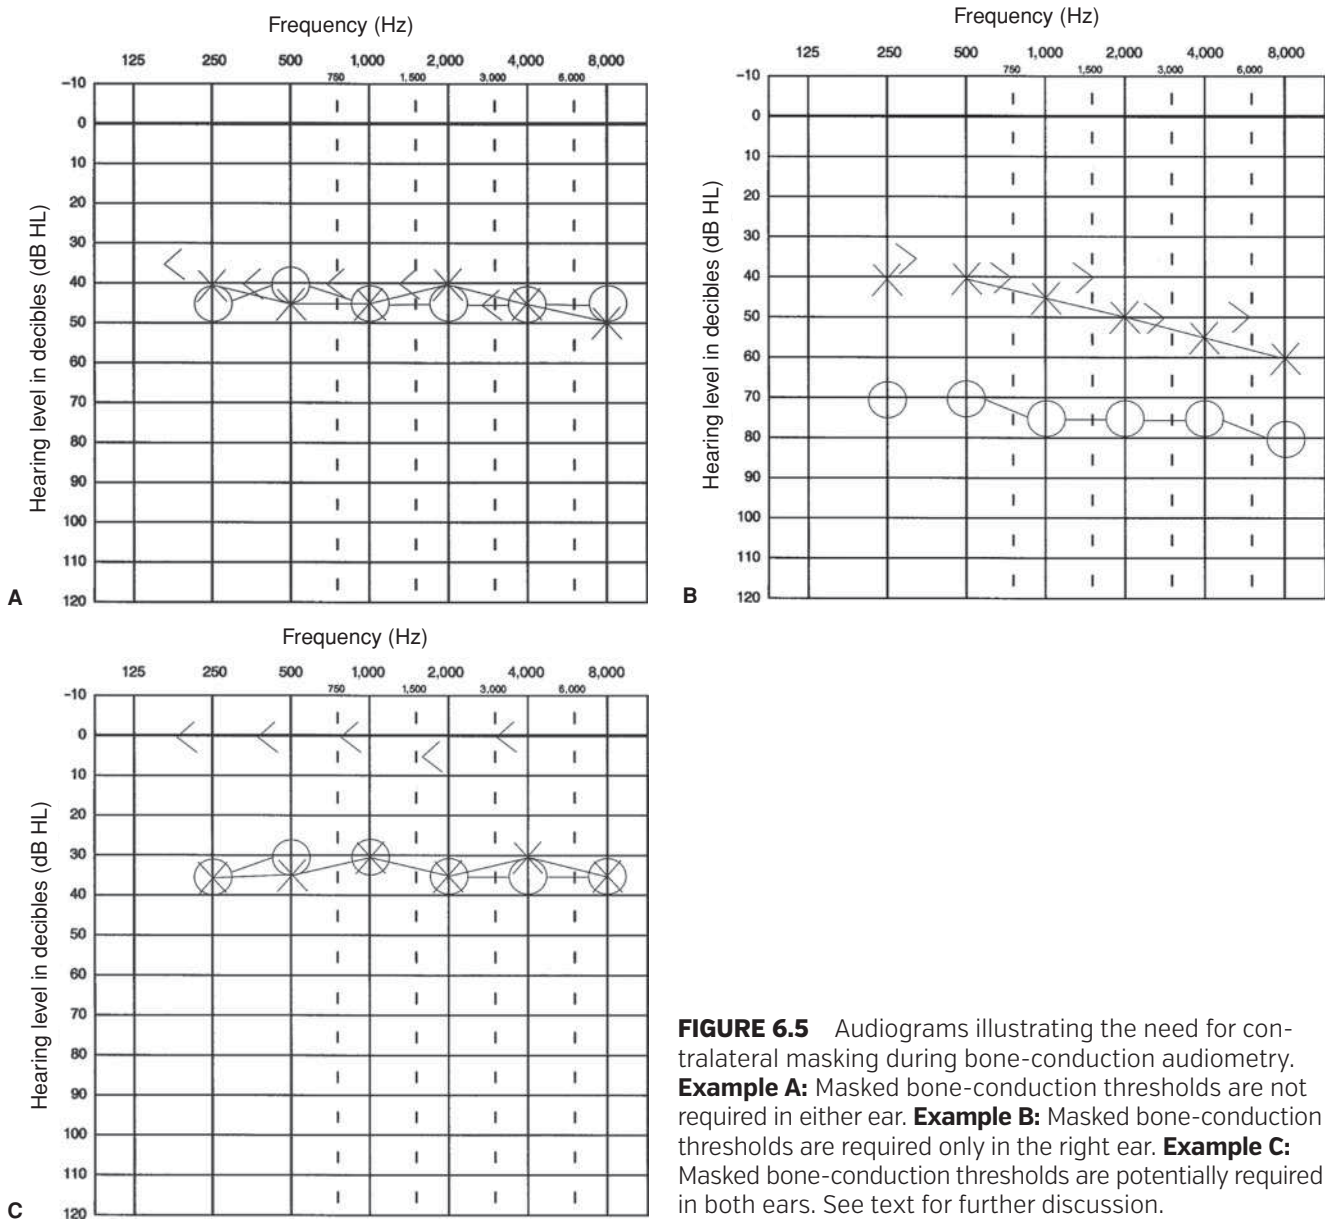

FIGURE 6.5 Audiograms illustrating the need for contralateral masking during bone-conduction audiometry. **Example A:** Masked bone-conduction thresholds are not required in either ear. **Example B:** Masked bone-conduction thresholds are required only in the right ear. **Example C:** Masked bone-conduction thresholds are potentially required in both ears. See text for further discussion.

Unmasked air- and bone-conduction thresholds are provided in each case.

Example A. Contralateral masking is not required during bone-conduction testing in either ear. When we compare the unmasked bone-conduction thresholds to the air-conduction thresholds in each ear, there are no potential air-bone gaps of 15 dB or greater. For example, consider the thresholds at 2,000 Hz. Comparison of the unmasked bone-conduction threshold to the air-conduction thresholds suggests a potential air-bone gap of 5 dB in the right ear and 0 dB in the left ear. Because the unmasked bone-conduction threshold does not suggest the presence of significant air-bone gaps in either ear, our conclusion is that the hearing loss is sensory/neural bilaterally. Obtaining masked bone-conduction thresholds, although they would provide ear-specific information, would not provide additional diagnostic information.

Example B. Comparison of unmasked bone-conduction thresholds to the air-conduction thresholds in the left ear does not suggest the presence of significant air-bone gaps. Consequently, masked bone-conduction thresholds are not required in the left ear. Our conclusion is that the hearing loss is sensory/neural.

However, masked bone-conduction thresholds will be required in the right ear. Comparison of unmasked bone-conduction thresholds to the air-conduction thresholds in the right ear suggests potential air-bone gaps ranging from 25 to 35 dB. The unmasked bone-conduction thresholds may reflect hearing in the better (i.e., left) ear. Bone-conduction thresholds in the right ear may be as good as the unmasked responses. They also may be as poor as the air-conduction thresholds in that ear. Because we do not have ear-specific information for bone-conduction thresholds, the loss in the right ear can be either mixed or sensory/neural. To make a definitive statement about the type of hearing loss, it will be necessary to obtain masked bone-conduction thresholds in the right ear.

Example C. There is evidence that contralateral masking will be required when measuring bone-conduction thresholds in both ears. Comparison of unmasked bone-conduction thresholds to the air-conduction thresholds suggests potential air-bone gaps ranging from 30 to 35 dB in each ear. As in the previous example, bone-conduction thresholds in each ear may be as good as the unmasked responses. They may also be as poor as the air-conduction thresholds in that ear. To make a definitive statement about the type of hearing loss, it will be necessary to obtain masked bone-conduction thresholds in both ears.

Speech Audiometry

Because speech audiometry is an air-conduction procedure, the rules for when to mask will be similar to those used during puretone air-conduction audiometry. There are three factors to consider when making a decision about the need

for contralateral masking during speech audiometry: (1) IA, (2) presentation level of the speech signal (in dB HL) in the test ear, and (3) bone-conduction hearing sensitivity (i.e., threshold) in the nontest ear.

Contralateral masking is indicated during speech audiometry whenever the presentation level of the speech signal (in dB HL) in the test ear ($Presentation\ Level_{Test\ Ear}$) equals or exceeds the best puretone bone-conduction threshold in the nontest ear ($Best\ BC_{Nontest\ Ear}$) by a conservative estimate of IA:

$$Presentation\ Level_{Test\ Ear} - Best\ BC_{Nontest\ Ear} \geq IA$$

Because speech is a broadband signal, it is necessary to consider bone-conduction hearing sensitivity at more than a single puretone frequency. Konkle and Berry (1983) and Sanders (1991) recommend the use of the bone-conduction puretone average of 500, 1,000, and 2,000 Hz or some other average that is predictive of the SRT. ASHA (1988) recommends that the puretone bone-conduction thresholds at 500, 1,000, 2,000, and 4,000 Hz should be considered. Martin and Blythe (1977) suggest that 250 Hz can be eliminated from any formula for determining the need for contralateral masking when measuring the SRT. Yet, the nontest ear bone-conduction threshold at 250 Hz may be an important consideration when measuring the SDT. Olsen and Matkin (1991) state that the SDT may be most closely related to the best threshold in the 250 to 4,000 Hz range when audiometric configuration steeply rises or slopes. Therefore, following the recommendation of Coles and Priede (1975), the most conservative approach involves considering the best bone-conduction threshold in the 250- to 4,000-Hz frequency range.

The examples presented in Figures 6.6 and 6.7 illustrate the need for contralateral masking during threshold and suprathreshold speech audiometry, respectively. First consider the audiogram presented in Figure 6.6. Audiometry was performed using supra-aural earphones. Puretone testing (using appropriate contralateral masking during both air- and bone-conduction audiometry) reveals a severe-to-profound, sensory/neural hearing loss of gradually sloping configuration in the right ear. There is a very mild, sensory/neural hearing loss of relatively flat configuration in the left ear. Given the difference between ears observed during puretone audiometry, it is anticipated that contralateral masking may be needed during assessment of SRT in the poorer ear.

There are different approaches that can be used when determining the need for contralateral masking during measurement of SRT. The most efficient and recommended approach involves predicting the speech threshold using the puretone threshold data in the poorer ear and, on that basis, determining the need for contralateral masking. For example, SRT is measured at 20 dB HL in the left ear, a finding consistent with the puretone results. Given the relatively low HL at which the SRT was established in the better (i.e.,

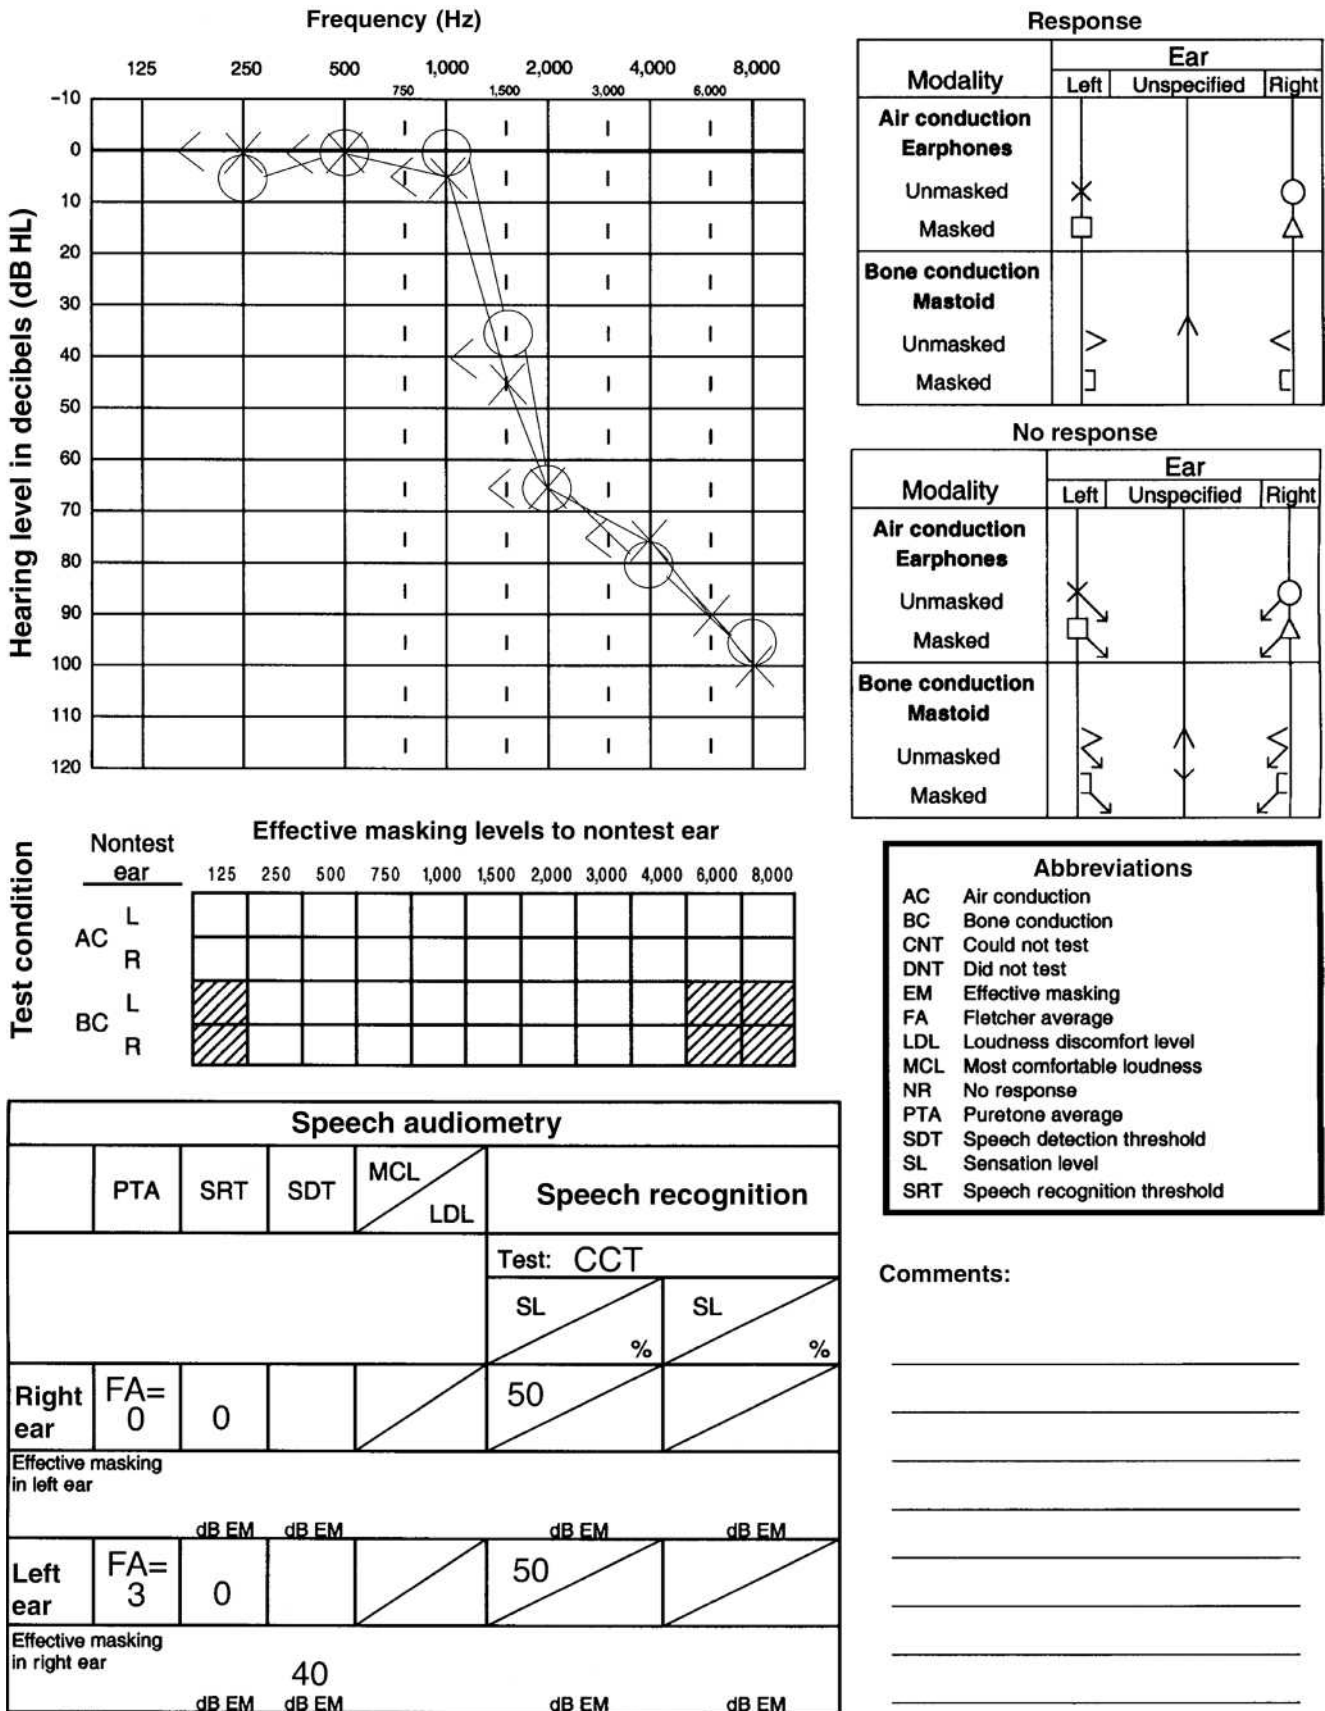

FIGURE 6.7 Audiogram illustrating the need for contralateral masking during measurement of supra-threshold speech recognition. See text for further discussion.

left) ear, it is expected that contralateral masking will not be required when measuring the SRT. Specifically, the SRT of 20 dB HL in the left ear does not equal or exceed the best bone-conduction threshold of 55 dB HL in the nontest ear by a conservative estimate of IA (40 dB):

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$20 \text{ dBHL} - 55 \text{ dBHL} \geq 40 \text{ dB? No}$$

However, if we predict that an SRT will be measured at about 80 dB HL in the right ear (based on the puretone average), then contralateral masking will be required because the estimated speech threshold of 80 dB HL equals or exceeds the best bone-conduction threshold of 15 dB HL in the nontest ear by 40 dB, our estimate of IA for speech:

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$80 \text{ dBHL} - 15 \text{ dBHL} \geq 40 \text{ dB? Yes}$$

Stated differently, the difference between the predicted presentation level in the test ear and the best bone-conduction threshold in the nontest ear equals or exceeds our estimate of IA. It is important to note, however, that a decision about the need for contralateral masking during measurement of speech threshold must always take into account not only the presentation level at the measured SRT, but also all supra-threshold levels used during threshold measurement. This will be discussed further in the section addressing selection of masking levels during speech audiometry.

During our earlier discussion of the need for contralateral masking during puretone air-conduction audiometry, it was indicated that a correct decision about the need for contralateral masking can be made sometimes by simply comparing the air-conduction thresholds of the two ears. Similarly, a decision about the need for contralateral masking during measurement of speech thresholds can be often made by comparing speech thresholds in the two ears.

Contralateral masking is required during measurement of speech threshold when the speech threshold in the test ear ($ST_{\text{Test Ear}}$) equals or exceeds the speech threshold in the nontest ear ($ST_{\text{Nontest Ear}}$) by a conservative estimate of IA:

$$ST_{\text{Test Ear}} - ST_{\text{Nontest Ear}} \geq \text{IA}$$

Consider again the audiogram presented in Figure 6.6. Recall that we predicted that SRT would be measured at about 80 dB HL in the right ear. In this particular example, comparison of the two speech thresholds (i.e., the measured SRT of 20 dB HL in the left ear and the predicted SRT of 80 dB HL in the right ear) would lead us to a correct decision about the need for contralateral masking when measuring SRT in the poorer ear without the need to consider bone-conduction hearing sensitivity in the nontest ear. The difference between the predicted SRT in

the right ear (80 dB HL) and the measured SRT in the left ear (20 dB HL) equals or exceeds 40 dB, our estimate of IA for speech:

$$ST_{\text{Test Ear}} - ST_{\text{Nontest Ear}} \geq \text{IA}$$

$$80 \text{ dB HL} - 20 \text{ dB HL} \geq 40 \text{ dB? Yes}$$

An alternative approach that can be used when making a decision about the need for contralateral masking during assessment of SRT involves measuring unmasked speech thresholds in both ears. Consider again the example presented in Figure 6.6. Assume that unmasked SRTs were measured at 65 and 20 dB HL in the right and left ears, respectively. Again there is an indication that contralateral masking will be required when measuring the SRT in the right ear. The presentation level of 65 dB HL (i.e., the unmasked SRT) in the test ear equals or exceeds the best bone-conduction threshold of 15 dB HL in the nontest ear by 40 dB, our estimate of IA for speech:

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$65 \text{ dBHL} - 15 \text{ dBHL} \geq 40 \text{ dB? Yes}$$

Similarly, the difference between the unmasked SRT in the right ear (65 dB HL) and the measured SRT in the left ear (20 dB HL) equals or exceeds our estimate of IA (40 dB). Although this approach can sometimes provide the audiologist with a more accurate estimate of the patient's IA for speech (which may be useful when selecting appropriate masking levels), it often just increases the number of steps needed to establish the true SRT in the test ear.

The audiogram presented in Figure 6.7 illustrates the need for contralateral masking during assessment of supra-threshold speech recognition. Puretone testing reveals normal hearing through 1,000 Hz, steeply sloping to a severe-to-profound sensory/neural hearing loss in the high frequencies bilaterally. SRTs were measured at 0 dB HL in both ears, a finding consistent with the puretone findings. Contralateral masking was not required during puretone and speech threshold audiometry. Suprathreshold speech recognition will be assessed using the California Consonant Test (CCT). This is a closed-set word recognition test that is sensitive to the speech recognition difficulties of individuals with high-frequency hearing loss (Owens and Schubert, 1977). If we use the recommended sensation level (SL) of 50 dB (Schwartz and Surr, 1979), then presentation level for both ears will be 50 dB HL (i.e., 50 dB relative to the SRT of 0 dB HL).

Let us now consider the need for contralateral masking during assessment of suprathreshold speech recognition. We will consider the need for masking using two types of air-conduction transducers: Supra-aural and 3A insert earphones. The advantage of insert earphones will become apparent.

Let us assume that supra-aural earphones are being used during speech audiometry. Contralateral masking will be required when assessing suprathreshold speech recognition in both ears because the difference between the presentation level of 50 dB HL in the test ear and the best puretone bone-conduction threshold of 0 dB HL in the nontest ear equals or exceeds 40 dB, our conservative estimate of IA for speech:

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$\text{Right Ear} \quad 50 \text{ dBHL} - 0 \text{ dBHL} \geq 40 \text{ dB? Yes}$$

$$\text{Left Ear} \quad 50 \text{ dBHL} - 0 \text{ dBHL} \geq 40 \text{ dB? Yes}$$

A different outcome results if we substitute 3A insert earphones for the supra-aural arrangement. Because of the greater IA offered by 3A insert earphones, contralateral masking will not be required when assessing suprathreshold speech recognition in either ear. Specifically, the difference between the presentation level of 50 dB HL in the test ear and the best puretone bone-conduction threshold of 0 dB HL in the nontest ear does not equal or exceed 60 dB, our conservative estimate of IA for speech:

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$\text{Right Ear} \quad 50 \text{ dBHL} - 0 \text{ dBHL} \geq 60 \text{ dB? No}$$

$$\text{Left Ear} \quad 50 \text{ dBHL} - 0 \text{ dBHL} \geq 60 \text{ dB? No}$$

The example presented in Figure 6.7 illustrates two important concepts related to assessment of suprathreshold speech recognition. First, it should not be assumed that contralateral masking is never required when assessing individuals with symmetrical sensory/neural hearing loss. Second, the need for contralateral masking often can be eliminated by using an air-conduction transducer that provides greater IA (i.e., 3A insert earphone).

MASKING CONCEPTS

Before proceeding to a discussion of clinical masking procedures, a brief review of basic masking concepts, including masking noise selection and calibration, will be presented. Generally, masking relates to how sensitivity for one sound is affected by the presence of another sound. ANSI/ASA (2010) defines masking as follows:

The process by which the threshold of hearing for one sound is raised by the presence of another (masking) sound. The amount by which the threshold of hearing for one sound is raised by the presence of another (masking) sound, expressed in decibels (p 7).

Consider the following example. Absolute threshold for a 1,000-Hz puretone stimulus is initially determined to be 40 dB HL. Another sound, white noise, is now presented simultaneously to the same ear. Absolute threshold for the 1,000-Hz signal is redetermined in the presence of the white noise and increases to 60 dB HL. Sensitivity to the puretone signal has been affected by the presence of the white noise. This increase in threshold of one sound in the presence of another is defined as masking. Because the puretone threshold was raised by 20 dB (i.e., a threshold shift of 20 dB), the white noise has produced 20 dB of masking.

There are two basic masking paradigms: ipsilateral and contralateral. In an ipsilateral masking paradigm, the test signal and the masker are presented to the same ear. In a contralateral masking paradigm, the test signal and masker are presented to opposite ears. Masking is used clinically whenever it is suspected that the *nontest* ear is participating in the evaluation of the test ear. Consequently, masking is always applied to the nontest or contralateral ear. Masking reduces sensitivity of the nontest ear to the test signal. The purpose of contralateral masking, therefore, is to raise the threshold of the nontest ear sufficiently so that its contribution to a response from the test ear is eliminated.

Masking Noise Selection

Standard diagnostic audiometers provide three types of masking stimuli: narrowband noise, speech spectrum noise, and white noise. Our clinical goal is to select a masker that is efficient (Hood, 1960). An efficient masker is one that produces a given effective level of masking with the least overall sound pressure level.

To better understand this concept of masker efficiency, let us review the classic masking experiment conducted by Fletcher (1940). White noise is a broadband stimulus that contains equal energy across a broad range of frequencies. Because of its broadband spectrum, it has the ability to mask puretone stimuli across a broad range of frequencies (Hawkins and Stevens, 1950). Fletcher addressed which frequency components of broadband noise contribute to the masking of a tone.

Fletcher (1940) conducted what is known as a centered masking experiment. Initially, a very narrow band of noise was centered around a puretone signal. The bandwidth of the noise was progressively widened, and the masking effect on the puretone signal was determined. Fletcher observed that the masked puretone threshold increased as the bandwidth of the masking noise was increased. However, once the noise band reached and then exceeded a “critical bandwidth,” additional masking of the puretone signal did not occur.

This concept of the critical band as first described by Fletcher (1940) consists of two components:

1. When masking a puretone with broadband noise, the only components of the noise that have a masking effect

on the tone are those frequencies included within a narrow band centered around the frequency of the tone.

2. When a puretone is just audible in the presence of the noise, the total noise power present in the narrow band of frequencies is equal to the power of the tone.

The first component of the critical band concept has clinical implications when selecting an appropriate masker during puretone audiometry. The second component has relevance when calibrating the effective masking (EM) level of the masking stimulus.

White noise is adequate as a masker for puretone stimuli. However, it contains noise components that do not contribute to the effectiveness of the masker. The additional noise components outside the tone's critical band simply add to the overall level (and loudness) of the masking stimulus. Therefore, the most efficient masker for puretone stimuli is a narrow band of noise with a bandwidth slightly greater than the critical band surrounding the tone. It provides the greatest masking effect with the least overall intensity. Sanders and Rintelmann (1964) confirmed that narrowband noise was a far more efficient masker for puretone stimuli than white noise. For a given sound pressure level (50, 70, and 90 dB SPL), narrowband noise centered at the frequency of the puretone signal (ranging from 250 to 4,000 Hz) consistently produced a greater masking effect (about 10 to 20 dB) than white noise.

The masking noise typically used during puretone audiometry, therefore, is narrowband noise centered geometrically around the audiometric test frequency. ANSI/ASA (2010) specifies the band limits (i.e., the upper and lower cutoff frequencies) of narrowband masking noise. To minimize the perception of tonality that often is associated with very narrow bands of noise, the bands specified by ANSI/ASA are somewhat wider than the critical bands for EM. The goal is to avoid confusion of the masker with the signal.

Speech spectrum noise (i.e., weighted random noise for the masking of speech) is typically used as a masker during speech audiometry. Speech is a broadband stimulus that requires a broadband masker. Although white noise is an adequate masker, it is not the most efficient. Speech spectrum noise is white noise that has been filtered to simulate the long-term average spectrum of speech. The average spectrum of speech contains the greatest energy in the low frequencies with spectrum level decreasing as a function of increasing frequency (Dunn and White, 1940). Speech spectrum noise has a more limited bandwidth than white noise. It is a more efficient masker than white noise, producing a masking advantage of 8 dB (Konkle and Berry, 1983). ANSI/ASA (2010) specifies that the spectrum of weighted random noise for the masking of speech should have a sound pressure spectrum level that is constant from 100 to 1,000 Hz, decreasing at a rate of 12 dB per octave from 1,000 to 6,000 Hz.

Calibration of Effective Masking Level

When a masking noise is presented to the nontest ear, we are interested in how much masking is produced. Consequently, masking noise is calibrated in EM level (dB EM).

ANSI/ASA (2010) defines EM level for puretones as “the sound pressure level of a band of noise whose geometric center frequency coincides with that of a specific pure tone that masks the pure tone to 50% probability of detection” (p 7). (Reference EM levels, calculated by adding an appropriate correction value to the reference equivalent threshold sound pressure level [RETSPL] at each frequency, are provided in the current ANSI/ASA specification for audiometers.) It is also indicated that, in individuals with normal hearing, “the amount of effective masking... is equal to the number of decibels that a given band of noise shifts a pure-tone threshold... when the band of noise and the pure tone are presented simultaneously to the same ear” (ANSI/ASA, 2010, p 7).

Stated differently, effective masking (in dB EM) refers to

1. The HL (dB HL) to which puretone threshold is shifted by a given level of noise; and
2. The puretone threshold shift (in dB) relative to 0 dB HL provided by a given level of noise.

Although contralateral masking is used clinically during hearing assessment, the following examples of ipsilateral masking will facilitate an understanding of the concept of EM level.

Example 1: A puretone air-conduction threshold is measured at 0 dB HL in the right ear. A narrowband noise geometrically centered at the test frequency is presented to the same ear at 50 dB EM. This EM level of 50 dB will shift puretone threshold to 50 dB HL.

Example 2: A puretone air-conduction threshold is measured at 30 dB HL in the right ear. A narrowband noise geometrically centered at the test frequency is presented to the same ear at 50 dB EM. This EM level of 50 dB will shift puretone threshold to 50 dB HL.

These examples illustrate two important points. First, a given level of EM will shift all unmasked puretone thresholds to the same dB HL. Of course, if unmasked puretone threshold is greater than a particular level of EM, then no threshold shift will occur. For example, a masker of 50 dB EM will not have a masking effect if the unmasked puretone threshold is 70 dB HL. Second, EM refers to the amount of threshold shift only relative to 0 dB HL.

Speech spectrum noise is also calibrated in EM level. Just as HL for speech (dB HL) is specified relative to the SRT, EM level is also referenced to the SRT. Specifically, EM for speech refers to the dB HL to which the SRT is shifted by a given level of noise. ANSI/ASA (2010) defines EM level for speech as the “sound pressure level of a specified masking noise that masks a speech signal to 50% probability of

recognition” (p 8). (If the speech spectrum noise has spectral density characteristics as specified by ANSI/ASA and if the sound pressure level of the masker is equal to the RET-SPL for speech, then the masker is calibrated in dB EM.) ANSI/ASA (2010) also states that in individuals with normal hearing, “the amount of effective masking... is equal to the number of decibels that a masking noise shifts a speech recognition threshold... when the masking noise and speech signal are presented simultaneously to the same ear” (p 8).

Consider the following example. SRT is measured at 0 dB HL. Speech spectrum noise is then presented to the same ear at 50 dB EM. This EM level of 50 dB will shift the SRT to 50 dB HL.

Calibration of masking noise in EM level greatly simplifies clinical masking procedures. When masking noise is calibrated in dB EM, then the decibel value indicated on the masking level control will indicate the masking effect produced in the nontest ear. This clearly facilitates the selection of appropriate masking levels during clinical testing.

CLINICAL MASKING PROCEDURES

All approaches to clinical masking address two basic questions. First, what is the minimum level of noise that is needed in the nontest ear to eliminate its response to the test signal? Stated differently, this is the *minimum masking level* that is needed to avoid *undermasking* (i.e., even with contralateral masking, the test signal continues to be perceived in the nontest ear). Second, what is the maximum level of noise that can be used in the nontest ear that will not change the true threshold or response in the test ear? Stated differently, this is the *maximum masking level* that can be used without *overmasking* (i.e., with contralateral masking, the true threshold or response in the test ear has been changed). Because of limited IA for air-conducted sound, the masking stimulus presented to the nontest ear can also cross over to the test ear and produce masking of the test signal (i.e., overmasking). Stated simply, the purpose of clinical masking is to make the test signal inaudible in the nontest ear without affecting the true response to the signal in the test ear. Therefore, the major goal of any clinical masking procedure is the avoidance of both undermasking and overmasking.

Studebaker (1979) has identified two major approaches to clinical masking: psychoacoustic and acoustic. Psychoacoustic procedures are “those based upon observed shifts in the measured threshold as a function of suprathreshold masker effective levels in the nontest ear” (Studebaker, 1979, p 82). These approaches are also identified as threshold shift or shadowing procedures. Acoustic procedures are “those based upon calculating the approximate acoustic levels of the test and masker signals in the two ears under any given set of conditions and on this basis deriving the required masking level” (Studebaker, 1979, p 82). These procedures

are also referred to as calculation or formula methods. Psychoacoustic approaches are considered appropriate for threshold measurements, whereas acoustic methods are typically most efficient for suprathreshold measurements.

Puretone Audiometry

Formulas and equations have been presented for the calculation of minimum and maximum masking levels during puretone audiometry (Lidén et al., 1959; Martin, 1967, 1974; Studebaker, 1962, 1964). A brief discussion of these formulas will facilitate an understanding of the manner in which appropriate levels of masking are selected during puretone threshold testing.

MINIMUM MASKING LEVEL

Lidén et al. (1959) and Studebaker (1964) offered formulas for calculating minimum masking level during puretone air-conduction audiometry that include consideration of IA, HL of the test signal, and air-bone gaps in the nontest ear. Although this “formula” approach to calculating minimum masking level is necessary during administration of suprathreshold auditory tests (this approach will be discussed later in the section addressing masking in speech audiometry), it proves somewhat disadvantageous during threshold audiometry. First, it can be time consuming. Second, the clinician may not have all required information to accurately calculate minimum masking level at that point in time. (The reader is referred to Yacullo, 1996 for further discussion of the derivation of these equations and formulas.)

The simplified method described by Martin (1967, 1974) is recommended for clinical use. Martin has suggested that formulas are unnecessary during threshold audiometry and has simplified the calculation of minimum masking level. Specifically, the “initial” masking level (in dB EM) during air-conduction threshold testing is simply equal to air-conduction threshold (in dB HL) of the nontest ear (i.e., $AC_{\text{Nontest Ear}}$). It should be noted that the initial masking level is calculated in the same manner regardless of the air-conduction transducer being used (i.e., supra-aural earphone or 3A insert earphone).

The audiometric data presented in Figure 6.8 will be used to facilitate an understanding of the calculation of masking levels during puretone threshold audiometry. Audiometry was performed using supra-aural earphones. Unmasked air- and bone-conduction thresholds at 500 Hz are provided; masked air- and bone-conduction thresholds are also included for later discussion. Unmasked puretone air-conduction testing suggests that contralateral masking will be required only when measuring air-conduction threshold in the left ear. Specifically, the unmasked air-conduction threshold of 65 dB HL in the left ear equals or exceeds the threshold (both air and bone conduction) in the nontest ear by a conservative estimate of IA (i.e., 40 dB).

FIGURE 6.8 An example illustrating the calculation of initial and maximum masking levels during puretone threshold audiometry. See text for further discussion.

According to Martin (1967, 1974), the initial masking level (in dB EM) is equal to 5 dB EM (i.e., $AC_{\text{Nontest Ear}}$).

Martin (1967, 1974) explains the derivation of this simplified equation in the following way. A signal detected at threshold is assumed to have an SL of 0 dB, regardless of whether it is perceived in the test or nontest ear. Therefore, a cross-hearing response during puretone threshold testing theoretically represents a *threshold* response in the nontest ear. Given this assumption, the initial masking level required is one that will just mask a signal of 0 dB SL (i.e., threshold) in the nontest ear. Because of the manner in which masking stimuli are calibrated clinically (i.e., EM level, dB EM), a masker presented at a level (in dB EM) equal to the air-conduction threshold (in dB HL) in the nontest ear should just mask the threshold response in the nontest ear. Given the example presented in Figure 6.8, a masker level of 5 dB EM (which is equal to the air-conduction threshold in the right ear) should be sufficient to just mask a threshold response to the test signal in the right ear. Martin also indicates that the simplified approach will lead to the selection of the same masker level as when using the more complex formulas for calculating minimum masking level.

Martin (1974) recommends that approximately 10 dB should be added to the initial masking level to account for intersubject variability. Remember that dB EM refers to the HL (dB HL) to which threshold is shifted by a given level of noise. Calibration of EM is based on the averaged responses of a group of normal-hearing subjects. Therefore, a given EM level will not prove equally effective for all subjects. If masked thresholds are normally distributed around the average effective level and if the standard deviation of the

distribution is about 5 dB, then Studebaker (1979) recommends that a safety factor of not less than 10 dB should be added to the calculated minimum masking level. Given this recommendation, Martin's simplified equation for initial masking level (in dB EM) during air-conduction threshold audiometry can be stated as follows:

$$\text{Initial Masking Level} = AC_{\text{Nontest Ear}} + 10 \text{ dB}$$

Considering again the example presented in Figure 6.8, the initial masking level is now calculated as 15 dB EM:

$$\begin{aligned} \text{Initial Masking Level} &= AC_{\text{Nontest Ear}} + 10 \text{ dB} \\ &= 5 \text{ dB HL} + 10 \text{ dB} \\ &= 15 \text{ dB EM} \end{aligned}$$

It is important to differentiate the terms *minimum masking level* and *initial masking level* during air-conduction threshold audiometry. Earlier in this discussion, a general definition of minimum masking level was provided. Minimum masking level was defined as the minimum level of noise needed in the nontest ear to eliminate its response to the test signal. Related to puretone threshold audiometry, a more specific definition of minimum masking level can be offered: Minimum masking level is the minimum level of noise needed to eliminate the contribution of the nontest ear *to establish the true or correct threshold in the test ear*. Initial masking level is simply the first level of noise introduced to the nontest ear. This initial level of masking is often not sufficient to establish the threshold in the test ear; higher levels of masking are often required. This concept will be addressed again in our discussion of the recommended clinical masking procedure during puretone threshold audiometry.

Lidén et al. (1959) and Studebaker (1964) also have offered formulas for minimum masking level during bone-conduction testing that are derived from the same theoretical constructs used during air-conduction testing (see Yacullo, 1996 for further discussion). Again, the formula approach during bone-conduction threshold audiometry is not clinically practical. The use of Martin's simplified approach is recommended. Specifically, initial masking level during bone-conduction audiometry is equal to the air-conduction threshold of the nontest ear. However, we will need to add the OE to the initial masking level to compensate for covering (i.e., occluding) the nontest ear with an earphone (Martin, 1967, 1974; Studebaker, 1964). Martin's simplified equation for initial masking level (in dB EM) during bone-conduction threshold testing can be stated as follows:

$$\text{Initial Masking Level} = AC_{\text{Nontest Ear}} + \text{OE} + 10 \text{ dB}$$

Bone-conduction thresholds are always obtained with the test ear unoccluded or uncovered. However, when an earphone covers or occludes the nontest ear during masked

bone-conduction audiometry, an OE can be created in the nontest ear. The nontest ear consequently can become more sensitive to bone-conducted sound for test frequencies below 2,000 Hz, particularly when using supra-aural earphones (Berger and Kerivan, 1983; Berrett, 1973; Dean and Martin, 2000; Dirks and Swindeman, 1967; Elpern and Naunton, 1963; Goldstein and Hayes, 1965; Hodgson and Tillman, 1966). During the application of contralateral masking, there is increased probability that the nontest ear will respond when obtaining a masked bone-conduction threshold in the test ear. Studebaker (1979) points out that the OE does not actually affect the hearing sensitivity of the occluded ear, but rather increases the sound pressure level of the signal reaching the cochlea. The reader is referred to Tonndorf (1968, 1972) for further discussion of the contribution of the external auditory meatus to bone-conduction thresholds.

There is evidence suggesting that the OE is decreased significantly when using deeply inserted insert earphones (Berger and Kerivan, 1983; Chaiklin, 1967; Dean and Martin, 2000). Berger and Kerivan (1983) and Dean and Martin (2000) studied the magnitude of the OE in normal-hearing subjects using E-A-R foam eartips and supra-aural earphones as occluding devices. Their overall results are remarkably similar. First, the average OEs in the low frequencies are greatly reduced when occluding the ear using an E-A-R foam eartip with deep insertion. Second, the advantage of a greatly reduced OE for the E-A-R foam eartip is lost when a partial or shallow insertion is used. Third, partial or shallow insertion of an E-A-R foam eartip yields average OEs that are similar to those measured with supra-aural earphones. Different theories have been offered to explain the reduced OE for an occluding device that is deeply inserted into the ear canal. The reader is referred to Berger and Kerivan (1983), Tonndorf (1972), and Yacullo (1996) for further discussion.

The clinician can use either individually determined (Dean and Martin, 2000; Martin et al., 1974) or fixed OE values (i.e., based on average data reported in the literature) when calculating initial masking level. Based on the largest average OEs reported in the literature (Berger and Kerivan, 1983; Berrett, 1973; Dean and Martin, 2000; Dirks and Swindeman, 1967; Elpern and Naunton, 1963; Goldstein and Hayes, 1965; Hodgson and Tillman, 1966), the following values are recommended for clinical use.

When using supra-aural earphones, the following fixed OE values are recommended: 30 dB at 250 Hz, 20 dB at 500 Hz, and 10 dB at 1,000 Hz. When using 3A insert earphones with deeply inserted foam eartips, the following values are recommended: 10 dB at 250 and 500 Hz and 0 dB at frequencies of 1,000 Hz or higher.

It should be noted that the OE is decreased or absent in ears with conductive hearing impairment (Martin et al., 1974; Studebaker, 1979). If the nontest ear exhibits a potential air-bone gap of 20 dB or more, then the OE should not be added to the initial masking level at that frequency.

Consider again the example presented in Figure 6.8. Assume that we have subsequently measured a masked air-conduction threshold of 85 dB HL in the left ear. A masked bone-conduction threshold will also be required in the left ear. Comparison of the unmasked bone-conduction threshold of 5 dB HL with the masked air-conduction threshold of 85 dB HL in the left ear suggests a potentially significant air-bone gap (i.e., ≥ 15 dB). Initial masking level is calculated in the same manner regardless of the air-conduction transducer used for the delivery of the masking stimulus. The only difference in calculation relates to applying a different correction factor for the OE when testing in the lower frequencies. Using the recommended fixed OE values for supra-aural earphones, initial masking level during bone-conduction testing at 500 Hz is calculated as follows:

$$\begin{aligned}\text{Initial Masking Level} &= AC_{\text{Nontest Ear}} + \text{OE} + 10 \text{ dB} \\ &= 5 \text{ dB HL} + 20 \text{ dB} + 10 \text{ dB} \\ &= 35 \text{ dB EM}\end{aligned}$$

In this particular example, it is appropriate to account for the OE because there is no evidence of a significant air-bone gap in the nontest (i.e., right) ear. The use of a supra-aural earphone for delivery of masking in the lower frequencies, however, will result in greater initial masking levels than when using a 3A insert because of a larger OE correction factor.

MAXIMUM MASKING LEVEL

Maximum masking level refers to the maximum level of noise that can be used in the nontest ear that will not shift or change the true threshold in the test ear. Two factors influence maximum masking level during puretone audiometry: (1) The bone-conduction threshold of the test ear ($BC_{\text{Test Ear}}$) and (2) IA of the air-conducted masking stimulus (Lidén et al., 1959). Maximum masking level (M_{Max}), based on the original concept described by Lidén et al., can be summarized using the following equation:

$$M_{\text{Max}} = BC_{\text{Test Ear}} + \text{IA} - 5 \text{ dB}$$

If $BC_{\text{Test Ear}} + \text{IA}$ is just sufficient to produce overmasking, then clinically, we want to use a masking level that is somewhat less than the calculated value. Consequently, 5 dB is subtracted from the level that theoretically produces overmasking. Because we are concerned about an undesired masking effect in the test ear, bone-conduction sensitivity in that ear must be considered. As a result, overmasking is more of a potential problem when bone-conduction sensitivity is very good in the test ear. Overmasking, on the other hand, is generally not an issue when bone-conduction hearing sensitivity is poor. The poorer the bone-conduction hearing sensitivity is in the test ear, the greater the levels of masking that can be used without overmasking.

The following two points are important to remember. First, the equation for maximum masking level is the same for both air- and bone-conduction audiometry. Masking noise is always delivered through an air-conduction transducer (e.g., insert or supra-aural earphone) regardless of the transducer used for measuring puretone threshold (i.e., air- or bone-conduction transducer). Second, maximum masking level is generally higher when using 3A insert earphones because of increased IA, particularly in the lower frequencies.

Consider again the example presented in Figure 6.8. We will now calculate the maximum masking level that can be used during both masked air- and bone-conduction audiometry:

$$\begin{aligned} M_{\text{Max}} &= BC_{\text{Test Ear}} + IA - 5 \text{ dB} \\ &= 80 \text{ dB HL} + 60 \text{ dB} - 5 \text{ dB} \\ &= 135 \text{ dB EM} \end{aligned}$$

Rather than using the very conservative IA estimate of 40 dB when using supra-aural earphones, in this case, we will use the more accurate estimate of 60 dB. If the bone-conduction threshold in the right (i.e., nontest) ear is assumed to be 5 dB HL (i.e., the unmasked bone-conduction threshold) and the unmasked air-conduction threshold in the left ear is 65 dB HL, then there is evidence that IA is at least 60 dB. If 140 dB EM is just sufficient to produce overmasking (i.e., $BC_{\text{Test Ear}} + IA$), then 135 dB EM is the maximum level of noise that can be used in the nontest ear that will not shift or change the true threshold in the test ear. It should be noted that 135 dB EM is a level that significantly exceeds the output limits for standard audiometers.

Generally, it is neither time efficient nor necessary to calculate maximum masking level during puretone threshold audiometry, particularly when using psychoacoustic or threshold shift masking procedures (which will be described shortly). In addition, the estimated maximum masking level is typically very conservative and not an accurate indication of the true maximum. In the above example, we calculated a relatively accurate estimate by using a more accurate value of IA (rather than the conservative value) and the actual bone-conduction threshold in the test ear (i.e., 80 dB HL). However, the true bone-conduction threshold (obtained with appropriate contralateral masking) in the test ear is typically not known when maximum masking level is estimated during both air- and bone-conduction threshold audiometry. Because only an unmasked bone-conduction threshold is available at the time that masking levels are determined, we are required to use the unmasked threshold as the estimate of bone-conduction hearing sensitivity in the test ear. Let us calculate again M_{Max} using the unmasked bone-conduction response as the estimate of bone-conduction threshold:

$$\begin{aligned} M_{\text{Max}} &= 5 \text{ dB HL} + 60 \text{ dB} - 5 \text{ dB} \\ &= 60 \text{ dB EM} \end{aligned}$$

Clearly in this case, our calculation based on the unmasked bone-conduction threshold (i.e., 60 dB EM) is an underestimate of the actual maximum level (i.e., 135 dB EM).

Whenever an unmasked bone-conduction threshold is used during determination of maximum masking, the resultant value is typically smaller than the masking level that will actually result in overmasking. Although the actual calculation of maximum masking level during puretone threshold audiometry is often of limited use, consideration of the maximum level of noise that can be used in the nontest ear can alert the audiologist to the possibility of overmasking, particularly in cases of conductive hearing loss when bone-conduction hearing sensitivity is very good.

RECOMMENDED CLINICAL PROCEDURE

The most popular method for measuring masked puretone thresholds was first described by Hood in 1957 (Hood, 1960). The Hood method, also referred to as the plateau, threshold shift, or shadowing procedure, is a psychoacoustic technique that relies on observations about the relationship between masker level in the nontest ear and measured threshold in the test ear. Hood originally described a masking procedure that was applicable for measurement of masked bone-conduction thresholds. However, it proves equally effective for measurement of air-conduction thresholds as well.

The example presented in Figure 6.9 will help facilitate an understanding of the underlying concept of the threshold shift procedure. Unmasked puretone air-conduction thresholds, obtained using supra-aural earphones, were measured at 10 dB HL in the right ear and 60 dB HL in the left ear (Figure 6.9A). Contralateral masking will be required when testing the left ear because there is a difference between the test and nontest ears that equals or exceeds a conservative estimate of IA (i.e., 40 dB). An initial masking level of 20 dB EM (i.e., $AC_{\text{Nontest Ear}} + 10 \text{ dB}$) is now presented to the right ear, and puretone threshold is re-established. Recall that the purpose of contralateral masking is to raise the threshold of the nontest ear sufficiently to eliminate its contribution when measuring a response in the test ear. Assuming that overmasking is not occurring, then contralateral masking should have an effect only on the responsiveness of the nontest ear.

There are two possible outcomes when puretone threshold is re-established in the presence of contralateral masking: (1) No measured puretone threshold shift (e.g., puretone threshold remains constant at 60 dB HL; Figure 6.9B) or (2) a measured puretone threshold shift (e.g., puretone threshold shifts from 60 to 70 dB HL; Figure 6.9C). If contralateral masking in the nontest ear does not produce a masking effect, then it is concluded that the unmasked puretone threshold represents a response from the test ear. Conversely, if contralateral masking in the nontest ear does produce a

FIGURE 6.9 Example illustrating the underlying concept of the plateau or threshold shift masking procedure. See text for further discussion. [From Yacullo WS. [1996] *Clinical Masking Procedures*. 1st ed. Boston, MA: Allyn & Bacon, © 1996, p 69. Adapted by permission of Pearson Education, Inc., Upper Saddle River, NJ.]

masking effect, then it is concluded that the unmasked puretone threshold represents a response from the nontest ear. The underlying concept of the Hood procedure is that the introduction of masking to the nontest ear will produce a masking effect (i.e., a threshold shift) only if the nontest ear is contributing to the observed response. Decisions about which ear is contributing to the measured threshold are based on whether a threshold shift occurs when masking is introduced to the nontest ear.

Hood (1960) outlined two essential steps of the plateau masking procedure: (1) Demonstration of the shadowing effect and (2) identification of the changeover point. The hypothetical example presented in Figure 6.10 illustrates basic concepts of the plateau masking procedure. Puretone testing using supra-aural earphones reveals unmasked air-conduction thresholds of 0 dB HL in the right ear and 40 dB HL in the left ear (Figure 6.10A). Unmasked bone-conduction threshold is 0 dB HL. Because there is a 40-dB difference between ears, contralateral masking will be required when measuring air-conduction threshold in the left ear. (Masked air- and bone-conduction thresholds in the left ear are included for later discussion.)

The masking function presented in Figure 6.10B shows the relationship between measured puretone threshold (in dB HL) in the test ear and EM level (in dB EM) in the nontest

ear. Masking noise is introduced at an initial masking level of 10 dB EM (i.e., $AC_{\text{Nontest Ear}} + 10$ dB), and puretone threshold is re-established. Threshold shifts to 50 dB HL. When the masker level is raised sequentially to 20 and 30 dB EM, puretone threshold continues to shift by 10 dB. A shadowing effect has occurred because the masked puretone threshold “shadows” the threshold of the nontest or masked ear with each increment in EM level. Because a threshold shift occurs when masking level is raised, it is concluded that the masking noise and the tone are restricted to the nontest ear.

When the masker is raised from 30 to 100 dB EM, puretone threshold no longer shifts and remains stable at 70 dB HL. A plateau has been reached. Because there is no additional masking effect (i.e., a threshold shift) when masker level is increased, it is concluded that the nontest ear is no longer contributing to the observed response. Puretone threshold of the test ear (i.e., 70 dB HL) has been reached. Hood (1960) refers to the initial point on the masking function where puretone threshold remains stable with increasing masking level as the “changeover point.” In this example, the changeover point of 30 dB EM also corresponds to minimum masking level, the minimum amount of noise required to establish the true threshold in the test ear. Masker levels that result in no threshold shift (i.e., the plateau) represent adequate masking (i.e., 30 through 100 dB EM). Masker

FIGURE 6.10 Hypothetical example illustrating the concepts of undermasking, adequate masking, and overmasking using the threshold shift or plateau masking procedure. See text for explanation. [From Yacullo WS. [1996] *Clinical Masking Procedures*. 1st ed. Boston, MA: Allyn & Bacon, © 1996, p 72. Adapted by permission of Pearson Education, Inc., Upper Saddle River, NJ.]

levels less than 30 dB EM represent undermasking. That is, there is insufficient masking to establish the true puretone threshold in the test ear.

When the masker level exceeds 100 dB EM (i.e., 110 and 120 dB EM), however, a puretone threshold shift with each increment in masking level is again observed. Overmasking is now occurring. The masking noise has reached the test ear through cross hearing, and a masking effect (i.e., a threshold shift) is observed in the test ear. Assuming that a masked bone-conduction threshold is measured subsequently in the left ear at 65 dB HL, then an estimate of maximum masking level is 100 dB EM ($BC_{\text{Test Ear}} + IA - 5 \text{ dB}$: 65 dB HL + 40 dB - 5 dB). Whereas the plateau and overmasking portions of the masking function represent responses from the test ear, the undermasking or shadowing portion represents responses from the nontest ear. It should be apparent from the masking function in Figure 6.10 that the width of the masking plateau is defined by the minimum and maximum masking levels.

The clinical goal of the plateau procedure is to establish the HL at which puretone threshold remains unchanged with increments in masking level. Two important variables that relate to the plateau procedure are (1) the magnitude of the masker increment and (2) the number of masker increments needed to establish a masking plateau. Although Hood (1960) originally recommended that masker level be changed in increments of 10 dB, others have suggested that the level should be a 5-dB step size (Martin, 1980; Silman and Silverman, 1991). Martin (1980) suggests that accuracy

is increased somewhat by using a masker increment of 5 dB. It is somewhat arbitrary whether a 5- or 10-dB step size is used for increasing masker level. Either step size is acceptable. However, the smaller step size of 5 dB is strongly recommended whenever the masking plateau is narrow and there is increased risk of overmasking (i.e., cases of bilateral conductive hearing loss).

Hood (1960) did not specify the number of masker increments needed to establish a masking plateau. Clinically, it is neither time efficient nor necessary to measure the entire masking plateau. It is generally agreed that a masking "plateau" has been established when masker level can be increased over a range of at least 15 to 20 dB without shifting puretone threshold (Kaplan et al., 1993; Martin, 1980; Sanders, 1991; Silman and Silverman, 1991).

The recommended clinical procedure (Yacullo, 1996, 2004), based on the major components of Hood's shadowing technique, is summarized as follows:

1. Masking noise is introduced to the nontest ear at the initial masking level. Puretone threshold is then re-established.
2. Level of the tone or noise is increased subsequently by 5 dB. If there is a response to the tone in the presence of the noise, the level of the noise is increased by 5 dB. If there is no response to the tone in the presence of the noise, the level of the tone is increased in 5-dB steps until a response is obtained.

3. A plateau has been reached when the level of the noise can be increased over a range of 15 to 20 dB without shifting the threshold of the tone. This corresponds to a response to the tone at the same HL when the masker is increased in three to four consecutive levels.
4. Masked puretone threshold corresponds to the HL of the tone at which a masking plateau has been established.

If a 10-dB step size is used for increasing masking level, then the plateau corresponds to a range of 20 dB (i.e., a response to the tone at the same HL when the masker is increased in two consecutive levels).

The recommended procedure for establishing a masking plateau does not require that puretone threshold be formally established each time that the masking level is increased. This approach would significantly increase the time required to establish a masking plateau. Rather, the tone is presented once at the same HL as the previous response. If no response

occurs, the tone is increased in 5-dB steps until audibility is achieved. However, the HL of the tone may be increased inappropriately because of a decision-making process based on a single response. This may lead to imprecision when measuring the masked threshold. Therefore, it is recommended that masked puretone threshold be re-established using a standardized threshold procedure (e.g., ASHA, 2005) in the presence of the final level of masking noise that resulted in a plateau. This sometimes leads to a 5-dB improvement in the masked puretone threshold. However, the decision to re-establish masked puretone threshold at the end of the plateau procedure will be influenced by time considerations.

Remember that the goal of the plateau procedure is to establish the HL at which puretone threshold remains unchanged with increments in masking level. Given this goal, there are three major outcomes that can result when measuring puretone threshold. These outcomes are illustrated in the three examples presented in Figure 6.11. In

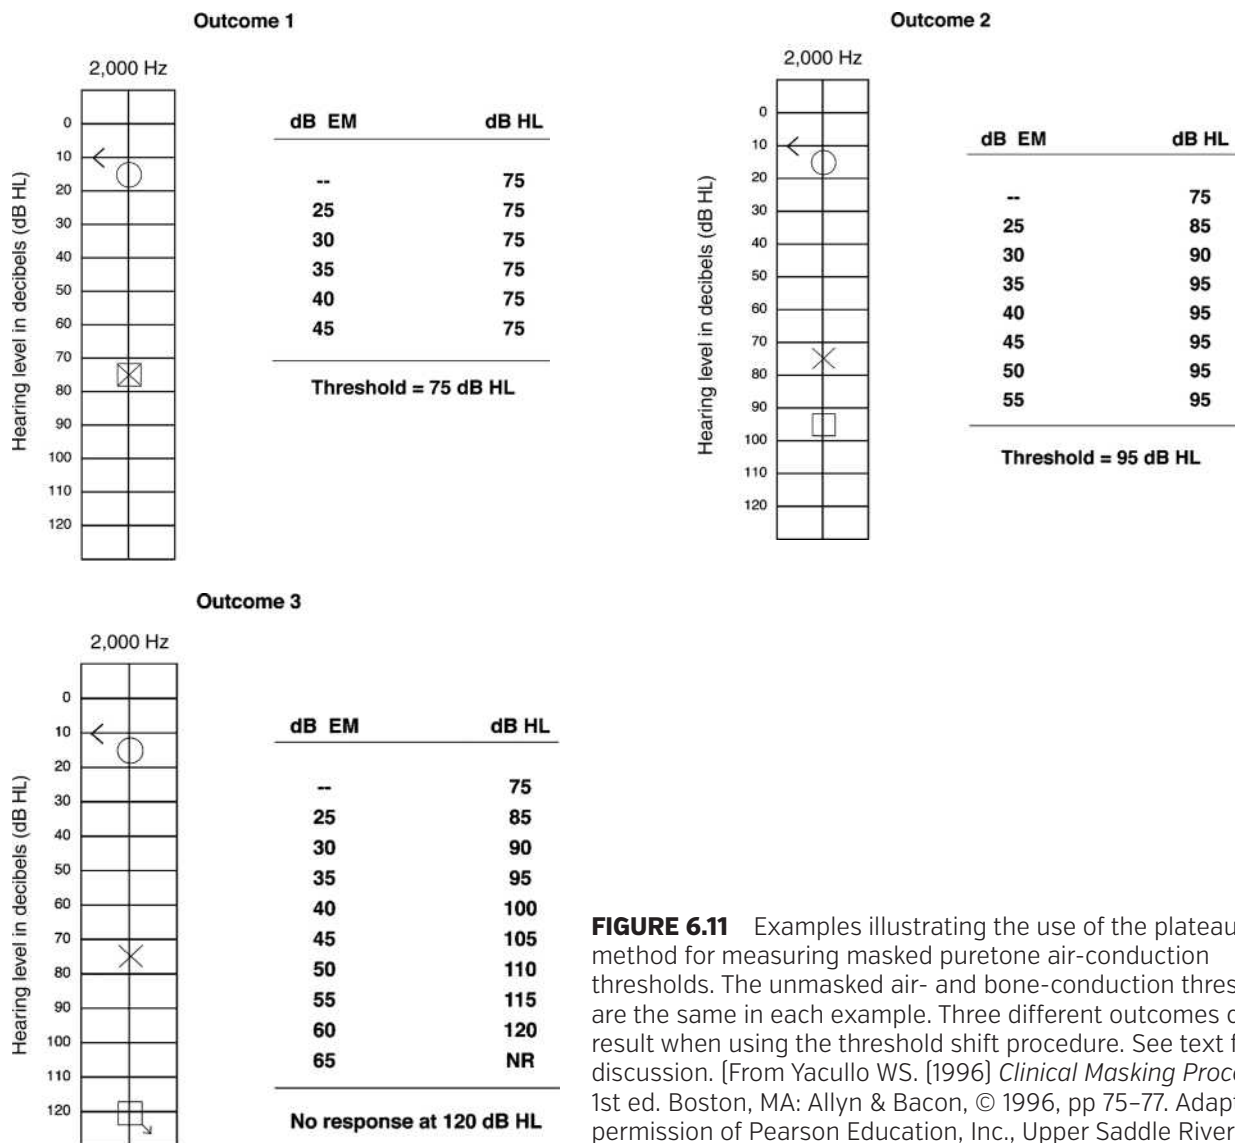

FIGURE 6.11 Examples illustrating the use of the plateau method for measuring masked puretone air-conduction thresholds. The unmasked air- and bone-conduction thresholds are the same in each example. Three different outcomes can result when using the threshold shift procedure. See text for discussion. [From Yacullo WS. [1996] *Clinical Masking Procedures*. 1st ed. Boston, MA: Allyn & Bacon, © 1996, pp 75-77. Adapted by permission of Pearson Education, Inc., Upper Saddle River, NJ.]

each example, the unmasked puretone thresholds at 2,000 Hz are the same. Unmasked puretone air-conduction thresholds, obtained using 3A insert earphones, were measured at 15 dB HL in the right ear and 75 dB HL in the left ear. Contralateral masking will be required when measuring air-conduction threshold in the left ear; an initial masking level of 25 dB EM is presented to the right ear, and puretone threshold is re-established.

In the first outcome, the unmasked puretone threshold of 75 dB HL remains unaffected with increasing masking level. The level of the noise was increased over a range of 20 dB without shifting the threshold of the tone. In this example, the initial masking level occurs at the masking plateau. Contralateral masking has confirmed that the unmasked puretone threshold represents a response from the test ear.

In the second outcome, the initial masking level produces a puretone threshold shift. A masking plateau is reached, however, when masking level is increased from 35 to 55 dB EM (i.e., a masking range of 20 dB). Because masked puretone threshold remains stable at 95 dB HL with increasing masking level, puretone threshold is recorded as 95 dB HL. Contralateral masking has confirmed that the unmasked puretone threshold represents a cross-hearing response from the nontest ear.

In the third outcome, the initial masking level again produces a puretone threshold shift. However, puretone threshold continues to shift to the output limits of the audiometer with increasing masking level. A plateau is not obtained. Therefore, it is concluded that there is no measurable hearing in the left ear. This conclusion is correct assuming that overmasking has not occurred.

Turner (2004a, 2004b) has described a masking method that can replace the plateau procedure in some masking situations. A disadvantage of the plateau method is that it can be time consuming. The “optimized” masking method described by Turner, which is based on the principles of the masking plateau, can reduce the number of masking levels required to reach the plateau and establish threshold. The method is optimized because it uses the maximum possible masking levels without overmasking. This is accomplished through the use of higher initial masking levels and maximum masker increments. However, there are some masking situations where the optimized approach is not appropriate. The reader is referred to the two articles by Turner (2004a, 2004b) for further discussion.

THE MASKING DILEMMA

There are clinical situations where minimum masking levels can result in overmasking. Studebaker (1979) states that a “masking dilemma” results when the width of the masking plateau is very narrow or nonexistent. Remember that the width of the masking plateau is defined by minimum and maximum masking levels. Generally, a masking dilemma results whenever there is a significant hearing loss

in the nontest ear and a conductive hearing loss in the test ear. The presence of significant hearing loss in the nontest ear requires higher initial masking levels; the presence of a conductive hearing loss in the test ear (i.e., normal bone-conduction hearing sensitivity) decreases the maximum masking level. The consequence of a reduced or nonexistent masking plateau is the inability to establish correct masked thresholds in the test ear.

The classic example of a masking dilemma is demonstrated with a bilateral, mild-to-moderate conductive hearing loss. The possibility for overmasking exists when measuring masked air- and bone-conduction thresholds in both ears. Naunton (1960) states that, in some cases of bilateral conductive hearing loss, it is not possible to mask the nontest ear without simultaneously producing a masking effect in the test ear.

One solution to the masking dilemma is the use of insert earphones (Coles and Priede, 1970; Hosford-Dunn et al., 1986; Studebaker, 1962, 1964). Recall that the use of 3A insert earphones significantly increases IA for air-conducted sound, particularly in the lower frequencies (Killion et al., 1985; Sklare and Denenberg, 1987). There are two advantages of using insert earphones in cases of bilateral conductive hearing loss. First, the need for masking during measurement of air-conduction thresholds is often eliminated because of greater IA for air-conducted sound. Second, the use of insert earphones reduces the probability of overmasking in cases where contralateral masking is required. The use of an air-conduction transducer with increased IA increases the range between the minimum and maximum masking levels, thereby increasing the width of the masking plateau and the range of permissible masking levels (Studebaker, 1962).

CENTRAL MASKING

The introduction of contralateral masking can produce a small threshold shift in the test ear even when the masking level is insufficient to produce overmasking. Wegel and Lane (1924) referred to this phenomenon as central masking. It has been hypothesized that threshold shifts in the presence of low levels of masking are mediated through central nervous system processes (Lidén et al., 1959). Central masking has been reported to influence thresholds measured during both puretone and speech audiometry (Dirks and Malmquist, 1964; Lidén et al., 1959; Martin, 1966; Martin and DiGiovanni, 1979; Martin et al., 1965; Studebaker, 1962). Although the threshold shift produced by central masking is generally considered to be approximately 5 dB (Konkle and Berry, 1983; Martin, 1966), variable results have been reported across subjects and studies. There is also some indication that central masking effects increase with increasing masking level (Dirks and Malmquist, 1964; Martin et al., 1965; Studebaker, 1962).

There is currently no agreed upon procedure that accounts for central masking effects during threshold audiometry. However, it is generally not recommended that the effect of central masking be subtracted from masked thresholds. First, it is difficult to determine an appropriate correction factor given the variability of the central masking effect across subjects. Second, the typical central masking effect size of about 5 dB is considered to be within good test-retest reliability during threshold measurements. It is important to remember that the use of contralateral masking can somewhat influence the measured masked thresholds and should be taken into account when interpreting audiometric test results. For example, a difference of 5 dB between unmasked and masked thresholds is generally not considered significant. This difference may simply reflect (1) central masking effects and/or (2) normal variability related to test-retest reliability.

MASKED AUDIOGRAM INTERPRETATION

Unmasked and masked puretone thresholds are typically recorded on the same audiogram. Therefore, audiogram interpretation will involve consideration of both masked and unmasked responses. ASHA (1990) has published guidelines for audiometric symbols and procedures for graphic representation of frequency-specific audiometric findings. These guidelines have been followed throughout this chapter.

Figure 6.12 presents an audiogram in which contralateral masking was required when obtaining both air- and bone-conduction thresholds in the left ear. Air-conduction audiometry was performed using supra-aural earphones. Puretone testing reveals a mild conductive hearing loss of flat configuration in the right ear. Masked air- and bone-conduction responses indicate a severe-to-profound, sensory/neural hearing loss of gradually sloping configuration in the right ear.

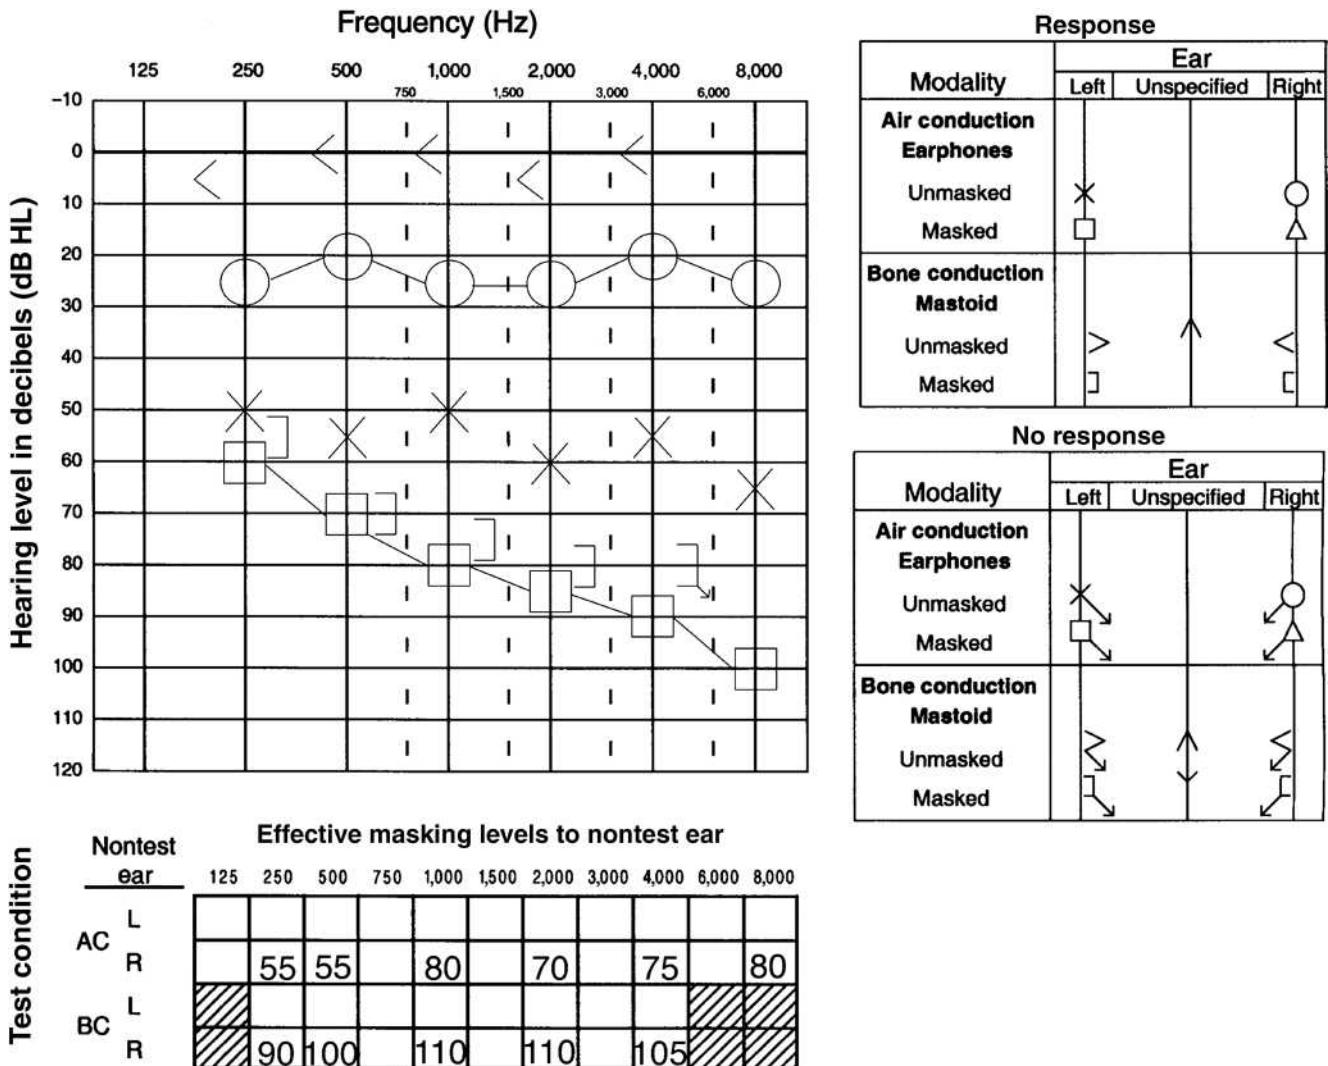

FIGURE 6.12 An example illustrating audiogram interpretation using unmasked and masked puretone thresholds.

It should be noted that the unmasked air-conduction thresholds in the left ear are not considered when interpreting hearing status. Because a significant threshold shift (i.e., >5 dB) occurred when contralateral masking was introduced to the nontest ear, the unmasked air-conduction responses in the left ear actually represent cross-hearing responses from the better (i.e., right) ear. In this case, the unmasked air-conduction thresholds should not be connected with lines. In cases where contralateral masking is required, it is acceptable to record only the masked thresholds (ASHA, 1990).

Although the results of unmasked bone-conduction audiometry suggested that masked bone-conduction thresholds were required in both ears because of potential air-bone gaps, contralateral masking was required only when testing the left ear. Whenever there is an asymmetrical hearing loss, it is traditional to first measure masked bone-conduction thresholds in the poorer ear. There is the assumption that the unmasked bone-conduction thresholds may more likely reflect hearing in the better ear. When masked bone-conduction thresholds were subsequently measured in the left ear, results suggested a sensory/neural hearing loss. Consequently, we can correctly assume that the unmasked responses are originating from the better (i.e., right) ear. Depending on the outcome when measuring masked bone-conduction thresholds in the poorer ear, it is not always necessary to also measure masked thresholds in the opposite ear. As the above example illustrates, ear-specific information can be inferred from unmasked bone-conduction responses in some cases.

It is traditional to record masking levels when obtaining masked air- and bone-conduction thresholds. Assuming that the clinician has used the recommended threshold shift (i.e., plateau) procedure, then a range of masking levels will be used when establishing threshold. ASHA (1990) recommends that the final level of masking used to obtain masked threshold should be recorded for the nontest ear. A table for recording EM levels to the nontest ear is typically provided on an audiogram form. Consider again the audiogram presented in Figure 6.12. For example, a masked puretone air-conduction threshold was measured at 85 dB HL at 2,000 Hz in the left ear; this threshold was obtained with a final masking level of 70 dB EM in the right ear.

Speech Audiometry

The speech audiometry test battery is traditionally composed of two major components: (1) Measures of hearing sensitivity for speech (i.e., speech threshold) and (2) measures of suprathreshold speech recognition. Although the psychoacoustic or threshold shift procedure proves efficient when measuring SDT, the acoustic masking procedure is the method of choice when assessing threshold and suprathreshold speech recognition.

PSYCHOACOUSTIC MASKING PROCEDURES

Recall that the psychoacoustic or threshold shift masking procedures rely on the observation of shifts in the measured threshold in the test ear as a function of masking levels in the nontest ear. The plateau procedure can be applied easily during measurement of speech thresholds (Konkle and Berry, 1983; Studebaker, 1979). A major advantage of the plateau procedure is that information about bone-conduction hearing sensitivity in each ear is not required when selecting appropriate masking levels. Although the plateau procedure can be applied during measurement of both masked recognition and detection thresholds, it proves most efficient during measurement of SDT because of the nature of the response task (i.e., detection rather than recognition).

ASHA's most recent guidelines for determining threshold level for speech were published in 1988. Recommended procedures for measuring both detection and recognition thresholds are described. Given that determination of SDT involves a detection task that is similar to the one used in puretone threshold audiometry, ASHA recommends using a test procedure that follows published guidelines for measuring puretone threshold (e.g., ASHA, 2005). Therefore, the plateau masking procedure recommended earlier for use during puretone threshold audiometry can be used equally effectively when measuring masked SDT.

Consider the example presented in Figure 6.13. Audiometry was performed using 3A insert earphones. puretone testing reveals normal hearing in the right ear. There is a profound sensory/neural hearing loss of fragmentary configuration in the left ear. (Contralateral masking was required during measurement of air- and bone-conduction thresholds in the left ear.) An SRT of 5 dB HL was measured in the right ear, a finding that supports the puretone results. When spondaic words were presented at suprathreshold levels in the left ear, the patient was not able to correctly recognize any words. Consequently, a decision was made to measure an SDT.

An unmasked SDT is measured at 75 dB HL in the left ear. Because the difference between the unmasked SDT in the test ear (i.e., 75 dB HL) and the SRT in the nontest ear (i.e., 5 dB HL) clearly exceeds our conservative estimate of IA for speech (i.e., 60 dB) when using 3A insert earphones, contralateral masking will be required.

Using the recommended plateau masking procedure, speech spectrum noise is introduced to the nontest ear at an initial masking level, that is, an EM level (in dB EM) equal to the speech threshold of the nontest ear ($SRT_{\text{Nontest Ear}}$) plus a 10-dB safety factor:

$$\text{Initial Masking Level} = SRT_{\text{Nontest Ear}} + 10 \text{ dB}$$

In this example, initial masking level is equal to 15 dB EM. SDT is then re-established in the nontest ear in the presence of the initial masking level. Depending on the patient's response to the speech in the presence of the noise, the level

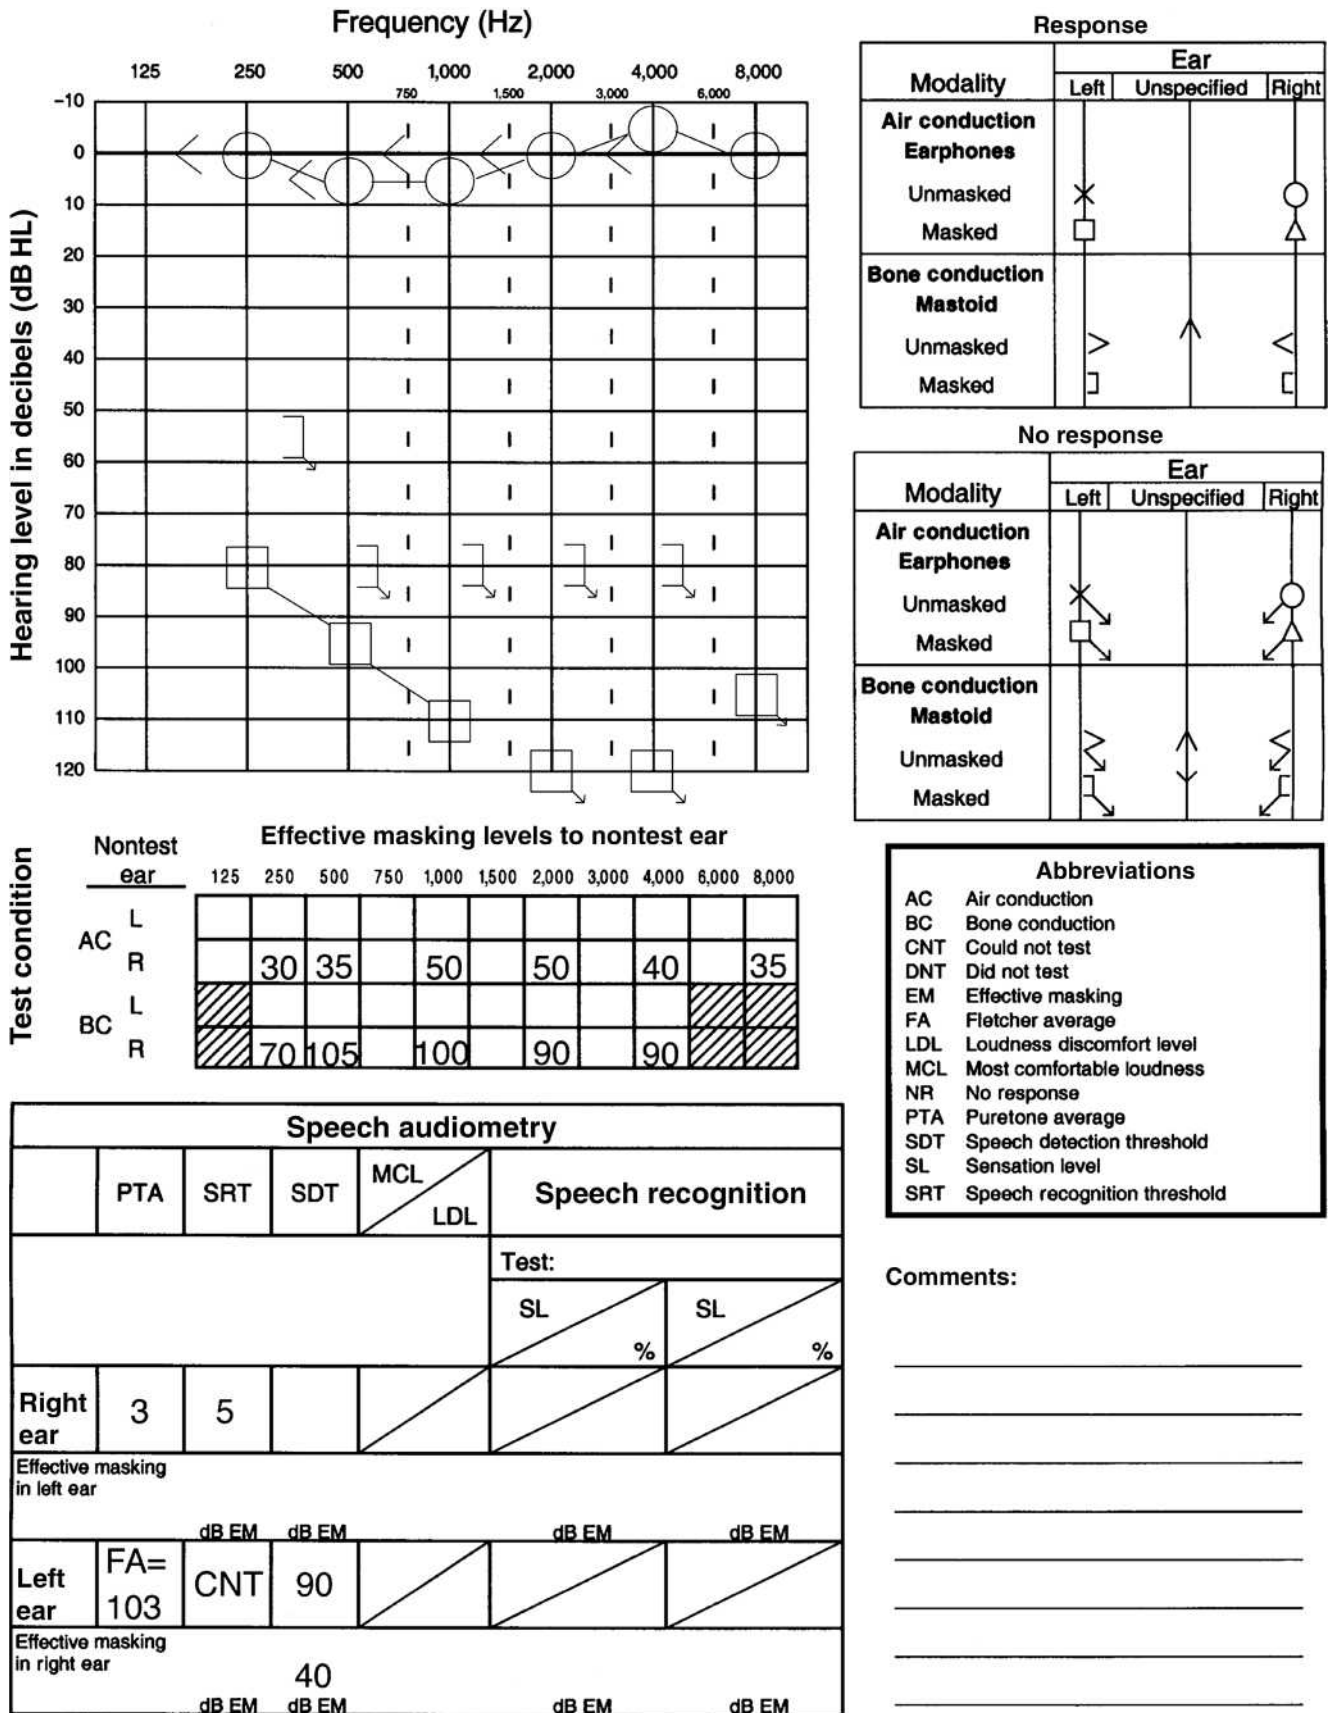

FIGURE 6.13 An example illustrating the use of the threshold shift masking procedure for determining speech detection threshold.

of the speech or noise is increased by 5 dB until a masking plateau has been reached. Remember that it is acceptable to use a 10-dB masker increment when establishing a masking plateau. In this particular case, the risk of overmasking is essentially nonexistent because of the poor bone-conduction hearing sensitivity in the test ear (and the use of an air-conduction transducer with increased IA for presenting the masking noise). Therefore, the use of a 10-dB masker increment can be easily justified. Masked SDT is subsequently measured at 90 dB HL (using 40 dB EM).

Although the plateau masking procedure can be used during assessment of masked SRT, it can prove very time consuming. Recall that only a single detection response to speech is required when measuring masked SDT before making a decision about increasing the level of the speech or masker. The use of the plateau procedure for measuring masked SRT, however, requires that threshold be re-established (i.e., 50% correct recognition of spondaic words) at each masking level until a plateau is reached. The acoustic method proves to be the method of choice when measuring masked SRT because of its greater time efficiency (Konkle and Berry, 1983; Studebaker, 1979) and will be discussed in the following section.

ACOUSTIC MASKING PROCEDURES

Recall that acoustic masking procedures are based on calculating the estimated acoustic levels of the test and masking stimuli in the two ears during a test condition and, on this basis, selecting an appropriate masking level. A major disadvantage of the acoustic or formula approach is that the application requires knowledge about air-bone gaps in both test and nontest ears (Konkle and Berry, 1983; Studebaker, 1979). Knowledge about air-bone gaps in the nontest ear is required to calculate minimum masking level. Information about bone-conduction hearing sensitivity in the test ear is required to calculate maximum masking level. Assuming that complete puretone threshold data are available before performing speech audiometry, however, formula approaches for calculating required masking levels prove very effective during measurement of both threshold and suprathreshold speech recognition.

The underlying concepts of minimum and maximum masking levels for speech are similar to those offered earlier for puretone stimuli. Minimum masking level for speech (M_{Min}), originally described by Lidén et al. (1959), can be defined using the following equation:

$$M_{\text{Min}} = \text{Presentation Level}_{\text{Test Ear}} - \text{IA} \\ + \text{Largest Air-Bone Gap}_{\text{Nontest Ear}}$$

Presentation Level_{Test Ear} represents the HL (dB HL) of the speech signal at the test ear, IA is equal to IA for speech, and Largest Air-Bone Gap_{Nontest Ear} represents the largest air-bone gap in the nontest ear in the 250- to 4,000-Hz

frequency range. Presentation Level_{Test Ear} – IA, an estimate of the HL of the speech signal reaching the test ear, represents the minimum masking level required. The presence of air-bone gaps in the nontest (i.e., masked) ear, however, will reduce the effectiveness of the masker. Consequently, minimum masking level must be increased by the size of the air-bone gap.

Lidén et al. (1959) recommended that the *average* air-bone gap in the nontest ear, calculated using frequencies of 500, 1,000, and 2,000 Hz, be accounted for when determining the minimum masking level. Coles and Priede (1975) suggested a more conservative approach and recommended that the largest air-bone gap at any frequency in the range from 250 to 4,000 Hz be considered. Remember that speech is a broadband signal. Therefore, bone-conduction hearing sensitivity across a range of frequencies in the nontest ear must be considered. There is the assumption that the largest air-bone gap will have the greatest effect on masking level. Following the conservative recommendation of Coles and Priede (1975), it is recommended that the largest air-bone gap across the frequency range in the nontest ear be accounted for when determining minimum masking level.

Maximum masking level (M_{Max}) for speech, originally described by Lidén et al. (1959), can be defined using the following equation:

$$M_{\text{Max}} = \text{Best BC}_{\text{Test Ear}} + \text{IA} - 5 \text{ dB}$$

Best BC_{Test Ear} represents the best bone-conduction threshold in the test ear in the frequency range from 250 to 4,000 Hz, and IA is equal to IA for speech. If Best BC_{Test Ear} + IA represents a level that will just produce overmasking in the test ear, then a slightly lower masking level should be used clinically. Consequently, a value of 5 dB is subtracted from the calculated level.

Lidén et al. (1959) originally recommended that the *average* puretone bone-conduction threshold in the test ear, again calculated using frequencies of 500, 1,000, and 2,000 Hz, should be accounted for when estimating maximum masking level. However, a more conservative approach includes consideration of the *best* bone-conduction threshold in the test ear over a wider range of frequencies (i.e., 250 to 4,000 Hz). There is the assumption that the best bone-conduction threshold in the test ear is the most susceptible to the effects of overmasking.

The optimal masking level during speech audiometry is one that occurs above the minimum and below the maximum masking levels (Konkle and Berry, 1983; Lidén et al., 1959; Studebaker, 1979). Minimum and maximum masking levels represent, respectively, the lower and upper limits of the masking plateau. Studebaker (1979) states that a major goal of the acoustic or formula approach is to apply rules that will place the masking level at approximately the middle of the range of correct values (i.e., the middle of the

masking plateau). This concept was originally discussed by Luscher and König in 1955 (cited by Studebaker, 1979).

Studebaker (1962) first described an equation for calculating midmasking level during puretone bone-conduction audiometry. The basic concepts underlying the midplateau procedure, however, can be easily applied during speech audiometry. Yacullo (1999) states that a simple approach to calculating the midmasking level (M_{Mid}) involves determining the arithmetic mean of the minimum and maximum masking levels:

$$M_{\text{Mid}} = (M_{\text{Min}} + M_{\text{Max}})/2$$

For example, if M_{Min} is equal to 40 dB EM and M_{Max} is equal to 80 dB EM, then M_{Mid} , the masking level that falls at midplateau, is 60 dB EM. When a masking level falls at the middle of the acceptable masking range (i.e., midmasking level), then the risk of undermasking and overmasking is minimized (Studebaker, 1962). It should be noted that midplateau actually represents a range of values surrounding the midmasking level. Consequently, there is some flexibility in using a somewhat higher or lower masking level.

Yacullo (1999) states that there are two major advantages of the midplateau masking procedure. First, IA is eliminated as a source of error when determining an appropriate masking level. Masking levels are often determined using very conservative estimates of IA. However, IA has equal yet opposite effects on minimum and maximum masking levels. Although the value of IA used for determining minimum and maximum masking levels will influence the width of the masking plateau, the midmasking level remains the same.

Second, midmasking level can be determined for both threshold and suprathreshold speech measures by using the same formula approach (Konkle and Berry, 1983). The midplateau procedure avoids a potential problem during measurement of suprathreshold speech recognition that is related to calibration of EM level and percent correct response criterion. Recall that EM level for speech is specified relative to the SRT (i.e., 50% correct recognition of spondaic words) (ANSI/ASA, 2010). Suprathreshold speech recognition performance, however, can range from 0% to 100%. Konkle and Berry (1983) indicate that a major advantage of the midplateau procedure is that the middle of the masking plateau (i.e., the optimal masking level) is not influenced by different listener response criteria used during assessment of threshold and suprathreshold speech recognition. The reader is referred to Konkle and Berry (1983) and Studebaker (1979) for more detailed discussion.

Studebaker (1979) has described a somewhat different acoustic masking procedure for use during speech audiometry that is consistent with the goal of selecting a masking level that occurs at midplateau. Specifically, the recommended masking level is equal to the presentation level of the speech signal in dB HL at the test ear, adjusted appropri-

ately for air-bone gaps in the test and nontest ears. In cases where there are no air-bone gaps in either ear, the selected masking level is simply equal to the HL of the speech signal. To avoid the use of very high levels of contralateral masking that can sometimes result, Studebaker indicates that it is permissible to reduce the masking level by 20 to 25 dB below the presentation level of the speech signal. The reader is referred to Studebaker (1979) for a more comprehensive discussion.

According to the results of a survey of audiometric practices in the United States, many audiologists “base their masking level for word-recognition testing on the stimulus level presented to the test ear and subtract a set amount, such as 20 dB” (Martin et al., 1998, p 100). Although selection of a masking level that is equal to the presentation level at the test ear minus 20 dB may appear somewhat arbitrary, it can actually be supported by sound theoretical constructs.

Yacullo (1996, 1999) has described a simplified approach, based on the underlying concepts of both the midplateau and Studebaker acoustic procedures, that can be used when selecting contralateral masking levels during speech audiometry. Although this approach was originally described for use during assessment of suprathreshold speech recognition (Yacullo, 1996), it also proves equally effective during measurement of SRT (Yacullo, 1999). Stated simply, EM level is equal to the presentation level of the speech signal in dB HL at the test ear minus 20 dB:

$$\text{dB EM} = \text{Presentation Level}_{\text{Test Ear}} - 20 \text{ dB}$$

Given two prerequisite conditions (which will be discussed shortly), the selected masking level will fall approximately at midplateau. Unfortunately, inappropriate use of this simplified approach can result in undermasking or overmasking.

Jerger and associates (Jerger and Jerger, 1971; Jerger et al., 1966) appear to be the first to report the use of a masking procedure that involved presenting contralateral masking noise at a level 20 dB less than the presentation level of the speech signal at the test ear. Specifically, it was reported that “whenever the speech level to the test ear was sufficiently intense that the signal might conceivably cross over and be heard on the nontest ear, the latter was masked by white noise at a level 20 dB less than the speech presentation level on the test ear” (Jerger and Jerger, 1971, p 574). It should be noted, however, that Jerger and associates used white noise as a contralateral masker rather than the typically used speech spectrum noise. In addition, the white noise was not calibrated in EM level for speech.

More recently, Hannley (1986) and Gelfand (2009) have discussed briefly the simplified approach to masking. Gelfand indicates, however, that using an EM level equal to the HL of the speech signal at the test ear minus 20 dB generally proves most effective in cases of sensory/neural hearing loss. In fact, the desired outcome may not occur when

there are significant air-bone gaps in the nontest ear (e.g., conductive hearing loss).

Yacullo (1999) states that the simplified masking procedure when used appropriately can significantly reduce the calculations required for the determination of optimal (i.e., midmasking) masking level. Specifically, the method proves effective given the following two conditions: (1) There are no significant air-bone gaps (i.e., ≥ 15 dB) in either ear and (2) speech is presented at a moderate SL (i.e., 30 to 40 dB SL) relative to the measured or estimated SRT. If these two prerequisites are met, then the selected masking level should occur approximately at midplateau.

Acoustic masking procedures are recommended when assessing threshold and suprathreshold speech recognition. The following two examples help illustrate the use of the midplateau masking procedure, as well as the simplified approach when applicable, for measurement of suprathreshold speech recognition and SRT.

The example presented in Figure 6.14 illustrates the use of the midplateau masking procedure during assessment of suprathreshold speech recognition. Puretone testing reveals a mild, sensory/neural hearing loss of flat configuration in the right ear. There is a moderate-to-severe, sensory/neural hearing loss of gradually sloping configuration in the left ear. SRTs were measured at 35 dB HL in the right ear and 55 dB HL in the left ear, findings that support the puretone results. Suprathreshold speech recognition will be assessed at 40 dB SL using Central Institute for the Deaf (CID) W-22 monosyllabic word lists.

Let us first consider the situation where supra-aural earphones are being used during audiometry. Contralateral masking will be required only when measuring suprathreshold speech recognition in the left ear. Specifically, the presentation level of 95 dB HL (i.e., SRT of 55 dB HL + 40 dB SL) exceeds the best bone-conduction threshold of 30 dB HL in the nontest ear by a conservative estimate of IA for speech (i.e., 40 dB):

$$\text{Presentation Level}_{\text{Test Ear}} - \text{Best BC}_{\text{Nontest Ear}} \geq \text{IA}$$

$$95 \text{ dB HL} - 30 \text{ dB HL} \geq 40 \text{ dB}$$

$$65 \text{ dB HL} \geq 40 \text{ dB}$$

We will use the midplateau masking procedure to select an appropriate contralateral masking level. Remember that the midplateau masking procedure involves a three-step process: Calculation of (1) minimum masking level (M_{Min}), (2) maximum masking level (M_{Max}), and (3) midmasking level (M_{Mid}):

$$\begin{aligned} M_{\text{Min}} &= \text{Presentation Level}_{\text{Test Ear}} - \text{IA} \\ &\quad + \text{Largest Air-Bone Gap}_{\text{Nontest Ear}} \\ &= 95 \text{ dB HL} - 40 \text{ dB} + 5 \text{ dB} \\ &= 60 \text{ dB EM} \end{aligned}$$

$$\begin{aligned} M_{\text{Max}} &= \text{Best BC}_{\text{Test Ear}} + \text{IA} - 5 \text{ dB} \\ &= 45 \text{ dB HL} + 40 \text{ dB} - 5 \text{ dB} \\ &= 80 \text{ dB EM} \end{aligned}$$

$$\begin{aligned} M_{\text{Mid}} &= (M_{\text{Min}} + M_{\text{Max}})/2 \\ &= (60 + 80)/2 \\ &= 70 \text{ dB EM} \end{aligned}$$

An EM level of 70 dB is appropriate for three reasons. First, it occurs at midplateau. Second, it occurs at least 10 dB above the calculated minimum. Remember that a safety factor of at least 10 dB or greater should be added to the calculated minimum value to account for intersubject variability with respect to masker effectiveness (Martin, 1974; Studebaker, 1979). Finally, it does not exceed the calculated maximum masking level.

It should be noted that the width of the masking plateau is typically underestimated when a conservative estimate of IA is used for determining the minimum and maximum masking levels. If IA is actually greater than the conservative estimate of 40 dB, then the width of the masking plateau will increase. For example, if this patient actually exhibits IA for speech of 55 dB (rather than the conservative estimate of 40 dB), then the minimum level will be decreased and the maximum level will be increased by the same amount (i.e., 15 dB). Although the width of the masking plateau increases, the midmasking level remains the same. As stated earlier, a major advantage of the midplateau method is that IA is eliminated as a source of error when selecting an appropriate masking level.

We now will take another look at the example presented in Figure 6.14 and substitute 3A insert earphones for the supra-aural arrangement. Contralateral masking will also be required when assessing suprathreshold speech recognition in the left ear. The presentation level of 95 dB HL (i.e., SRT of 55 dB HL + 40 dB SL) exceeds the best bone-conduction threshold of 30 dB HL in the nontest ear by a conservative estimate of IA for speech (i.e., 60 dB). We will again use the midplateau masking procedure to select an appropriate level of contralateral masking. The calculations are the same for both supra-aural and 3A insert earphones with the exception that an IA value of 60 dB will be substituted in our equations for minimum and maximum masking levels. Masking levels for use with insert earphones are summarized below:

$$M_{\text{Min}} = 40 \text{ dB EM}$$

$$M_{\text{Max}} = 100 \text{ dB EM}$$

$$M_{\text{Mid}} = 70 \text{ dB EM}$$

It should be apparent that an increase in IA has equal yet opposite effects on the minimum and maximum

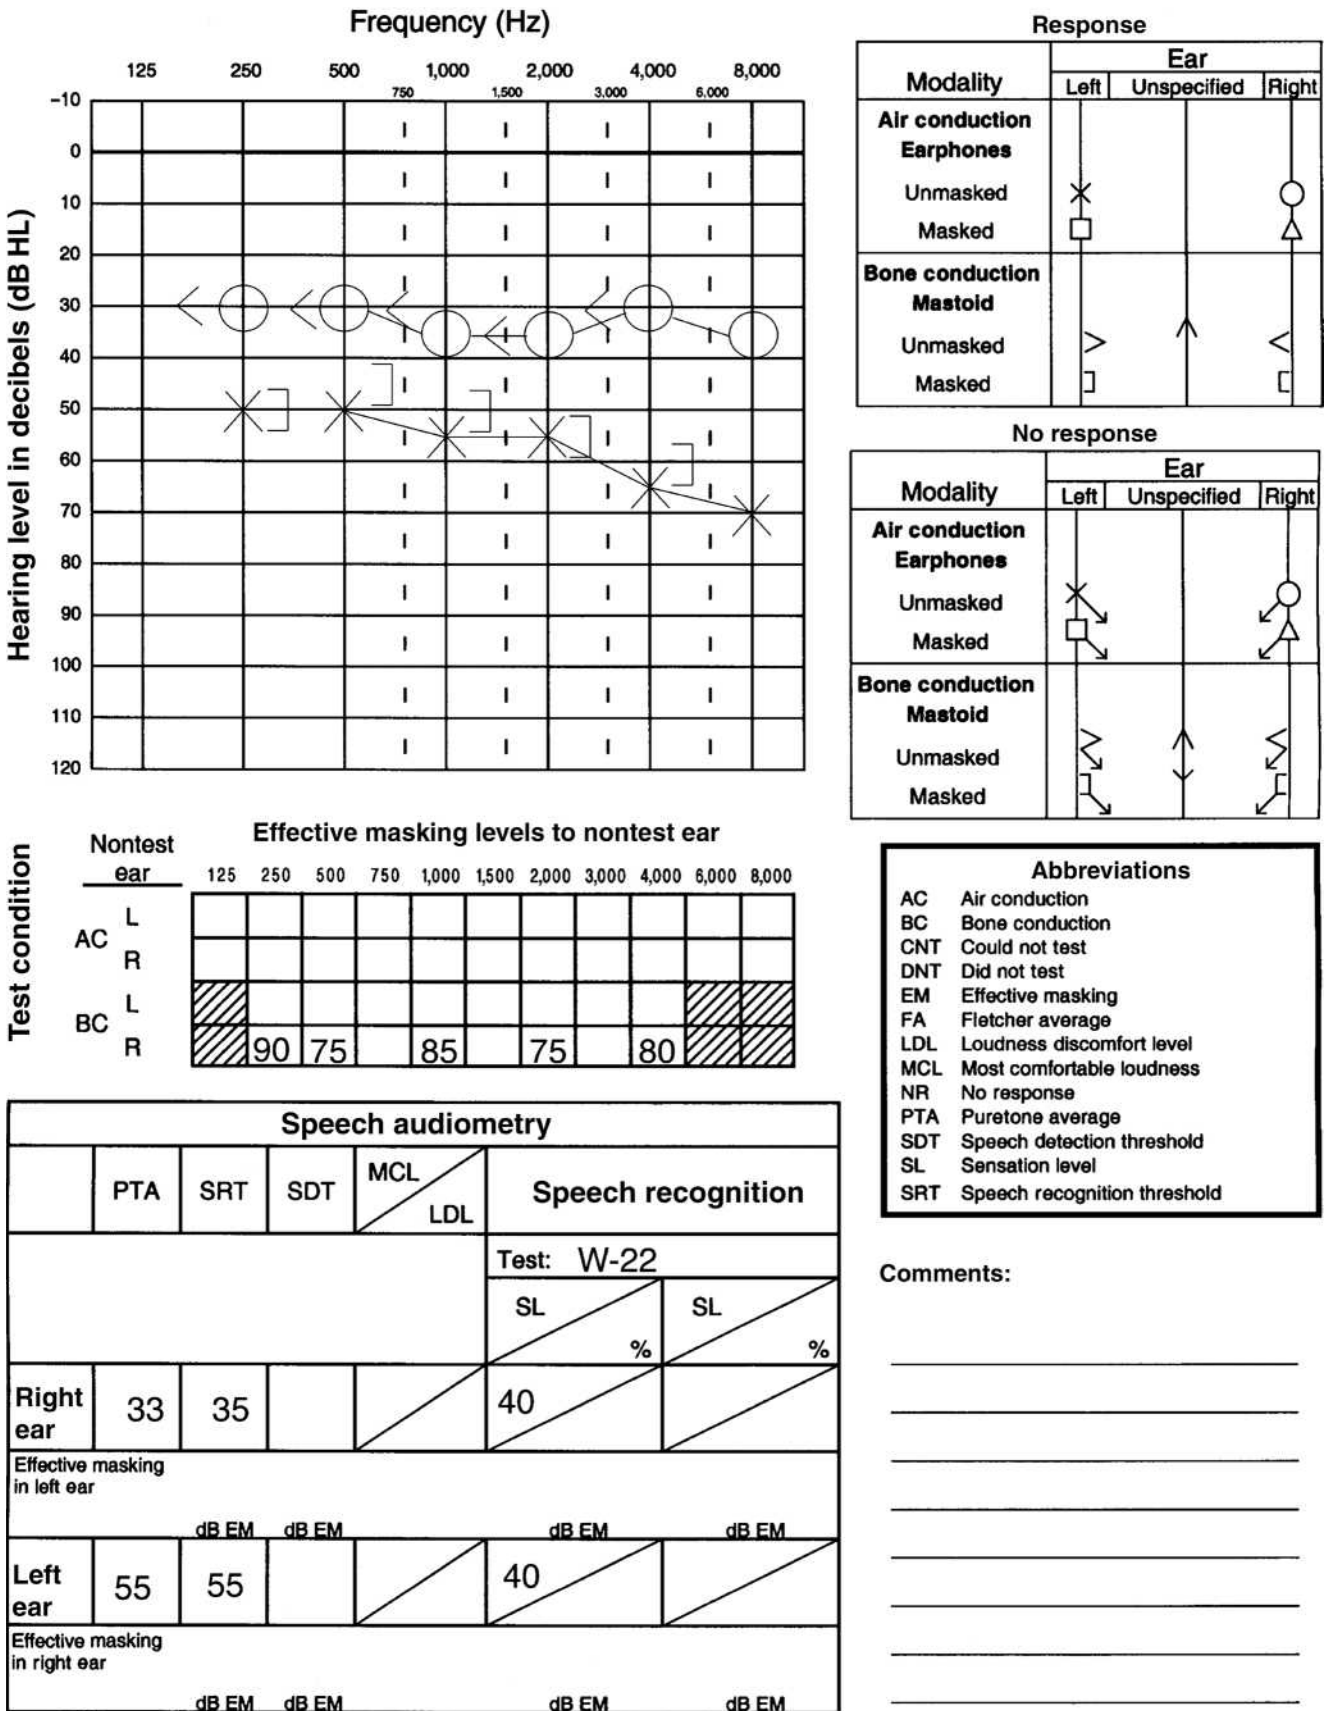

FIGURE 6.14 An example illustrating the use of the midplateau and simplified masking procedures during assessment of suprathreshold speech recognition.

masking levels. Because IA is increased by 20 dB when using insert earphones, the width of the masking plateau is increased by 40 dB. The midmasking level, however, remains the same.

We now will take one final look at the example presented in Figure 6.14 and consider the use of the simplified masking approach. Because the two prerequisite conditions are met, the simplified approach should result in the selection of an optimal masking level (i.e., midmasking level). Recall that EM level is simply calculated as the presentation level of the speech signal in dB HL at the test ear minus 20 dB. The same equation will be applicable when using any earphone (i.e., 3A and supra-aural):

$$\begin{aligned} \text{dB EM} &= \text{Presentation Level}_{\text{Test Ear}} - 20 \text{ dB} \\ &= 95 \text{ dB HL} - 20 \text{ dB} \\ &= 75 \text{ dB} \end{aligned}$$

It should be noted that the masking level of 75 dB EM calculated using the simplified approach is in good agreement (i.e., ± 5 dB) with the value (i.e., 70 dB EM) determined using the midplateau procedure. Yacullo (1999) indicates that there are two major advantages to using the simplified masking approach with 3A insert earphones, which are the result of a wider masking plateau. First, there is greater flexibility in deviating somewhat from the calculated midmasking level while still remaining within an acceptable range of midplateau. It should be noted that the midplateau actually represents a small range of values surrounding the midmasking level. This range of acceptable values essentially increases when using 3A insert earphones. The use of the simplified masking approach can sometimes result in the selection of high masking levels, even though overmasking is not occurring. Consequently, the audiologist can justify subtracting a value of greater than 20 dB (e.g., 25 or 30 dB) from the presentation level at the test ear when using insert earphones. In the example presented in Figure 6.14, an EM level equal to the presentation level in the test ear minus 25 or 30 dB (e.g., 65 or 70 dB EM) would still result in an acceptable masking level that falls within the vicinity of midplateau, yet clearly exceeds the minimum level by a sizeable amount.

Second, there is greater flexibility in deviating slightly from the recommended prerequisite conditions (i.e., no air-bone gaps in either ear, use of moderate SLs) while still remaining within an acceptable range of midplateau and without significantly increasing the potential for overmasking. Consequently, there is greater margin for error when selecting an appropriate level of masking.

The example presented in Figure 6.15 illustrates the application of the midplateau and simplified masking procedures during measurement of SRT. Audiometry was performed using 3A insert earphones. Puretone testing reveals normal hearing in the right ear. There is a severe sensory/neural hearing loss of flat configuration in the left ear. Based on the puretone findings, it is predicted that SRTs will be

measured at approximately 0 dB HL in the right ear and 70 dB HL in the left ear. Prior to measurement of speech thresholds, we can accurately predict whether contralateral masking will be required. Contralateral masking will be required only when measuring SRT in the left ear because the estimated speech threshold of 70 dB HL exceeds the best bone-conduction threshold of 0 dB HL in the nontest ear by a conservative estimate of IA for speech (i.e., 60 dB). An unmasked SRT is subsequently measured in the left ear at 0 dB HL, a finding consistent with the puretone results.

It has already been demonstrated that the simplified masking procedure proves very effective during assessment of suprathreshold speech recognition. However, it can also be applied effectively during measurement of SRT. When selecting an appropriate contralateral masking level when measuring SRT, it is important to consider not only the HL at which the speech threshold is finally established, but also the highest presentation levels used throughout the threshold procedure. Regardless of the SRT procedure used, spondaic words are presented typically at both suprathreshold and threshold levels.

For example, ASHA (1988) recommends a descending threshold technique for measuring SRT that is based on the earlier work of others (Hirsh et al., 1952; Hudgins et al., 1947; Tillman and Olsen, 1973; Wilson et al., 1973). The initial phase involves familiarizing the patient with the spondaic words at a comfortable, suprathreshold HL. (Familiarization with test words is strongly recommended regardless of the SRT procedure.) The preliminary phase involves setting the HL to 30 to 40 dB above the estimated or predicted SRT before descending in 10-dB decrements until two words are missed. In fact, an HL of 30 to 40 dB above the predicted SRT typically results in a comfortable listening level for most patients during the familiarization phase. The test phase involves initially presenting test words at HLs approximately 10 dB higher than the calculated SRT. The calculation of threshold, based on a statistical precedent, takes into account the patient's responses at higher HLs.

Consider again the example presented in Figure 6.15. If the ASHA-recommended procedure is used to measure SRT, then the highest HLs employed (during the familiarization and preliminary phases) will be about 30 to 40 dB above the estimated SRT. In this example, we will use a moderate SL of 30 dB above the estimated SRT (i.e., 70 dB HL + 30 dB SL = 100 dB HL) during the familiarization and preliminary phases.

The use of the simplified approach to selecting an appropriate level of contralateral masking should prove effective in this case because both prerequisite conditions have been met. First, there are no significant air-bone gaps in either ear. Second, speech is presented at a moderate SL (i.e., 30 dB) when the highest HLs are used during the test procedure (i.e., familiarization and preliminary phases). Assuming that 100 dB HL is the highest presentation level

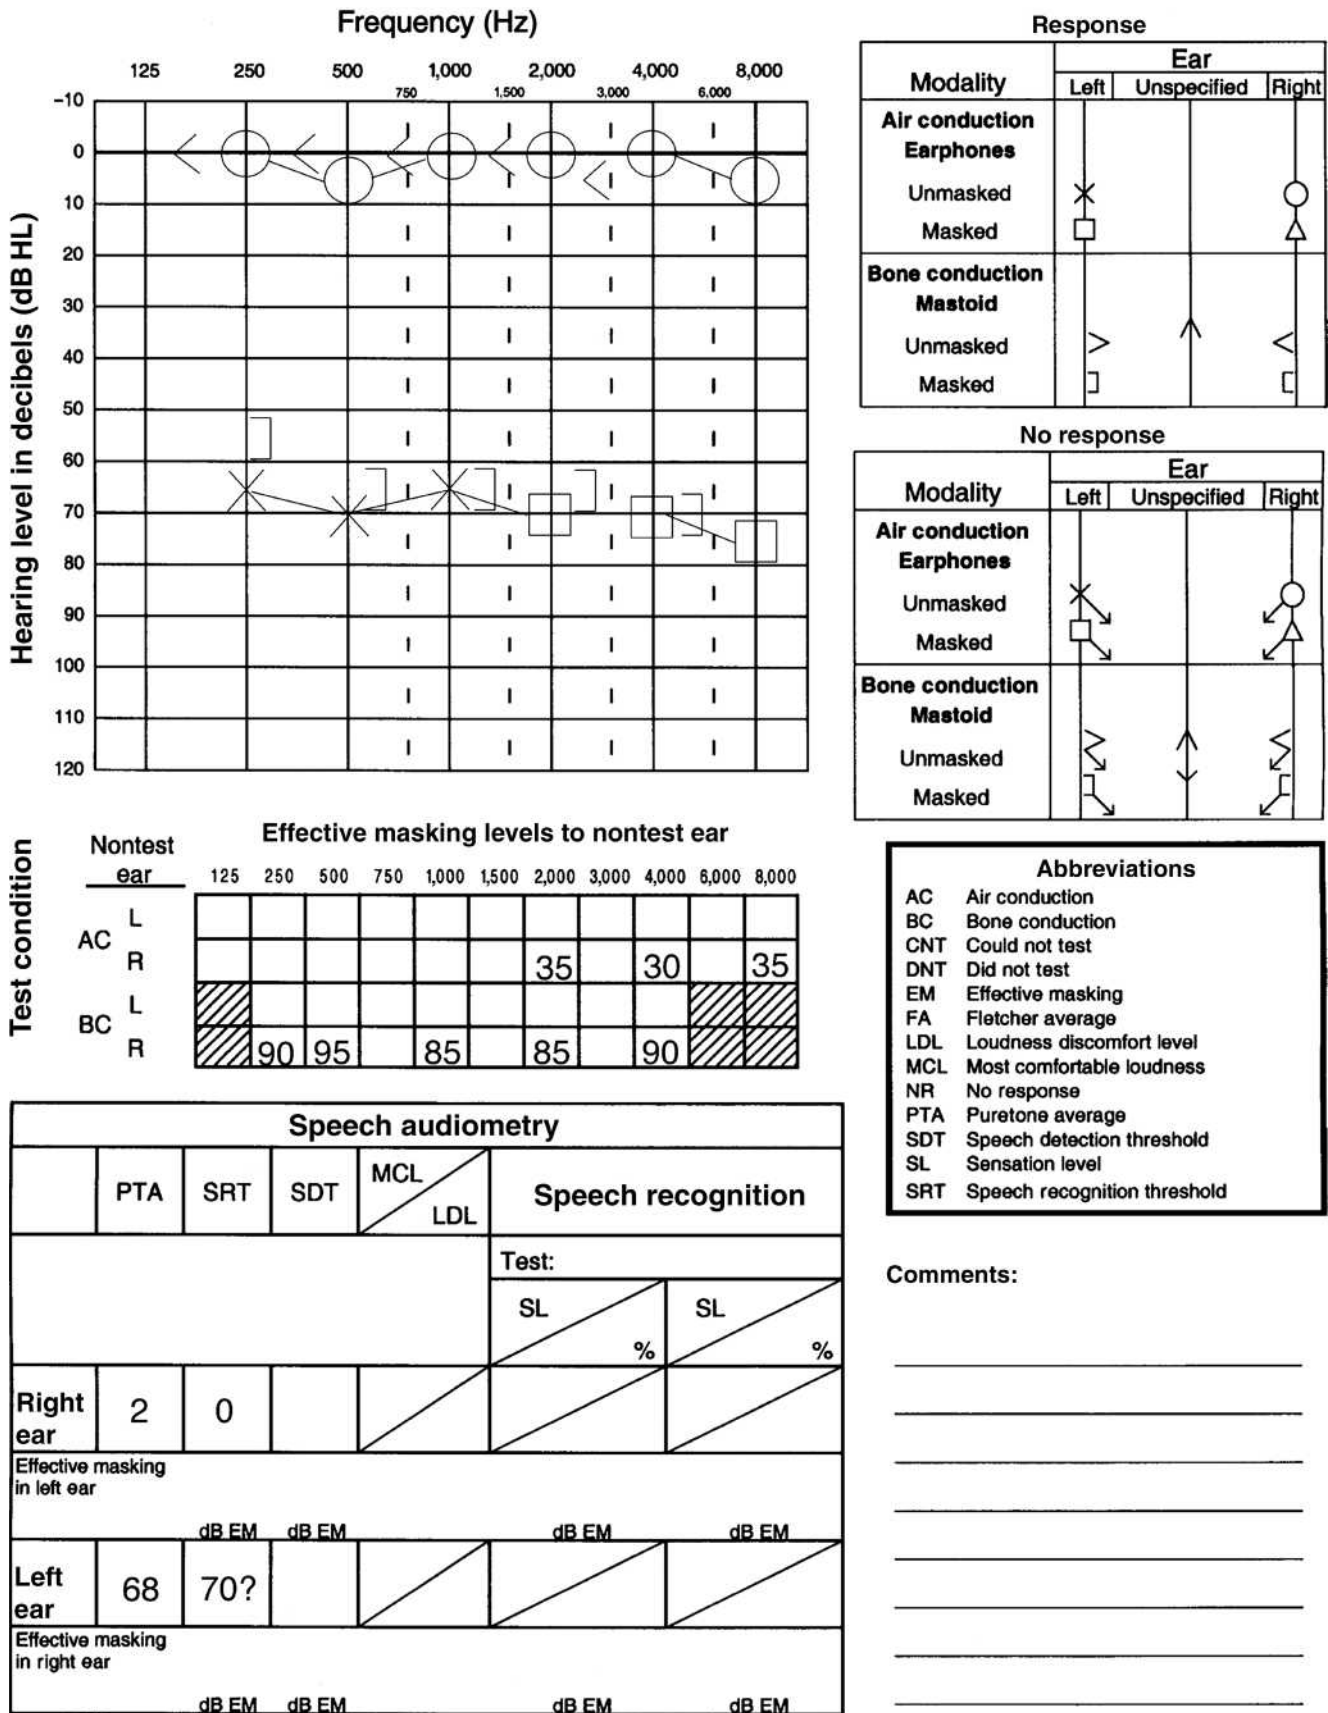

FIGURE 6.15 An example illustrating the use of the midplateau and simplified masking procedures during assessment of speech recognition threshold.

used during our test procedure, then EM level in the nontest ear is calculated as follows:

$$\begin{aligned}\text{dB EM} &= \text{Presentation Level}_{\text{Test Ear}} - 20 \text{ dB} \\ &= 100 \text{ dB HL} - 20 \text{ dB} \\ &= 80 \text{ dB}\end{aligned}$$

We can verify the appropriateness of the selected masking level by using the midplateau method:

$$\begin{aligned}M_{\text{Min}} &= \text{Presentation Level}_{\text{Test Ear}} - \text{IA} \\ &\quad + \text{Largest Air-Bone Gap}_{\text{Nontest Ear}} \\ &= 100 \text{ dB HL} - 60 \text{ dB} + 0 \text{ dB} \\ &= 40 \text{ dB EM}\end{aligned}$$

$$\begin{aligned}M_{\text{Max}} &= \text{Best BC}_{\text{Test Ear}} + \text{IA} - 5 \text{ dB} \\ &= 55 \text{ dB HL} + 60 \text{ dB} - 5 \text{ dB} \\ &= 110 \text{ dB EM}\end{aligned}$$

$$\begin{aligned}M_{\text{Mid}} &= (M_{\text{Min}} + M_{\text{Max}})/2 \\ &= (40 + 110)/2 \\ &= 75 \text{ dB EM}\end{aligned}$$

The masking level of 80 dB EM selected using the simplified approach is in good agreement (i.e., ± 5 dB) with the value determined using the midplateau approach (i.e., 75 dB EM). Although spondee words will be presented at lower HLs when measuring the SRT, it is not necessary to decrease the original level of masking. First, the selected masking level is appropriate for the highest HLs used during all phases of threshold determination. Second, the selected masking level does not exceed the maximum masking level (i.e., overmasking will not occur).

It can be argued that the simplified approach (as well as the midplateau method) can result in the use of unnecessarily high masking levels during measurement of SRT. As was discussed earlier, the midplateau represents a range of masking levels. The audiologist can justify subtracting a value of greater than 20 dB (e.g., 25 or 30 dB) from the presentation level at the test ear, particularly when using insert earphones. In this example, a masking level of 70 or 75 dB EM (rather than the original level of 80 dB EM) still falls within an acceptable range of midplateau, while still occurring significantly higher than the minimum.

Yacullo (1999) states that the simplified masking approach during speech audiometry has wide applicability. First, it can be used with a large and diverse patient population, including those with normal hearing and sensory/neural hearing loss. Second, it can be used equally effectively when using either supra-aural or insert earphones. Third, the procedure can be used in clinical situations where moderate SLs are used. For example, the majority of audiologists in the United States continue to adminis-

ter suprathreshold word recognition tests at a specified SL referenced to the SRT (Martin and Morris, 1989; Martin et al., 1994, 1998), typically 30 or 40 dB (Martin and Morris, 1989; Martin et al., 1994). Finally, it can be applied effectively during both threshold and suprathreshold measures of speech recognition.

Direct calculation of midmasking level is strongly recommended in cases where there is potential risk of overmasking. Yacullo (1999) states that any factor that increases minimum masking level or decreases maximum masking level will reduce the width of the masking plateau and increase the probability of overmasking. For example, the presence of significant air-bone gaps in the nontest ear and/or the use of higher SLs (i.e., ≥ 50 dB) will increase minimum masking level. The presence of significant air-bone gaps in the test ear will decrease maximum masking level. In cases where the masking plateau is either very narrow or nonexistent (e.g., unilateral or bilateral conductive hearing loss), knowledge about minimum and maximum masking levels will allow the clinician to make well-informed decisions about appropriate contralateral masking levels.

FOOD FOR THOUGHT

1. Discuss how IA influences decisions about the need for contralateral masking during puretone and speech audiometry.
2. Discuss how the OE influences measured IA for air-conduction transducers (i.e., supra-aural and 3A insert earphones with deeply inserted foam eartips). How does the OE influence contralateral masking levels during bone-conduction audiometry?
3. The plateau masking procedure originally was described by Hood as a method for contralateral masking during puretone threshold audiometry. Discuss how the underlying principles of the masking plateau are applied to procedures for contralateral masking during speech audiometry.

Case History

Douglas L. Beck

INTRODUCTION

Audiologists must critically and judiciously gather and examine all information related to sound perception, tinnitus, hearing, hearing loss, listening (in quiet and noise), dizziness, balance problems, and birth history (for newborns and infants). The audiologist creates and interprets anatomic and physiologic information within the context of a case history, to render an appropriate diagnosis. Audiologists are charged with the responsibility of diagnosing and “nonmedically” treating hearing loss. Traditional wisdom reveals two key ingredients to a correct differential diagnosis: An excellent case history and a thorough physical examination. Given these two key ingredients, the differential diagnosis “emerges” to the trained professional as the only clear answer (i.e., a single differential diagnosis) or potentially a series of equally plausible diagnoses emerge, indicating multiple remaining questions and avenues to be explored and resolved. Indeed, case history gathering is an important skill which facilitates the correct differential diagnosis if the clinician obtains relevant and focused information. Obtaining and using the case history requires skill, patience, practice, and knowledge.

In general, if you’re not looking for something, you won’t find it. However, simply looking for something doesn’t mean you will find it. For example, if you’re looking for zebras in a cow pasture, you probably won’t find them. Of course this doesn’t mean zebras don’t exist. However, it may indicate zebras generally don’t hang out in cow pastures. To find the correct solution to a given problem, we must pose the right question, formulate reasonable options and alternatives, and ultimately, choose the most probable alternative.

When gathering and assembling case histories, healthcare professionals must narrow the focus and filter the information available quickly and efficiently while pulling together what is most important. The case history questions should be reasonable, and result driven, allowing for an evidence-based outcome.

Across healthcare disciplines (including audiology), the method of choice for obtaining the case history is the “medical model.” The medical model efficiently directs the professional to the “chief complaint” (CC) and helps organize information into a rational hierarchy with the most important or likely concerns at the forefront.

Researchers have designed decision trees and analysis weightings and other complex models which are powerful and accurate and, theoretically, will assist in finding the correct diagnosis. However, when the audiologist is working with the patient, assembling the case history is essentially a person-to-person event. Frankly, having good people skills and adjusting our approach (i.e., course corrections) to the client we are addressing, matter a great deal.

CASE HISTORY TOOLS

There are three primary tools used to create a case history: Interviews, questionnaires, and the subjective, objective, assessment, and plan (SOAP) format. These three tools are often used in tandem, but can certainly be used as preferred by the professional.

The audiologist, as a licensed or regulated healthcare professional, has a legal obligation to the patient’s health and well-being. The audiologist must be aware of the warning signs of dangerous and treatable medical and surgical conditions and should refer to the appropriate professional when “red flags” are noticed. Red flags include a sudden hearing loss, ear pain, draining or bleeding ears, unilateral symptoms of hearing loss or tinnitus, conductive hearing loss, dizziness, and other referral criteria. Assembling the case history provides an opportunity to identify red flags while considering a multitude of diagnostic and treatment alternatives.

Interview Techniques

Of course, there is no “one correct way” to interview patients. Flexibility is the key, as professionals, patients, work settings, and the particulars of each situation vary. Nonetheless, it is always a good idea to proceed in an orderly and professional manner. Interviews should be patient centered, friendly, and private, in accordance with applicable laws, rules, and regulations.

While gathering the case history, ascertaining an “index of suspicion” regarding the CC is an important part of the interview. If the index of suspicion for the item highest on our list is low, we generally need to look for more probable alternatives. If the index of suspicion is high, we ask further questions to confirm or refute our suspicions.

For example, a patient presenting with a fluctuating low-frequency sensory/neural hearing loss (SNHL) and tinnitus in the same ear, with aural fullness and occasional vertigo, has a low index of suspicion for otosclerosis, but has a reasonably high index of suspicion for Ménière's disease. The high index of suspicion for Ménière's disease would lead us to ask probing questions to note whether the presenting symptomatology is in agreement with a Ménière's diagnosis or would lead us in another direction, such as an acoustic neuroma.

The competent professional understands the probabilities of certain things occurring and the related signs and symptoms of each. Although Ménière's disease is a relatively rare disorder, occurring in less than 1% of the general population, it is a common diagnosis for patients with the symptoms described earlier. Of course, we do not make a medical diagnosis of a disease. However, if the data come together with what we know about the patient the audiologist might include "Consistent with Ménière's disease," in the report.

Three scenarios follow to illustrate the interview technique.

SCENARIO ONE

Review any/all assembled paperwork (chart, lab notes, test results, history, etc.) before meeting the patient for the initial consultation. Shake hands and greet the patient, their spouse, significant other, family, and so on, and always introduce yourself. This is an amazingly simple protocol, but it is often overlooked, and when it is overlooked, it sets an unprofessional tone for the rest of the encounter. I usually say, "Good morning. My name is Dr. Beck, I'm an audiologist. Please come in Mr. Smith."

After exchanging greetings and after sitting down in the office, inquire as to why the patient scheduled today's visit.

"Thanks for coming in today Mr. Smith. What brings you to the office?"

Mr. Smith: "I would like a comprehensive audiometric evaluation to confirm my bilateral sensory/neural noise-induced hearing loss that my otolaryngologist diagnosed last week. I am very interested in acquiring two digital hearing aids, and by the way, I am wealthy and do not have insurance. I pay cash, and money is no object. I want to hear everything as best I can."

Because this patient has already been seen and diagnosed by the ear, nose, and throat (ENT) specialist, the index of suspicion for some other disease process or a medical/surgical issue is extremely low.

SCENARIO TWO

Mr. Smith: "Well doc, you know how it is. My wife always complains I have the TV up too loud and it drives her outta the room. I like to be able to hear the darn thing so I keep it a

little loud. The same thing happens with the car radio when we're driving to the store. When she sets the volume, I just hear noise and can't tell anything about what they're saying. When I was a boy, I could hear a pin drop from 40 paces."

"I understand. How long have you been playing the TV and radio louder than your wife likes it?"

"Let's see, I started working at the steel fabrication factory 14 years ago, and my son was born 8 years ago....so yeah, it's been at least 8 or 10 years. When I let her set the volume, I can hear the voices, but I really can't understand what they're saying. That drives me nuts. I told her and I'm telling you too, I ain't gonna wear no hearing aids."

Given the information presented in this scenario, one can make several, reasonable, assumptions. We could assume that Mr. Smith has a noise-induced SNHL, likely impacting 4,000 Hz, and because he cannot hear the consonant sounds (high frequencies), he cannot clearly understand the words spoken to him. We might also assume that Mr. Smith is not going to wear hearing aids and that there is little we can do to assist. However, there are other options and protocols to employ:

"Mr. Smith, have you had a hearing test before?"

"Not since the Army, back some 20 years ago."

"Do both ears seem about the same, or is one ear better than the other?"

"The left ear is terrible—can't hear thunder with that one."

"I see. Do you have any ear pain?"

"None at all. My ears feel fine."

"Okay then. May I take a look?"

"Sure, help yourself."

At this point, the audiologist has a rather low index of suspicion for a tumor, such as an acoustic neuroma, because they occur in about 0.00001% of the population, but a higher index of suspicion for more likely possibilities, including a unilateral sudden sensory/neural loss that went undiagnosed (or maybe Mr. Smith works with his left ear toward a loud machine while wearing hearing protection only in the right ear, or perhaps he experienced head trauma on the left or an explosion near his left side during boot camp; there are lots of possibilities). The examination of the pinna, concha, ear canal, and tympanic membranes is normal. The audiologist says, "Okay, your ears look fine," and the interview continues to determine which diagnosis has the highest index of suspicion.

"Mr. Smith, let me make sure I understand... the right ear is the better ear and the left ear has been bad for a long time. Have you ever had the left ear checked?"

"Yes. I had the doctor look at it a year or two ago when it went bad. He put me on antibiotics and that was the end of it. It didn't get better though, so I left it alone."

“Okay. What about drainage, anything coming out of your ears?”

“No sir.”

“Any dizziness or spinning sensations?”

“Not any more. Well, maybe a little. When my left ear was going bad, I had some dizziness, but the doctor looked at it and put me on antibiotics, and the dizziness got better after a while.”

“So the dizziness started and the left ear went bad all about a year or two ago?”

“That’s right.”

“Okay, very good. Are you on any medications?”

“Just a cholesterol pill and a baby aspirin, that’s about it.”

“Okay, and one last thing I’d like to ask you before we do the hearing test—do you have any ringing or buzzing noises in your ears?”

“Yeah, the darn left ear can’t hear anything, but it sure makes a racket. Kinda like a “shhhhh” noise going on in there. Keeps me up at night sometimes.”

The audiologist does a comprehensive audiometric evaluation and determines the following audiometric profile:

Right ear: Normal peripheral hearing. Tympanogram normal (type A), ipsilateral reflexes within normal limits (WNL). Word recognition score (WRS) = 96%. Speech reception threshold (SRT) = 15 dB HL.

Left ear: Flat 85 dB sensory/neural (SN) loss. Tympanogram normal (type A), ipsilateral reflexes absent @105 dB stimulus level. WRS = 8%, SRT = SAT (speech awareness threshold used because speech understanding was extremely poor) = 80 dB HL.

The index of suspicion for a left retrocochlear disorder is very high at this point. The case history supports this possibility, and the test results indicate a possible retrocochlear diagnosis for the left ear.

The audiologist refers the patient to an otolaryngologist (preferably an otologist or neurotologist) based on the high index of suspicion for a retrocochlear hearing loss. The otologist meets with and interviews the patient and refers the patient for a magnetic resonance imaging (MRI) study with contrast (gadolinium). A 3-cm vestibular schwannoma (acoustic neuroma) is diagnosed. Mr. Smith is scheduled for surgery 3 weeks later, and the tumor is removed via the translabyrinthine approach.

SCENARIO THREE

Mr. Smith: “Let’s see, I started working at this really noisy factory 14 years ago, and my son was born 8 years ago...

so yeah, it’s been at least 8 or 10 years. When my wife sets the TV, it sounds like everyone is mumbling; I can hear the voices, but I really can’t understand what they’re saying. That drives me nuts. I told her and I’m telling you too, I ain’t gonna wear no hearing aids.”

Given the information presented above, one can make several assumptions. We could assume Mr. Smith has a noise-induced SNHL, impacting frequencies around 4,000 Hz, and because of the reduced amplitude and distortion affecting mostly the high-frequency consonant sounds, he cannot clearly hear the words spoken to him. We can also be comfortable in thinking that Mr. Smith is not going to wear hearing aids, which reduces what we can do to assist him. However, there are other options and protocols to explore.

“Mr. Smith, have you had a hearing test before?”

“Not since the Army, back some 20 years ago.”

“Do both ears seem about the same, or is one ear better than the other?”

“They’re just about the same”

“I see. Any ear pain?”

“None at all. My ears feel fine.”

“That’s good. May I take a look?”

“Sure doc, knock yourself out.”

The pinna, concha, ear canal, and tympanic membranes are normal in appearance. The audiologist says, “Your ears look fine,” and the interview continues.

“Okay, what about drainage? Is there anything coming out of your ears?”

“No sir.”

“Any dizziness or spinning sensations?”

“Nope.”

“Very good. Are you taking any medications?”

“Just a cholesterol pill and a baby aspirin, that’s about it.”

“The last question I’d like to ask you before we do the hearing test is do you have any ringing or buzzing noises in your ears?”

“Yeah...maybe a little when it’s really quiet, nothing that really bothers me though.”

The audiologist does a comprehensive audiometric evaluation and determines the following audiometric profile:

Right ear: Moderate high-frequency sensory/neural hearing loss. Tympanogram normal (type A), ipsilateral reflexes are within normal limits (WNL). WRS = 96%. SRT = 45 dB HL.

Left ear: Moderate high-frequency sensory/neural hearing loss. Tympanogram normal (type A), ipsilateral reflexes are WNL. WRS = 92%. SRT = 45 dB HL.

“Mr. Smith, I’d like to review the results of today’s tests with you. Would you like to have your wife join us while I review the results?”

“Sure, that would be great. She’s in the waiting room.”

“Hi Mrs. Smith, please join us while I review the results of today’s examination. This way, the two of you will have the chance to learn about the results, and I can address your questions.”

In this third scenario, the index of suspicion for a noise-induced hearing loss is high, and there are no red flags and no indications of a medical or surgical problem. In essence, the same patient, in three different scenarios, has three separate sets of circumstances, each of which are typically revealed through an interview-based case history, which is more or less driven by the index of suspicion.

Questionnaires

Another very useful and efficient case history tool is the health questionnaire. A well-designed questionnaire is highly focused, simple, takes just a few minutes to fill out, and quickly directs the professional to the area(s) of greatest concern. Questionnaires regarding hearing health care can be presented to patients verbally or written. Written questionnaires are available in electronic and paper-based formats.

However, it is my personal preference to not have patients fill in downloadable, lengthy questionnaires at home. It is terrifically advantageous for the audiologist to spend the time working through a well-designed questionnaire with the patient, to establish rapport and trust and to allow the patient to tell their story. We learn much more about the patient and their situation when we put in the time to ask questions and listen to the patient and then write chart notes reflecting that conversation. Time spent asking questions and listening to and then questioning and clarifying their response is time well spent.

VERBAL PRESENTATIONS

Remember, if you are giving a patient a verbal presentation of a hearing questionnaire, there is already a reasonable index of suspicion for hearing loss. Therefore, sit about 3 ft away from the patient in a well-lit room, face the patient, be sure there is no background noise or visual distractions, and maintain the patient’s full attention.

PENCIL AND PAPER PRESENTATIONS

Keep in mind that, because the majority of patients seen by audiologists are over 55 years of age, large font, dark print, and maximal contrast between the printed words and the

background page are preferred and appreciated. Black print on a white background will be the easiest to read. Another important consideration is to use and/or design questionnaires that are easily assessed and tabulated, so the professional can scan the page to find the “positive” results, which will need to be considered.

In 2005, the Centers for Medicare and Medicaid Services (CMS) added a new benefit under Medicare Part B that will likely increase the quantity of pencil and paper-based hearing and balance screenings offered to patients. This benefit is “bundled” within the “Welcome to Medicare” examination. The examination has seven screening sections for physicians, nurses, or nurse practitioners to employ when addressing new patients. Importantly, the Medicare rules state that the screening tests must be in the form of questions or questionnaires and that the selected screening tests must be recognized by a national medical professional organization.

In addition to a wealth of other tests, the American Academy of Audiology (AAA) and the American Speech-Language-Hearing Association (ASHA) have recommended that the following questionnaire be used for this purpose: Hearing Handicap Inventory for the Elderly—Screening Version (HHIE-S; Ventry and Weinstein, 1982). There is likely to be greater popularity for screening tests. Therefore, audiologists should be familiar with the above-noted questionnaires and their format, scoring, and importance.

Subjective, Objective, Assessment, and Plan

Another way to gather useful case history information quickly is to use the standard subjective, objective, assessment, and plan (SOAP) format. The SOAP format is essentially a “medical model” case history-gathering tool. There are many variations on the SOAP format used by clinics, medical schools, and, often, military healthcare facilities.

Critics believe the SOAP format is impersonal and does not recognize the patient as a whole person. In addition, the SOAP format tends to treat the person as if he or she was the disease/disorder/problem, and it calls for the use of jargon and related abbreviations. Although jargon is commonly used in health professions, it can vary from location to location, and it may be nearly impossible for many well-educated colleagues to interpret. In the following examples, abbreviations will be used along with their explanations, which will immediately follow in parenthesis.

SUBJECTIVE

The subjective section provides a brief subjective history, often focusing on the CC as well as other clinical observations. The patient’s medical and audiology history would be placed in this section. Other entries in this section would be notes the patient/relative/friends offer regarding pain or

discomfort and related miscellaneous symptoms. An example follows:

Pt (patient) is 56-year-old, Caucasian, divorced female.
 NKA (no known allergies).
 Pt has one adult daughter (age 26 years).
 Pt has +BP (high blood pressure) that has been under control via meds for 3 years. Pt takes daily multivitamin.
 No other known medical issues.
 Pt consumes ETOH (alcohol) daily (one glass), stopped smoking 15 years ago.
 Previous surgery: C-section 26 years ago. Ingrown toenail (left big toe) operated on 22 years ago.
 Today CC: Hearing loss AD (right ear) × 1 mo (1 month duration) with tinnitus, no spinning/vertigo, no complaints AS (left ear).
 Pt presents for AE (audiometric evaluation).

OBJECTIVE

In medical charts, the objective section often includes measures of temperature, blood pressure, skin color, swelling, and other “objective” data that can be obtained in the office easily and quickly. This section is where the audiologist would write the “objective” test results. An example follows:

Puretones:

65 dB HL SNHL (sensory/neural hearing loss) AD (right)
 AS (left) WNL (within normal limits)

SRT (speech reception threshold):

70 dB HL AD, 15 dB HL AS

SAT (speech awareness threshold):

60 dB HL AD

15 dB HL AS

WRS (word recognition score):

24% AD at SAT plus 35 dB with contralateral masking

100% AS

OAEs (otoacoustic emissions):

AD ABS (absent)

AS WNL

Tympanograms:

WNL AU (within normal limits, both ears)

ASSESSMENT

The assessment section is where the physician or audiologist would make a statement about the probable “working” diagnosis, or the final diagnosis, and prognosis. For example,

Pt presents with probable AD SNHL (right sensory/neural hearing loss), possibly from untreated sudden SNHL, possibly retrocochlear?

PLAN

The plan is the “plan” as of this moment, moving forward. The physician may write the recommended prescriptions or may order blood tests, lab work, or radiology tests, as needed. The audiologist might write

Refer pt to ENT for AD asymmetric, SNHL to R/O (rule out) retrocochlear origin or other medical/surgical concerns. Assuming medical/surgical is R/O, proceed with hearing aid evaluation AD.

Although the SOAP format is a quick and an efficient way to gather the history and related information, it may ignore more global problems, while attending primarily to the CC.

SUMMARY

Gathering an efficient and thorough case history requires understanding, patience, and knowledge of hearing, hearing loss, and related disorders. Although there are options regarding the preferred method with which to gather a case history, there is no alternative to accuracy.

Whichever protocol(s) is (are) chosen, the clinician has the responsibility of assembling the information in a meaningful and relevant way to maximally address the needs, concerns, and well-being of the patient.

FOOD FOR THOUGHT

1. As we move forward, of course the electronic medical record (EMR) will play a more prominent role in medicine, audiology and will increasingly impact the case history. Although the EMR will eventually be standardized and comprehensive (at least we can hope!). Do you believe a better “Case History” will come about using a one-on-one dialog, rather than a checklist approach?
2. Do you feel that the human side (i.e., information, emotions and the relationship between the professional and the patient) will greatly impact the type of case history we use?
3. Although the standardized EMR will (eventually) enable the gathering and analysis of comprehensive and objective data, do you feel that this will reduce the value of dialog between the patient and the professional? That is, how important is the patient’s story more-or-less in their own words for the professional?

Diagnostic Audiology

Brian M. Kreisman, Jennifer L. Smart, and Andrew B. John

INTRODUCTION

Diagnostic audiology is the use of audiologic tests to determine the location of a problem in the auditory system and, in many cases, further insights about the disorder. Diagnostic audiology can be likened to crime shows you may watch on television. Each test serves as a clue that points toward a diagnosis of the patient's hearing disorder. However, if individual tests (or clues) are examined without taking other evidence into consideration, a wrong conclusion might be made. For audiologists to make correct diagnoses, an audiologic test battery is used. A test battery is a series or combination of tests used to assess the auditory system. For most of the examples in this chapter, we will limit discussion of diagnostic audiology to tests that are commonly performed in an audiologic clinic, including puretone air-conduction and bone-conduction testing, speech testing, tympanometry, acoustic reflex thresholds (ARTs, also called middle-ear muscle reflexes [MEMRs]), and otoacoustic emissions (OAEs). These tests are discussed more fully in other chapters in this textbook and we refer you to these chapters for specific test procedures and norms (see Table 8.1); however, it is important to understand how to utilize these tests synergistically to arrive at an accurate diagnosis for each patient. Audiometric tests are used in conjunction with one another to help reinforce or, alternatively, rule out the diagnosis of a particular type

of hearing loss or the site of lesion. The test battery is useful for determining some, but not all, auditory disorders.

Following a brief introduction to the cross-check principles employed by audiologists, this chapter will utilize a case study format. Finally, we will address the limitations of the test battery and discuss situations when referrals for other testing are indicated.

CROSS-CHECKING TEST RESULTS

The major reason that an audiologist uses a diagnostic battery is to be able to check the results of individual tests with each other. The idea that “the results of a single test are cross-checked by an independent test measure” is referred to as the cross-check principle (Jerger and Hayes, 1976, p. 614). Since the cross-check principle was first proposed, many manuscripts have revisited the concept as new diagnostic tests have been developed and different test batteries have been proposed to diagnose specific disorders. The goal of comparing the results of two or more tests is to increase the rate of correct identification of disorders (hit rate) and to decrease the rate of diagnosing a disorder when no disorder exists (false alarm rate) (Turner, 2003).

Cross-checks for Puretone Air Conduction

If you only obtained puretone air-conduction thresholds then you would not be able to accurately diagnose the type of hearing loss. Air-conduction audiometry is normally cross checked with bone-conduction audiometry or tympanometry to rule out a conductive component of the hearing loss. If a difference greater than 10 dB exists between the air-conduction and bone-conduction thresholds at the same frequency, a conductive component is indicated. Similarly, air-conduction thresholds for an ear may be within normal limits; however, if a tympanogram for that ear falls outside of the norms for middle-ear pressure and compliance (e.g., Jerger Type B or Type C), a conductive component may be present. ARTs can reveal more information about the type of loss based on the pattern of responses obtained, thus serving as an additional cross-check for puretone air conduction.

TABLE 8.1

Audiology Procedures Discussed in This Chapter

Test	Chapter
Puretone testing (air and bone conduction)	3
Speech testing (quiet)	5
Speech-in-noise testing	5
Tympanometry	9
Acoustic reflex thresholds	10
Otoacoustic emissions	19

Cross-checks for Puretone Audiometry

When puretone audiometry (air- and bone-conduction testing) suggests a significant air–bone gap, tympanometry and ARTs can be used to reinforce the diagnosis of the conductive element and to contribute to a specific diagnosis. OAEs also can be used as a cross-check of puretone audiometry. OAEs are used to assess the health of the outer hair cells of the cochlea, but their measurement may be affected by disorders in the conductive pathway. An audiologist might use OAEs as a cross-check to aid in potentially ruling out a nonorganic hearing loss, to verify outer hair cell function and the degree of cochlear hearing loss, and to further assist with the diagnosis of conductive components, auditory neuropathy spectrum disorder (ANSD), and other retrocochlear disorders. In addition, ARTs have been used to cross check puretone audiometry (Jerger et al., 1974), although other objective tests, such as tone-burst–stimulated auditory brainstem response (ABR), are considered to be better procedures for estimating hearing thresholds. Acoustic reflexes can be used to help identify the presence of hearing loss in young children as well as in adults with language and/or cognitive issues that may reduce the validity and reliability of behavioral measures (Hall, 2010). Acoustic reflexes can also be used to determine site of lesion within the auditory pathway, specifically in differentiating between cochlear and retrocochlear pathologies.

Cross-check for Puretone Average

A puretone average (PTA) is usually calculated as the average of the air-conduction thresholds at 500, 1,000, and 2,000 Hz for each ear. Normally, the PTA should agree with the speech recognition threshold (SRT), meaning that the PTA and SRT should be within 10 dB of one another in the same ear. One instance in which the audiometric thresholds may cause the PTA to be greater than the SRT by 10 dB is when the audiogram configuration is sharply sloping or sharply rising. In such instances, it is preferable to use a two-frequency PTA by averaging the two lowest (e.g., best) thresholds at 500, 1,000, and 2,000 Hz. The two-frequency PTA should then be in agreement with the SRT. Another instance in which the PTA and SRT may disagree is if a person is malingering or intentionally exaggerating a hearing loss. Outside of these special circumstances, we would expect SRTs and PTAs to be highly correlated (except when language or foreign language is a major factor). This allows us to use the SRT to validate the PTA (American Speech-Language-Hearing Association, 1988).

Considerations for Assessing Speech Understanding

One additional step that audiologists may take to address a patient's complaint of not being able to understand speech

in noisy environments is to administer a speech-in-noise test in addition to the word recognition testing in quiet. Although this is technically not a cross-check, the addition of a speech-in-noise test, especially with sentence stimuli, will provide a more realistic test environment to evaluate a common patient complaint. The puretone audiogram does not necessarily correlate with the amount of difficulty a listener will have in noise (Killion and Niquette, 2000). In addition, when word recognition testing is performed in quiet at a single speech presentation level, no guarantee exists that the test is measuring the patient's maximum speech understanding (Wiley et al., 1995).

Cross-check Considerations for Pediatric Testing

For children, it is imperative that the audiologist utilize the cross-check principle. The behavioral responses obtained via behavioral observation audiometry (BOA) or visual reinforcement audiometry (VRA) are considered to be accurate reflections of a child's true thresholds when these tests are conducted carefully (Madell and Flexer, 2008). However, because children often do not respond as consistently or as quickly as adults, it is possible that a child's behavioral responses may still be elevated compared to actual thresholds. As a result, the audiologist may judge the child's responses as unreliable (Baldwin et al., 2010). Regardless of the judged reliability of such measures, audiologists should use objective tests such as OAEs and tympanometry as cross-checks for pediatric behavioral responses (Baldwin et al., 2010; Littman et al., 1998; Madell and Flexer, 2008). In addition, OAEs and acoustic reflexes have been shown to be good cross-checks for ABR in young children (Berlin et al., 2010; Stach et al., 1993). The Joint Committee on Infant Hearing Position Statement (JCIH; American Academy of Pediatrics, 2007) also recommends that electrophysiological measures be employed as a cross-check for behavioral response audiometry for children younger than 6 months chronological age. The statement further stresses the importance of obtaining behavioral thresholds as soon as possible using the most age-appropriate method “to cross check and augment physiologic findings” (American Academy of Pediatrics, 2007, p. 910).

Electrophysiological Tests as Cross-checks

Although beyond the scope of this chapter, it should be noted that certain electrophysiological tests can be used to cross check behavioral measures, as well as to cross check each other and to help confirm diagnoses of certain disorders (Bachmann and Hall, 1998; Berlin et al., 2010; Gravel, 2002; Hall and Bondurant, 2009; Stapells, 2011). For example, Berlin et al. (2010) discussed the use of cross-checking

TABLE 8.2

Summary of Cross-checks Used in Diagnostic Audiology

Test	Test	Cross-check
Air conduction	Bone conduction	Rule out conductive component (air–bone gap)
Puretone audiometry	Tympanometry	Helps to verify/rule out middle-ear pathology (air–bone gaps); rule out nonorganic hearing loss
Puretone audiometry	Otoacoustic emissions	Helps to verify/rule out middle-ear pathology; helps to confirm outer hair cell function; rule out nonorganic hearing loss
Puretone audiometry	Acoustic reflexes	Helps to determine site of lesion (e.g., differentiate cochlear from retrocochlear hearing loss); helps to determine degree of hearing loss and rule out nonorganic hearing loss
Puretone average	Speech recognition threshold	Verify performance on both measures (SRT should correlate with PTA)
Speech in quiet (WRS)	Speech-in-noise tests	Compare speech perception in quiet (normal audiologic testing) to noise (more realistic test that addresses many patient complaints of not understanding in noise)
BOA	Electrophysiological measures	Better estimate/confirmation of true thresholds
VRA	Electrophysiological measures	Better estimate of true thresholds (if VRA responses unreliable)

Note: Tests do not need to be administered in this order.

test results to diagnose ANSD: “...the presence of a [cochlear microphonic] or reversing waves at the beginning of the trace does NOT make a diagnosis of ANSD...without the cross-check of middle-ear muscle reflexes (MEMR), OAEs, and an ABR latency-intensity function” (p. 32). For further information about these tests, the reader is referred to the chapters that discuss electrophysiological tests in the text. Table 8.2 summarizes many of the cross-check tests that are used in audiology.

Order of Tests Administered

Although we acknowledge that there is considerable variability in test protocols across clinics, we recommend that testing begin with the objective tests unless contraindicated. At least two major advantages can be found for testing objective measures first. The first advantage is that the audiologist will have a good idea of the type and degree of hearing loss before beginning the subjective tests. The second advantage is the reduced risk for misdiagnosis of disorders such as ANSD and vestibular schwannoma, as well as failure to detect a patient who is malingering. One caveat needs to be discussed with conducting objective tests first. With rising costs of health care we need to be cautious that we are doing tests that are necessary. It is possible that, if the patient’s hearing is completely normal (with no listening complaints) or the patient is profoundly deaf (with previous documentation to support the initial diagnosis), tests such as OAEs and acoustic reflexes will be unlikely to add further information about the patient (but we would

recommend that everyone have tympanometry for the reasons previously discussed). We think that a nonorganic component is more likely to be present during subjective testing and may not be discovered until cross-checked with objective tests. For these reasons, we recommend objective testing first. A suggested testing order is shown in Figure 8.1. Nevertheless, it should be noted that some audiologists advocate giving puretone and speech tests first when the patient may be more alert and can actively respond to these tests and then relax during the objective tests.

Beyond the Test Battery

Although the use of a test battery is important, it is also vital for the audiologist to remember the case history and the patient complaints. In some ways, one may consider this patient-reported information to be a cross-check of the test battery itself. The case studies presented below demonstrate examples of diagnostic audiology in action.

CASE STUDIES

The importance of objective testing in conjunction with subjective tests can be seen through the use of case examples. The following cases are a range of examples that highlight the use and benefit of incorporating the cross-check principle into your clinical practice. The cases will be presented with a brief history and test results. A discussion of potential difficulties and challenges in interpreting the audiologic data is incorporated within each case. Although

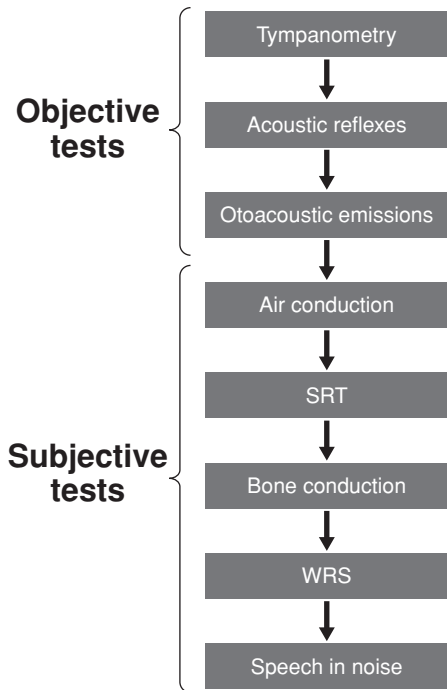

FIGURE 8.1 A suggested comprehensive diagnostic test battery.

there is an ideal order to the test sequence as noted above, the order of tests often varies because of tester preference, patient complaint, age of patient, and so on. Therefore, the test order in the cases below varies to better represent what may be actually done in a clinical setting or what a student clinician may see from his/her supervisors. For the sake of simplicity, all of the cases represent testing with standard audiologic procedures on adults. As you read through each

case, we encourage you to make a decision tree based on the order of tests presented in the case and then think about how you might decide to change the test order. It is important to review your clinical decision making periodically to ensure that your practice is evidence based.

Case 1

CASE HISTORY

Mr. Ang Kim, age 36, is being seen today after he failed the hearing screening at his company’s health fair. His medical history is generally unremarkable, though he reports that he is just getting over a sinus infection and recently underwent surgery for a slipped disc in his back. You have back-to-back patients today and because there is nothing remarkable in his history you decide to do a quick audiogram and send him on his way. Results from otoscopy, puretone, and speech audiometry are shown in Table 8.3 and Figure 8.2.

With subjective information alone this audiogram could indicate many things. For example, you may inaccurately diagnose Mr. Kim with a collapsed ear canal, an impacted cerumen plug, or a perforated tympanic membrane without additional tests to cross check your findings.

TABLE 8.3

	500 Hz	1,000 Hz	2,000 Hz	500 Hz	1,000 Hz	2,000 Hz
Right	NR	NR	NR	110 dB	110 dB	105 dB
Left	85 dB	80 dB	85 dB	110 dB	105 dB	105 dB

NR, no response to maximum presentation (110 dB HL).

Despite your busy schedule, you decide you need more information to make an accurate diagnosis, so you perform objective testing to cross check your subjective results. The results from immittance testing and OAE testing are shown in Tables 8.4–8.6.

With this information, you have several different tests to confirm your finding of a conductive hearing loss. The Type B tympanogram in the right ear reveals normal ear canal volume but no mobility. The normal ear canal volume suggests that the TM is not perforated and there is no cerumen plug. The pattern of the ARTs is consistent with a right conductive pathology. TEOAEs in the right ear are absent which is expected with a conductive pathology.

The combination of the subjective *and* objective test results correctly leads you to suspect otitis media with effusion and would require a referral for Mr. Kim to a physician. In this case, you are able to make an appropriate referral based on the information you obtained from a test battery incorporating both objective and subjective measures.

Case 2

CASE HISTORY

Mrs. Edith Jones, age 77, is being seen today for a hearing test. She does not perceive a listening difficulty but her husband was recently fit with hearing aids and insisted she have her hearing checked too. Her medical history is remarkable for high blood pressure and type 2 diabetes which are both controlled by medication.

You conduct a basic audiometric evaluation on Mrs. Jones. Results for otoscopy are displayed in Table 8.7

and puretone and speech audiometry results are shown in Figure 8.3.

If you decide not to proceed with further tests to cross check your results, you might diagnose this patient with normal hearing in the right ear and a mild conductive hearing loss in the left ear. You might then refer Mrs. Jones to an Ear Nose and Throat physician who would order more tests.

Instead, you decide to proceed and include additional tests in your battery that would provide a cross-check. We will review those results next (see Tables 8.8–8.10).

These results suggest that Mrs. Jones has normal hearing that contradicts your puretone findings. Normal results on tympanometry, ARTs, and TEOAEs are not consistent with a mild conductive hearing loss. With this information you review the patient's case history and puretone findings again and realize that the apparent conductive hearing loss in the right ear is likely the result of a collapsing ear canal. It is not uncommon for the pressure of the supra-aural headphones to cause the canal to collapse, particularly in older patients for whom the cartilage supporting the ear canal is soft. To confirm this finding you decide to retest Mrs. Jones with insert earphones. When you repeat your audiogram using the insert earphones, you measure Mrs. Jones's right-ear air-conduction thresholds at 5 or 10 dB HL for all frequencies tested. You are able to report to Mrs. Jones that her hearing appears to be normal!

Both cases 1 and 2 highlight the importance of using objective test results in conjunction with subjective test results to avoid misdiagnosis. Both audiograms revealed similar test results but very different actual diagnoses, which were only confirmed with the use of objective testing.

Case 3

You receive the following case, accompanied by a patient-signed medical information release, via fax. A recently graduated audiologist at a practice across town just finished testing Mr. Smith and would like a second opinion.

CASE HISTORY

Mr. Aaron Smith, 49, reports that he can no longer hear out of his left ear. He works in construction and reports that a transformer overloaded at his work site yesterday, resulting in a loud explosion which he believes caused his hearing loss. Mr. Smith reported that his hearing was normal prior to the explosion. He denies any aural fullness, tinnitus, or dizziness. His medical history is unremarkable and he denies any other injuries as a result of the explosion. Results of the audiologic testing are shown in Tables 8.11–8.13 and Figure 8.4.

You call the audiologist right away and review your concerns with her. Both the air-conduction and bone-conduction thresholds for the left ear need to be masked. Cross-hearing should have occurred before those thresholds were obtained. Furthermore, you would not expect to obtain no response for bone-conduction testing with the bone oscillator on the left side when the hearing in the right ear is evidently normal. You also note that the PTA and the SRT are not in agreement for the left ear. ARTs are better than you would expect them to be (given the puretone thresholds for the left ear). A patient with hearing thresholds at 90 dB HL would be expected to have ARTs in the range of 95 to 125 dB HL at 500 Hz and 100 to 125 dB HL at 1,000 and 2,000 Hz (Gelfand et al., 1990). Lastly,

TABLE 8.12

Tympanometry Results (226-Hz Probe Tone) for Case 3

	Right	Left
ECV	1.0 mL	1.1 mL
Compliance	0.5 mL	0.6 mL
Middle-ear pressure	5 daPa	–20 daPa

the WRS was only obtained at 20 dB SL in the left ear, yet Mr. Smith's WRS is 76%, which is better than expected. According to Dubno et al. (1995), a patient with a PTA of 90 dB HL would have an expected WRS of less than 24%. You suggest to the other audiologist that obtaining TEOAEs would further assist in this diagnosis. The audiologist performs TEOAEs (see Table 8.14) to confirm the suspected diagnosis and faxes the results to you.

Based on the pattern of test results, your suspected diagnosis is nonorganic hearing loss. Let us review the facts. First, the patient's left ear thresholds are elevated above where cross-hearing should have occurred. Second, the objective test results (tympanometry, ARTs, and OAEs) reveal no conductive component and suggest that outer hair cells are functioning normally. However, the puretone and speech audiometry results suggest a severe-to-profound unilateral hearing loss in the left ear, which is inconsistent with the objective results. Several cross-checks identified inconsistencies (e.g., ARTs and puretones; PTA–SRT agreement; puretone thresholds and OAEs). At this point, you could suggest that the audiologist reinstruct the patient and then retest the left ear, masking appropriately. If the thresholds for the left ear are still elevated, a Stenger test could be performed to confirm the accuracy of the left puretone thresholds. If the Stenger test result is positive (i.e., the patient does not respond to the stimulus), this would be additional evidence that the apparent hearing loss is nonorganic. This case highlights the importance of a high-quality diagnostic battery (including masking where appropriate) and use of cross-checks to confirm our test results.

Case 4

CASE HISTORY

Ms. Ashley Jackson, age 27, has had hearing problems all of her life. She has been told by her audiologist that she has only a mild sensory/neural hearing loss. Her doctor always tells her that her hearing is really very good. She tried hearing aids a few years ago but she says that they did not help at all. Unfortunately, Ms. Jackson cannot hold a job because of her hearing difficulties. Her bosses always cite miscommunication problems as the reason for her dismissal. Ms. Jackson is here today to see if her hearing has changed. Tables 8.15 and 8.16 show otoscopy and tympanometry results. Figure 8.5 shows puretone and speech audiometry results.

Ms. Jackson’s puretone results appear to be consistent with the previous hearing tests in her medical record. There are some red flags that warrant additional testing, though. First, her reports of listening difficulties and communication problems in her case history suggest that she may have more than a mild sensory/neural hearing loss. Additionally, her word recognition scores are poorer than expected given

her puretone thresholds. You would expect a patient with PTAs in this range to have WRS of 68% or better (Dubno et al., 1995). The next tests that should be performed are ARTs and OAEs. Tables 8.17 and 8.18 show the results of those tests.

Now that you have completed your testing, you cross check your test results. First, the patient’s ARTs are not consistent with her puretone thresholds. With a mild sensory/neural hearing loss you would expect acoustic reflexes to be present (Gelfand et al., 1990). The patient’s TEOAEs are present and robust which would not be expected based on Ms. Jackson’s puretone thresholds. These findings in conjunction with the poor WRS indicate a need for additional testing such as an ABR. You suspect that the patient has ANSD. Results of the ABR and a medical evaluation may help to confirm or rule out your suspected diagnosis. Without the addition of both ARTs and OAEs to the test battery, Ms. Jackson’s disorder might have been missed again. The recommendations for patients with ANSD or other retrocochlear pathologies are often very different from the recommendations for those who have a peripheral hearing loss. Misidentification of the site of lesion for a hearing loss like

Ms. Jackson’s might result in delayed or inappropriate rehabilitation recommendations. Unfortunately, ANSD can be missed easily in clinical practice if the audiologist does not perform a thorough test battery (Smart and Kelly, 2008).

Case 5

CASE HISTORY

Mr. Don Warner, age 58, is being seen today with his primary complaint being a constant ringing in his right ear. He notes that the ringing has been present off and on for over 3 years but it has become more bothersome recently. When asked about his hearing he admits that he has difficulty understanding what others are saying in noisy places. He denies aural fullness and dizziness. He plays tennis regularly and generally is in great health. Results from your testing are shown in Tables 8.19–8.22 and Figure 8.6.

The order of test administration is important. Because you performed immittance testing and TEOAEs first, you knew that the patient’s tympanic membrane is mobile, that the ART pattern is abnormal in the right ear, and that the outer hair cells of the right ear do not appear to be functioning normally. You were able to obtain this information before the patient provided any information through subjective test-

ing. The patient’s asymmetry in high-frequency audiometric thresholds and poor WRS in the right ear combined with the objective results suggest a retrocochlear pathology and warrant an ENT referral for additional testing. The patient’s report of unilateral tinnitus, the abnormal ART pattern, the asymmetry in puretone thresholds, and the apparent rollover in the patient’s right-ear word recognition are all suggestive of retrocochlear dysfunction. Taken in isolation, each might be sufficient for you to make a referral for a medical evaluation. However, having consistent results from several tests allows you to be more confident in your recommendation and provide the ENT with as much information as possible.

Case 6

CASE HISTORY

Mr. José Gonzalez, age 24, was seen today for an audiologic evaluation. He was just hired as a clerk for a federal judge and therefore has to undergo a rigorous physical examination, including a hearing test. Mr. Gonzalez denies any hearing difficulties, tinnitus, dizziness, or aural fullness. He reports that he is in great health and is currently training for a marathon.

Based on the testing you have completed thus far you would expect this patient has normal hearing. His case history and all objective tests suggest hearing within normal limits. You proceed with your puretone and speech testing.

Results from your testing are shown in Tables 8.23–8.26 and Figure 8.7.

The puretone and speech audiometry results are surprising because they conflict with the results from the objective tests. Specifically, ARTs and TEOAEs within normal limits are not consistent with a measured profound hearing loss in the left ear. Your first thought is nonorganic hearing loss. You decide to reinstruct Mr. Gonzalez and retest the left ear air-conduction thresholds. This time you tell Mr. Gonzalez that you are going to play some more beeps in his left ear and all he has to do is press the button when he hears the tone. He nods and appears to understand the instructions. You begin retesting at 1,000 Hz and Mr. Gonzalez does not respond at the maximum limits of the audiometer. As you enter the booth to reinstruct again, Mr. Gonzalez informs you that he never heard a beep and has been waiting for you to present the tone. In fact, he notes that he has not heard anything from the left earphone. You check the headphone jack connections and find that the left headphone jack is unplugged. After you plug in the jack and retest Mr. Gonzalez's left ear, you obtain thresholds within normal limits. It is important to note that the patient history and the objective test results were not consistent with the subjective test results. Although having a well-constructed test battery is important, you also want to be flexible with your test order and be vigilant to notice inconsistencies between test results as you go. This flexibility would allow you to notice the unplugged headphone jack sooner and save time and frustration for you and Mr. Gonzalez.

LIMITATIONS OF THE AUDIOLOGIC TEST BATTERY

The combination of well-validated test measures, precise patient instruction, careful scoring, and application of the cross-check principle should result in accurate diagnostic and rehabilitative decisions for most patients. It is important to remember, however, that real-world patients usually do not present as textbook cases. The case studies contained in this chapter and the diagnostic criteria published in the audiology test literature should be treated as guidelines rather than absolute rules. High-quality diagnosis depends on both the construction of a high-quality test battery and skill in interpreting ambiguous or seemingly contradictory test results. A good rule for daily practice is this: When test results seem in disagreement, first check the tester (rule out the clinician's own mistakes); then, check the equipment (rule out malfunction or equipment performing out of calibration); and finally, check the patient (rule out patient error or pseudohypacusis).

MAKING REFERRALS

No audiologist is an island. A team approach to the treatment of hearing and balance disorders, particularly in pediatric patients, is often indicated. Appropriate treatment of a patient seen for audiology evaluation may require consultation with specialists including (but not limited to) allergists, endocrinologists, neurologists, occupational therapists, ophthalmologists, psychiatrists, rheumatologists, and speech-language pathologists. Referral of pediatric patients with hearing loss to an ophthalmologist is particularly important; approximately 50% of children born with

severe-to-profound hearing loss also have abnormalities of vision (American Academy of Pediatrics, 2007).

Referral for Medical Otolaryngologic Evaluation

The most common referral made by audiologists is to a medical doctor. Sending a patient to an otolaryngologist, primary care physician, or pediatrician is indicated if the audiologic evaluation reveals evidence of an underlying medical condition. Symptoms may include ear pain, bleeding or drainage from the ear (otorrhea), tympanometric abnormality without known etiology, or physical abnormality observed during otoscopy. Patients who report frequent ear infections, fluctuating or sudden hearing loss, or balance disturbance should also be seen by a medical professional (see Table 8.27). Newly identified hearing loss is also reason for referral. Although some audiologists undertake cerumen management in their own practice, many others prefer to refer to an otolaryngologist or the patient's primary care physician for removal of impacted wax. Children who exhibit a previously undiagnosed hearing loss or who exhibit delays in speech or language development should be seen by a pediatric otolaryngologist or developmental pediatrician prior to any audiologic management.

With respect to the audiologic test battery, disagreement among objective and subjective test measures which cannot be resolved as tester, equipment, or patient error is indicative of need for medical referral. Abnormally poor speech scores relative to the audiogram, asymmetric hearing loss, and reports of aural fullness and/or tinnitus are other signs of possible serious ear disease which should be evaluated by a physician.

Referral for Auditory Processing Evaluation

Disagreement between objective and subjective hearing tests may be reason to refer a patient for an evaluation of auditory processing. Patients with apparently normal peripheral auditory function may still have difficulty processing complex signals such as speech. These individuals often report that they can hear well, but have difficulty understanding what others are saying, particularly in the presence of noise. Tests of speech perception in noise such as the Bamford–Kowal–Bench Speech-in-Noise Test (BKB-SIN; Etymotic Research, 2005), Quick Speech-in-Noise Test (QuickSIN; Etymotic Research, 2001), and Hearing in Noise Test (HINT; Nilsson et al., 1994) may help to confirm this difficulty. If performance on speech-in-noise tests is poor, particularly if

TABLE 8.27

Seven Signs of Serious Ear Disease

Sign	Possible Etiologies
Ear pain (otalgia) or sensation of fullness	Otalgia may be a result of disease of the ear (e.g., otitis media, otitis externa) or may be referred pain resulting from illness in the head or neck (e.g., temporomandibular joint dysfunction, tumors of the upper digestive tract)
Discharge (otorrhea) or bleeding from the ear	Otorrhea and bleeding may result from chronic otitis media, otitis externa, cholesteatoma, and other disorders of the temporal bone. Bleeding from the ear may also be a sign of traumatic injury to the ear or temporal bone tumor
Sudden or progressive sensory/neural hearing loss, even with recovery	Sudden sensory/neural hearing loss may result from viral infection, ischemic event, trauma, or VIII nerve pathology. Progressive hearing loss is associated with immune disorders and viral or bacterial infections. Fluctuating hearing loss is commonly noted in patients with Ménière's disease
Asymmetric hearing between the ears or tinnitus	Asymmetric hearing loss and/or unilateral tinnitus may be a result of a tumor on the VIII nerve
Hearing loss following injury, exposure to loud sound, or air travel	Blunt or penetrating trauma to the head and barotrauma may result in hearing loss that is conductive [disruption of tympanic membrane and/or ossicular chain] or sensory/neural [disruption of cochlear membranes]. Noise-induced sensory/neural hearing loss may be seen after isolated intense sound events [explosions, gunfire] or repeated exposure to loud noise
Slow or abnormal speech development in children	Delayed speech and language development in children is often a result of inability to hear certain sounds of speech. This may result from conductive hearing loss (usually related to otitis media) or permanent sensory/neural loss
Balance disturbance or dizziness	Balance disturbance may be a result of otologic (e.g., Ménière's disease, perilymph fistula) or neurologic disease (e.g., stroke, demyelinating disease)

Adapted from Hall JW III, Mueller HG. [1997] *Audiologists' Desk Reference*. Vol I. San Diego, CA: Singular.

the audiogram is normal or suggests good hearing sensitivity, auditory testing should be performed. Parental concerns about a child's ability to process speech in noisy or reverberant places may also indicate need for APD evaluation. Auditory processing evaluation and rehabilitation are described in Chapters 27 to 30 of this textbook.

Referral for Vestibular Evaluation

Formal vestibular evaluation may be indicated by patient history or results of a doctor's physical evaluation. The symptoms of vestibular dysfunction are often obvious to the patient, but he or she may not realize that they are a relevant part of the audiologic case history. Therefore, it is important for any audiologist's case history form to include questions specifically asking about vertigo or balance problems to elicit this information. Reports of dizziness (particularly recent dizziness), vertigo, or feelings of spinning suggest need for evaluation by a vestibular specialist and/or otolaryngologist. Reports of imbalance (as opposed to vertigo) are also reason for medical evaluation, but may require treatment by a physical therapist rather than an audiologist. Other specific indicators for vestibular testing include history of exposure to ototoxins (particularly vestibulotoxins, such as aminoglycoside antibiotics), bacterial meningitis, or perilymph fistula. Patients with genetic conditions such as Pendred syndrome, Usher syndrome, and CHARGE syndrome are also candidates for vestibular referral. Pediatric patients presenting with inner ear dysplasia of unknown origin or delays in motor or balance skills should also be referred. Vestibular evaluation (Chapter 21) and rehabilitation (Chapter 22) are discussed in detail later in this textbook.

Referral for Genetic Evaluation

Roughly 0.1% to 0.3% of children are born with some hearing loss, and about half of these cases appear to be related to some genetic cause. Of these genetic cases, about 30% are syndromic, meaning that they can be related to sets of clinically recognizable features or symptoms known to co-occur. The remaining 70% of genetic hearing loss cases are characterized by hearing loss in isolation and are referred to as nonsyndromic. Approximately 50% of cases of autosomal recessive nonsyndromic hearing loss are due to mutation in gap junction beta-2 (*GJB2*), the gene that encodes the gap junction protein connexin 26 (*CX26*) (Kelsell et al., 1997). Hearing loss resulting from connexin 26 mutation is typically present from birth and can range in severity from moderate to profound. More than 90 mutations of *GJB2* have been identified.

Testing for *GJB2* mutation is an emergent field in early hearing loss identification. Quick and low-cost screening methods have been developed and are available through many medical centers and genetic testing service providers. It should be noted that many patients and parents may be

hesitant to undergo formal genetic testing because of fears that their health insurance costs may increase if a genetic predisposition to disease is found. For these patients, a consultation with a genetic counselor may be preferable to a referral to a medical geneticist.

SUMMARY

A well-constructed and consistently administered test battery provides the foundation for high-quality audiologic diagnosis and care. The case studies contained within this chapter are intended to underscore the importance of the diagnostic battery in terms of test selection, test order, and use of cross-checks. When test discrepancies cannot be resolved or a patient presents with complaints or symptoms outside of the audiologist's scope of practice, a referral to an appropriate specialist is indicated. Consultation with other specialists can also help the audiologist form a more complete picture of a patient's hearing health, increasing the likelihood of success in audiologic or vestibular rehabilitation.

FOOD FOR THOUGHT

1. For each of the cases presented in this chapter, what are some ways that the test order may have affected your thought process regarding the potential diagnoses?
2. How might you modify the order that you administer tests in your test battery, or change particular tests, based on individual patient factors such as age or cognitive ability?
3. Imagine that you notice a colleague in your clinic administering tests in an order that you think is unhelpful or omitting tests that would help to differentiate between possible diagnoses. What might you say or do to suggest a different test battery or test sequence? What evidence might you use to support your suggestion?

SECTION II

Physiological Principles and Measures

Tympanometry and Wideband Acoustic Immittance

Lisa L. Hunter and Chris A. Sanford

INTRODUCTION

Tympanometry is one of the most frequently performed and important components of the basic audiologic evaluation. Tympanometry measures how the middle-ear system responds to sound energy and how it reacts dynamically to changes in atmospheric pressure. Because sounds must be transmitted from a low-impedance air medium in the ear canal to a higher impedance fluid medium (the labyrinth) for humans to hear, it is important to understand whether the middle ear is providing effective sound transmission. In fact, without the middle ear, humans would only be able to hear very loud sounds via bone conduction, since soft to moderate sounds would be reflected back by the tissues and bone of the head.

The middle ear acts as an “impedance matching” system, allowing sounds to be transmitted more effectively through an elaborate system of levers via the ossicles and by concentrating sound pressure, since the round window area is smaller than the tympanic membrane (TM). However, not all sounds are transmitted equally by the middle ear. Low-frequency sounds below 1,000 Hz and high-frequency sounds above 4,000 Hz are transmitted less efficiently. Thus, the filtering of sounds by the middle-ear system largely determines our hearing sensitivity for different frequencies. The middle ear transmits the most energy to the cochlea in the frequency range of 1,000 to 4,000 Hz and is matched to the frequency region in which the majority of speech cues are carried.

This chapter provides a review of principles of tympanometry, discussion of single-frequency tympanometry across the age span from infancy to adults, principles of multiple frequencies and subcomponents of tympanometry, new advances in wideband (WB) tympanometry, and applications of tympanometry in cases of middle-ear pathology. The overall goal of this chapter is to provide a foundation for graduate students in audiology to understand the principles and applications of basic and advanced tympanometry measures and to provide the practicing clinician with an update on newer measures and recent clinical research evidence for putting these advances into everyday practice.

OVERVIEW OF TYMPANOMETRY

Tympanometry is an objective, physiological measure of acoustic admittance of the middle ear as a function of air pressure in a sealed ear canal. Normally, our ears operate most efficiently at atmospheric or ambient pressure. Clinically, it is of interest to measure middle-ear function at greater and lesser pressures compared to ambient pressure for diagnostic purposes because many conditions can affect pressure within the middle ear. When pressure is varied over a range of positive to negative pressure compared to atmospheric pressure, the effect on middle-ear function can be observed graphically. Increases or decreases in air pressure cause the TM and ossicular chain to stiffen, and this change can be seen as a decrease in admittance of sound energy to the middle ear, as shown in Figure 9.1. This figure also illustrates the effect of varying pressure in the ear canal on distension or contraction of the ear canal and TM. The most efficient operating point in terms of ear canal air pressure is observed as a peak in the tympanogram. The most common tympanometric measurement is peak height or “static admittance,” which is a measure of the amount of acoustic energy that flows into the middle-ear system.

To obtain a tympanogram, a calibrated probe stimulus (either puretones or WB clicks) is presented to the outer ear canal with a microphone. Air pressure in the ear canal is varied above and below atmospheric (ambient) pressure, which causes the TM and ossicular chain to stiffen. As the air pressure is increased or decreased in the ear canal, the admittance flowing into the middle ear is decreased, so more sound pressure remains in the ear canal. At the microphone, this is read as an increase in probe sound pressure level. If you perform tympanometry in your own ear, listen carefully as the air pressure is varied—both positive and negative. You will hear a decrease in sound intensity as the pressure is increased or decreased, and you should hear an increase in sound intensity at the peak of the tympanogram, where admittance is greatest.

A normal tympanogram has a single clearly defined peak occurring near atmospheric pressure, as in Figure 9.2, type A. Problems in the middle ear cause alterations in the shape of the tympanogram. For example, the most common pathology that affects tympanometry is fluid in the middle ear space, or otitis media with effusion (OME). This condition

FIGURE 9.1 Effects of air pressure on the external ear canal and tympanic membrane as pressure is varied from ambient, to positive, and then to negative pressure. As the pressure is varied in the sealed ear canal, admittance is plotted as a function of ear canal air pressure on a tympanogram [upper panel]. The lower panels show effects of inducing positive and negative pressure in the ear canal on the external walls, ear canal volume, and volume of probe tone sound pressure level in the ear canal.

results in an increase in impedance (decreased admittance), which broadens or flattens the tympanogram, as shown in Figure 9.2, represented by type B. In severe cases, the tympanogram will be completely flat across all air pressures, indicating that the TM is stiffened and unable to transmit sound energy effectively at any air pressure. Another common condition, Eustachian tube (ET) dysfunction, causes middle-ear pressure to be decreased relative to atmospheric pressure, shown as type C. In ET dysfunction, the most effective energy transfer point is usually more negative, which shifts the peak of the tympanogram to the left. Rarely, positive pressure can be present in the middle-ear space, usually due to acute otitis media (AOM). In these cases, the tympanogram peak will be shifted to the right. In cases of a thinned tympanic membrane (TM) or ossicular discontinuity, decreased stiffness or an increase in peak height can occur because of TM thinning or ossicular discontinuity. In such cases, the height of the admittance tympanogram will be increased relative to normal, as in type A_D. Conversely, increased stiffness can occur in a variety of disorders from scarring of the tympanic membrane to otosclerosis and can reduce the peak height of the tympanogram, as shown in type A_S.

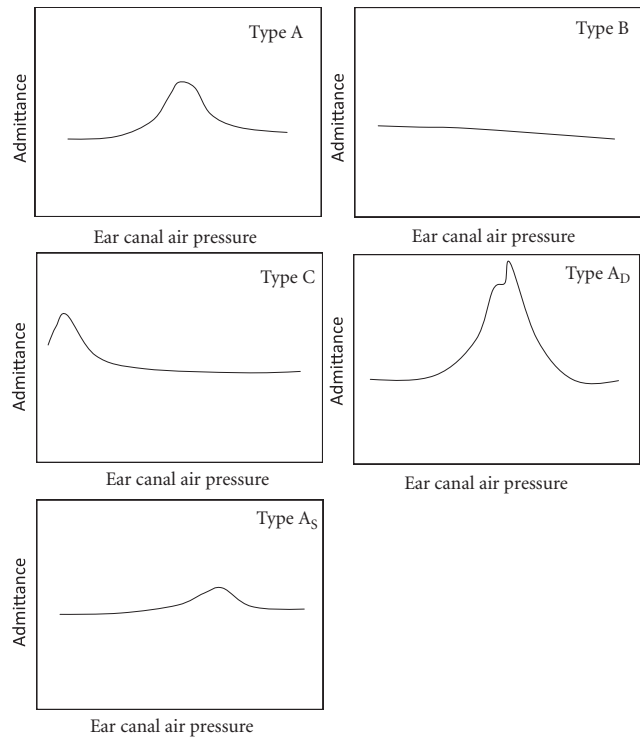

FIGURE 9.2 Lidén-Jerger classification scheme for tympanometric shapes, based on qualitative analysis of the height and location of the primary peak. [Modified from Lidén G. (1969) The scope and application of current audiometric tests. *J Laryngol Otol.* 83, 507-520 and Jerger J. (1970) Clinical experience with impedance audiometry. *Arch Otolaryngol.* 92, 311-324].

Table 9.1 provides categories for interpreting tympanometry results with respect to potential pathology. Tympanometry is widely variable in both normal and abnormal ears, thus caution should be used in inferring the pathology from tympanometry alone. Tympanometry should be combined with an otolaryngology examination and history to maximize its use as a diagnostically useful tool.

HISTORY OF TYMPANOMETRY

Tympanometry was invented by Terkildsen and Scott-Nielson in the form of an electroacoustic device that measured the admittance of the human ear across a range of sound pressures introduced into the sealed outer ear canal by a pressure pump. Terkildsen and Thomsen (1959) published the first tympanogram using the first commercially available aural acoustic immittance instrument, the Madsen ZO61. The ZO61 used a very low-frequency input puretone probe of 220 Hz with admittance measured as a function of ear canal air pressure. Amplitude and phase required to counterbalance the input sound were read on a voltmeter. The choice of a low-frequency probe tone (220 Hz) was partly at random, but also chosen to avoid high-frequency microphone artifacts and lower frequency electrical line

TABLE 9.1

Effects of Middle-Ear Pathologies

	Y	TW	Volume	Mass	Springiness	Resonant Frequency
Middle-ear effusion	Low	Wide	Normal	↑	↓	Low
Monomer or ossicular discontinuity	High	Narrow	Normal	↑	↑	Low
Perforation	Flat or variable	–	High	–	–	–
Tympanosclerosis	Normal to low	Normal	Normal	↑	↓	Low
Cholesteatoma	Low	Wide	Normal	–	↓	Low
Lateral ossicular fixation	Low	Wide	Normal	–	–	High
Medial ossicular fixation [otosclerosis]	Normal	Normal/narrow	Normal	–	↓	Normal to high

noise; it was also chosen for the sake of calibration ease. Terkildsen and Thomsen noted that for the relatively small size of the human ear canal, a low-frequency probe tone results in smaller calibration errors than higher frequency probe sources. Indeed, this problem of artifacts at higher probe tones has limited the frequency range to 1,000 Hz or below for single frequency tympanometry. Terkildsen and Thomsen published tympanograms obtained in normal ears and in ears with TM atrophy and otitis media.

In 1963, the more widely used Madsen ZO70 model appeared. The ZO70 model did not employ a phase adjustment and provided magnitude information in “compliance units” that were not calibrated in measurement units. The choice of the term “compliance” reflected the primary contribution of springiness, or compliance, in normal adult ears at 220 Hz. The use of “compliance units” became standard in clinical practice and most published literature. Because the uncalibrated compliance units could not be averaged or subjected to statistical comparison, the first classification schemes published were based on qualitative tympanometry shapes (A, B, and C shapes).

In 1973, an innovation in tympanometry appeared with the Grason Stadler Model 1720 otoadmittance meter, the first multicomponent and multifrequency tympanometer. This system separately measured subcomponents that contribute to total admittance. Two meters indicated susceptance and conductance, abbreviated as *B* and *G*, respectively. Susceptance includes both mass and spring components of admittance, whereas conductance includes just the friction component. This instrument provided 220-Hz as well as 678- and 1,000-Hz probe tones, which made it the first commercial multifrequency tympanometer. Importantly, this two-component admittance measuring technique allowed ear canal contributions to the measured response to be easily subtracted from the total admittance. Also, the GSI 1720 measured calibrated units, called millimhos (mmho), rather than arbitrary “compliance units.” These systems were used in many multicomponent and multifrequency tympanometry studies, as will be described later in this chapter.

Until 1987, immittance instruments, definitions, and terms were variable and there was no accepted standard. The first ANSI standard was published in 1987 with the goal of standardizing instrumentation, terminology, and recording practices. This allowed reporting of results across clinics so that data could be easily interpreted. The terms used in this chapter conform to the current ANSI standard for immittance instruments (S3.39, revised 2012).

More recently, innovations in tympanometry have taken the form of PC-based handheld clinical admittance systems that measure low-frequency, single-component tympanometry, as well as higher frequency (660, 800, and 1,000 Hz) and multicomponent (susceptance and conductance) tympanometry, as will be discussed in later sections.

Clinical research using tympanometry has been strongly influenced by the original choice of the 220- or 226-Hz probe tone as the standard. As a result, most clinical studies have focused on the low-frequency puretone probe. However, beginning with the early studies of tympanometry, there was recognition that higher frequencies produced different tympanometry patterns. In fact, the original publication by Lidén et al. (1970) provided results for both 220 and 800 Hz. At 220 Hz, three primary shapes were observed (A, B, C). At 800 Hz, two additional shapes were seen in pathologic ears—a broad double-peaked shape for ears with ossicular discontinuity and post-stapedectomy and a sharply notched pattern for eardrum atrophy or scarring. These same ears showed single peaks at 220 Hz. The reason for the difference was later determined to be due to stiffness effects at low frequencies and mass effects at high frequencies through modeling work by Vanhuysse et al. (1975).

Newer multifrequency and wideband (WB) immittance systems are now commercially available, and more clinical data using these instruments have recently been published that provide clinicians with more normative references, compared to results in various ear pathologies. WB immittance will be described later in this chapter along with normative ranges compared to results from ears with middle-ear disorders.

After the publication of the ANSI (1987) standard, manufacturers began to conform to the recommendation that immittance instruments provide calibrated physical units of measurement rather than arbitrary compliance units. Virtually all immittance instruments produced since then have been calibrated admittance meters. Quantitative analysis of tympanograms is preferable, especially when assessing infants and children, for whom different age-based normative values are needed. Judging tympanometric shape provides an overall impression, but to distinguish normal from abnormal tympanometry, four basic tympanometric measurements are required. These measurements are (1) equivalent ear canal volume (V_{ea}); (2) static-compensated acoustic admittance (Y_{tm}); (3) tympanometric peak pressure (TPP); and (4) tympanometric width (TW) or gradient.

Tympanometric Shape

Qualitative and quantitative approaches have been used in the interpretation of 226-Hz tympanograms. Since early instruments were uncalibrated and presented tympanometric results as arbitrary compliance units, qualitative measurements were necessary to describe tympanogram shapes. The most popular of these was the classification scheme originally described by Lidén (1969) and Jerger (1970). As shown in Figure 9.2, tympanograms using the Lidén–Jerger classification scheme are typed according to the height and pressure range of the tympanogram peak. Type A tympanograms have normal admittance and tympanometric peak pressure. Type B tympanograms have abnormally low admittance with no discernible peak. Type C tympanograms have normal admittance, with a peak occurring at negative middle-ear pressure. Lidén also described a type D tympanogram characterized by a double peak. Later, Feldman (1976) described subtypes A_D and A_S indicating abnormally high admittance and low admittance respectively. Although the qualitative classification approach is useful for identifying abnormal tympanometric features, and simplifies interpretation, its lack of precision can lead to diagnostic errors and misinterpretations. Without objective criteria for classification, there can be substantial clinical variability in distinguishing among types A, A_D , and A_S . Even distinguishing between types B and A is problematic when small or broad peaks occur, or shifts in the positive compared to the negative tails occur.

The following sections describe specific measures, which provide quantitative analysis of tympanometry. Use of these measures is recommended to clearly identify normal versus pathologic cases.

Equivalent Ear Canal Volume (V_{ea} or V_{ec})

Before performing tympanometry, the audiologist should examine the ear canal with otoscopy to identify cerumen

blockages, foreign bodies, drainage, TM perforation, or a collapsed canal. Any of these conditions can affect estimates of ear canal volume and other tympanometry measurements and thus should be documented. In the case of active drainage, it is best to defer tympanometry and refer the patient for medical assessment by a physician since the drainage can affect measurements, could transfer bacteria to the opposite ear or to other. Generally, if an open path to the TM can be visualized, cerumen blockages of less than 50% do not affect tympanometry measurements, although the volume will be less than for a clear ear canal.

The purpose of tympanometry is to accurately estimate the middle-ear admittance under varying ear canal air pressure. Because the probe tip of the admittance measurement system is remote from the surface of the TM, admittance measured at the probe tip reflects the combined admittance of the external auditory canal and the admittance of the middle ear. Accuracy of the middle-ear admittance estimate relies on obtaining an accurate estimate of the “equivalent” ear canal admittance (volume). Because the admittance of the volume of air in the ear canal contributes to the total middle-ear admittance measurement it must be subtracted out to determine the admittance because of the middle ear alone. This process is called tympanometric “compensation” and is used to determine admittance of the middle ear at the plane of the TM (Y_{tm}) as described in the following section. Figure 9.3 illustrates an admittance tympanogram and how the ear canal volume is compensated using a baseline method by subtracting out the admittance at either the positive or the negative “tail” of the tympanogram. The ear canal volume, referred to as V_{ea} , is affected by numerous factors such as the depth of insertion of the probe tip, the dimensions of the ear canal, and the amount of volume occupied by cerumen. The equivalent volume has also been referred to as V_{ec} or V_{eq} .

Most clinical immittance units provide a *baseline correction* feature when measuring tympanometry. Baseline correction subtracts the equivalent ear canal volume so that the tympanogram is plotted with admittance starting at 0 mmho at the positive or negative tail, depending on the instrument setting. The tympanogram shown in Figure 9.3 is plotted without baseline compensation. Baseline compensation may be done at either an extreme positive value, usually +200 daPa, or an extreme negative value, such as –400 daPa. At these extreme pressure values, it is assumed that the middle ear is sufficiently stiff to cause a decrease of the admittance of the middle ear close to zero. Therefore, assuming that the ear canal walls are rigid, the admittance measured at the probe tip could be attributed only to the air trapped in the ear canal itself. This measure is called “equivalent ear canal volume” because under standard reference conditions using a probe tone of 226 Hz, the volume of trapped air in a hard-walled cavity is equal to the acoustic volume of that same cavity. In other words, 1 cubic

FIGURE 9.3 A normal 226-Hz admittance tympanogram. TPP, tympanometric peak pressure; Y_{tm} , peak-compensated static admittance; either positive or negative tail pressure values are used to compensate for ear canal volume [V_{ea}].

centimeter (cc) or milliliter (mL) of trapped air equals the acoustic admittance of 1 mmho in a hard-walled cavity. This equivalency is the reason that some tympanometers measure admittance in cc or mL. For the sake of clarity, volume units should be used to when report V_{ea} (i.e., cc or mL) and acoustic admittance units (mmho) to report static admittance (Y).

Tympanograms are normally asymmetric, so that the negative tail value falls slightly below the positive tail, thus the volume estimate at extreme negative pressures is typically lower than the volume estimate at extreme positive pressures (Margolis and Shanks, 1985). This asymmetry is due to lower conductance at extreme negative pressures than at extreme positive pressures (Margolis and Smith, 1977). Physical volume differences also occur when positive air pressure pushes inward on the TM and as negative pressure pulls outward on the TM. If the negative tympanogram tail sharply descends below the positive tail, approaching 0 cc at the negative tail value, this usually indicates an ear canal collapse. Ear canal collapse occurs most frequently in newborns and infants due to highly compliant ear canals.

Actual physical volume of adult ear canals was measured by Shanks and Lilly (1981) by filling the ear canal with alcohol and then comparing the measured volumes to tympanometric estimates. The volume of the trapped air is more accurately estimated from the negative tail than from the positive tail, and at a probe frequency of 660 Hz rather than at 226 Hz. The V_{ea} estimated from either the positive or the negative tail value is always greater than the actual ear canal volume. Despite these known differences, clinical measurements of V_{ea} are most commonly taken from the admittance positive tail with a 226-Hz probe tone, which overestimates ear canal volume by about 40% (Shanks and Lilly, 1981). The normal range for V_{ea} is positively related to age because of increases in ear canal volume. A study by Margolis and Heller (1987) reported an average increase in ear canal volume from 0.63 in children to 1.46 in adults. Equivalent ear canal volume is larger in males than females

(Roup et al., 1998; Shahnaz and Davies, 2006) because males generally have a larger overall body size compared to females, and body size is correlated with ear canal size (Shahnaz and Davies, 2006). Table 9.2 provides normative values for V_{ea} for adults according to gender for V_{ea} measurement.

To interpret the V_{ea} measurement, the clinician must ensure that the probe tip is not blocked and perform otoscopy to determine if the TM is intact. In cases of blocked probes, cerumen impaction, or OME, tympanograms are generally flat or rounded. Tympanograms in ears with TM perforations are not usually flat, but may have irregular curves because of the geometry of the middle-ear space and effects of air pressure on ET opening. To interpret tympanograms when flattened or irregular shapes are obtained, it is necessary to compare V_{ea} to age-appropriate normative values. Equivalent volumes that are smaller than the lowest expected value for age may indicate a blockage of the probe tip or the ear canal. Blockages most commonly occur because of cerumen impaction or a probe tip angled against the ear canal wall. Figure 9.4 illustrates tympanograms that could occur in the same ear because of different conditions, and thus, result in different V_{ea} measurements.

Peak-Compensated Static Acoustic Admittance (Y_{tm})

Static admittance is the most often measured feature of the 226-Hz tympanogram and is commonly referred to as “compliance.” This older term is inaccurate, since admittance tympanometry includes not only compliance, but also mass and resistance. Although it is true that in normal adult ears at 226 Hz, compliance is the most dominant component, this is not the case for infants or in pathologic conditions. Static admittance is lower in middle-ear conditions that increase stiffness of the middle ear, including OME, cholesteatoma and ossicular adhesions, and space occupying lesions of the middle ear that contact the TM or ossicular chain. Conversely, in conditions that decrease stiffness, such as TM atrophy, ossicular disarticulation, or post-stapedectomy, static

Peak-compensated static admittance, Y_{tm} ; tympanometric width, TW; tympanometric peak pressure, TPP; equivalent ear canal volume, V_{ea} .

admittance is higher. Normative values and cutoff criteria for adults are provided in Table 9.2.

As discussed in the previous section, compensation at the extreme positive or negative pressure baseline is used to derive the V_{ea} . The peak of the tympanogram after subtraction of V_{ea} is called the “peak-compensated static acoustic admittance” or, more commonly, static admittance (Y_{tm}). Y_{tm} is derived through the formula $Y_{peak} - Y_{+400}$ for the positive tail method or $Y_{peak} - Y_{-400}$ for the negative tail method, as shown in Figure 9.3.

Measurement of static admittance can be affected by different procedural variables. One variable which has a very clear effect is the choice of pressure value for compen-

sation of ear canal volume. The compensated static admittance is typically higher when extreme negative (rather than extreme positive) pressure is used to estimate ear canal volume because of tympanometric asymmetry (Margolis and Smith, 1977; Shanks and Lilly, 1981). Other procedural variables that affect static admittance are pump speed, direction of pressure change, and repeated tests in close succession. Faster pump speeds produce higher static admittance, whereas decreasing the pressure from positive to negative produces lower static admittance than recording in the opposite direction.

Another procedural variable that can affect static admittance is whether the measurement is taken directly

FIGURE 9.4 Uncompensated tympanograms in various conditions, illustrating the effect of pathology on ear canal volume measurements.

from the admittance tympanogram or from the rectangular subcomponents (susceptance and conductance). Admittance is a vector quantity with both magnitude and phase, so it cannot be added or subtracted unless the phase angle of the two admittance values is similar. In adults at low frequencies, this assumption generally holds, but at higher frequencies and in young infants, this assumption is not valid. Therefore, at higher probe tone frequencies, it is necessary to convert admittance vector data to rectangular form, compensate for the effect of ear canal from admittance rectangular components (susceptance and conductance), and then convert the data back to admittance (see Hunter and Shahnaz, 2014 for further details and formulas for this calculation).

Tympanometric Gradient and Width (TW)

Sharpness of the tympanometric peak is associated with middle-ear pathology and is more sensitive to middle-ear effusion (MEE) than static admittance (Nozza et al., 1992, 1994). Two closely related measures of the sharpness of the tympanogram are the TW and gradient. Both measures provide an index of the shape of the tympanogram in the vicinity of the peak and quantify the relative sharpness (steepness) or roundness of the peak. The presence of MEE decreases the gradient and increases the width of the tympanogram.

The preferred and simpler measure is TW, which is measured by drawing a horizontal line halfway between the peak admittance and the baseline. The intersection of this line with either side of the tympanogram is the width, measured in daPa (de Jonge, 1986; Koebseil and Margolis, 1986). Calculation of TW is illustrated in Figure 9.5. A large TW is measured when the tympanogram is rounded and a small TW results when the tympanogram has a sharp peak. Normative values and cutoff criteria for adults are provided in Table 9.2.

An alternative measure of sharpness, tympanometric gradient, is a ratio measure of the steepness of the slopes on either side of the tympanometric peak. A method for measuring gradient was first proposed by Brooks (1968). There are several methods for calculating gradient, but the most common is to calculate the difference in acoustic admittance at the peak and the average of the acoustic admittance at +50 and -50 daPa relative to the acoustic admittance at peak pressure. A line is drawn across the tympanogram at this average admittance (A), and then A is divided by the peak height of either the positive or negative tail. This method is shown in Figure 9.6. The gradient is an index that ranges from 1.0 (flat tympanogram) to very high values depending on the value at TPP. The higher the gradient, the sharper and more narrow the tympanogram.

Two studies have compared gradient measures obtained with the various techniques in normal children and adults (de Jonge, 1986; Koebseil and Margolis, 1986). These studies concluded that the preferred method is TW rather than gradient, as the latter is highly correlated with static admittance and therefore redundant with static admittance. TW is also more straightforward to calculate, making it easy to determine even if the instrument does not provide automatic calculation.

Tympanometric Peak Pressure

The ET serves the important function of regulating pressure within the middle ear and thus protecting the eardrum, ossicles, and cochlea from extreme changes in pressure that could cause tissue damage. When the ET is not functioning normally, negative or positive pressure may develop within the middle ear. This condition is called ET dysfunction and will have the effect of stiffening the ossicular chain and the eardrum. Thus, the most effective operating point of the middle ear will not be at atmospheric pressure, but rather near the pressure contained within the middle ear. In cases of extreme negative pressure or a middle ear filled with

FIGURE 9.5 Calculation of tympanometric width [TW] in daPa from peak-compensated admittance [Y_{tm}]. TPP, tympanometric peak pressure; Y_{tm} , peak-compensated static admittance. Refer to text for measurement details.

FIGURE 9.6 Gradient measurement of the tympanogram. The distance from the peak to the average at ± 50 daPa from the peak on either side is denoted as A . The height (A) is then divided by the compensated peak static admittance. This measurement results in a ratio from 0 to 1.0. Further measurement details are provided in the text.

fluid, the tympanogram will not show an effective operating point or peak in immittance.

Related to ET function, the ear canal air pressure at which the peak of the tympanogram occurs is the TPP, as was shown in Figure 9.3. Because Y_{tm} reaches its highest value when the pressures on both sides of the TM are equal, TPP is an indicator, but not a direct measure, of the pressure in the middle-ear space. In fact, TPP overestimates the actual middle-ear pressure by as much as 100%. A TPP of -300 daPa, for example, could occur with actual middle-ear pressure of only -150 daPa. The value of measuring TPP is that it can detect the presence of negative or positive middle-ear pressure because of ET dysfunction. Positive pressure may occur in the early stages of acute otitis media (AOM) because of the production of gases secondary to inflammation of the mucosal lining of the middle ear. As the infection progresses, the inflammation results in swelling of the mucosa and production of mucous, known as OME. Because of the swelling, the ET is blocked and the fluid cannot naturally drain out of the ear into the throat; thus, a negative TPP develops. As the MEE increases and thickens, the tympanogram flattens and widens into a type B pattern. The majority of AOM cases spontaneously resolve within days to weeks. If they do not, they become chronic OME and are less likely to resolve if persisting longer than 2 to 3 months. As the MEE resolves, the flat tympanogram progresses back to negative pressure, finally returning to normal atmospheric pressure when ET function has returned to normal and once the fluid has dried or drained from the middle ear.

As discussed earlier, TPP measurement is imprecisely relative to actual middle-ear pressure, thus negative TPP does not provide reliable diagnostic specificity or sensitivity to otitis media in children (Nozza et al., 1994; Paradise et al., 1976), and thus is not currently recommended as a reason to refer children for treatment. In the absence of significant hearing loss, symptoms, or otoscopic abnormality, negative TPP probably does not indicate a significant middle-ear problem and by itself should not constitute a referral

for medical assessment or intervention. Positive middle-ear pressure can occur in patients with AOM.

TPP is useful for equilibrating ear canal air pressure to improve acoustic reflex thresholds and otoacoustic emission (OAE) responses (Trine et al., 1993). This is because better sound transmission occurs at TPP. Prieve et al. (2008) measured TEOAE and noise levels in 18 children under two conditions: On a day when the tympanogram TPP was normal and on a day when the tympanogram TPP was negative. They reported that TEOAE level decreased by about 4 dB from 1,000 to 4,000 Hz when TPP was negative, although negative TPP affected the overall pass rate in only 5% to 6% of cases.

Developmental and Aging Effects

Development and aging each affect tympanometry measures and thus need to be considered in normative criteria. Static admittance increases, ear canal volume increases, and TW decreases from infancy up to age 6 years (Roush et al., 1995). These changes are because of the increase in ear canal and middle-ear space, which make the middle-ear system more compliant with increased age. These changes continue into adulthood, especially for ear canal volume. Young adults aged 20 to 30 years have larger ear canal volume and narrower TW relative to children (Roup et al., 1998). Older adults (48 to 90 years) have lower static admittance, higher ear canal volume, and lower TW than younger adults (Wiley et al., 1996). Gender also affects immittance audiometry results. Several tympanometry studies have demonstrated a gender effect, with males having a higher static admittance and ear canal volume and narrower TW than females (Roup et al., 1998; Shahnaz and Davies, 2006; Wiley et al., 1996). Normative studies for adults are shown in Table 9.2.

Eustachian Tube Function Tests

The ET serves two main functions in the middle ear: pressure equalization (PE) and mucus drainage. Normally, the

ET is closed to protect the middle ear, but it opens during actions such as chewing, swallowing, and yawning. When the ET opens via active muscular contraction, a small amount of air is allowed into the middle ear, which serves to equalize pressure between the middle ear and ambient air. Pressure differences cause temporary low-frequency conductive hearing loss (CHL) because of stiffening of the TM and ossicular chain. Upper respiratory infections or allergies can cause the ET to become inflamed and swollen, trapping bacteria and causing ear infections. In children, the ET is shorter and straighter, as well as having poorer muscular control, which to otitis media. If the ET is blocked, it is unable to open to equalize pressure and negative pressure can develop. During activities that cause extreme pressure changes, such as flying or diving, ET malfunction can result in barotrauma (injury because of barometric pressure alterations). Barotrauma can cause TM perforation, CHL, and, in rare cases, a fistula of the oval window.

Measurement of TPP is an indirect measure of ET function, since significant negative or positive TPP indicates that the ET is not functioning normally to equalize middle-ear pressure. ET function tests are designed to actively test the function of the ET. ET function tests can be performed whether the TM is intact or not and are variants of tympanometry combined with active maneuvers to open the ET. A tympanogram is recorded before and after the maneuver, and shifts in TPP are observed. In an intact TM, shifts in TPP indicate ET functioning. In a perforated TM, the manometer of the immittance system can be observed for middle-ear pressure changes. Three main tests of ET function were described by Bluestone (1975) as discussed below.

VALSALVA TEST

The Valsalva test (Bluestone, 1975) introduces positive pressure into the middle ear via the ET using the classic Valsalva maneuver. A pretest tympanogram is recorded, the patient is instructed to perform the Valsalva maneuver by holding the nose and gently blowing air into the posterior nasopharynx. Then, a posttest tympanogram is recorded. Tubal opening is indicated by a positive shift in TPP.

TOYNBEE TEST

The Toynbee test (Bluestone, 1975) uses the classic Toynbee maneuver and is considered more reliable than the Valsalva test. The patient is instructed to hold the nose and swallow, which introduces negative pressure into the middle ear.

INFLATION–DEFLATION PROCEDURE

The inflation–deflation test (Bluestone, 1975) uses high positive pressure (inflation) or negative pressure (deflation) introduced into the ear canal using the tympanometer (± 400 daPa) while the patient is asked to swallow several

FIGURE 9.7 Baseline and posttest Eustachian tube function tympanograms. A positive shift is expected in the Valsalva and inflation tests. The Toynbee and deflation tests normally show a shift in the negative direction.

times (Bluestone, 1975). Pre- and posttest tympanograms are recorded. Tubal opening is indicated by a shift in the pressure peak in the opposite direction of applied pressure.

ET tests are simple to perform, are fast, and have face validity for the patient complaining of problems suggestive of ET dysfunction. Although easy to perform and seemingly useful, tests of ET function have become less popular over time because of a lack of evidence that they are predictive of pathologic problems. If TPP is normal and there are no clinical symptoms or signs of middle-ear problems, then there is no reason to suspect ET dysfunction and further ET function tests are not indicated. Based on complaints, history, or presence of negative pressure, ET dysfunction may be suspected and further tests may be useful. If ET tests are successful at demonstrating tubal opening, as shown in Figure 9.7, one can conclude that ET can open with active pressure, but do not tell us how the ET will function during various activities or conditions. If ET function tests do not demonstrate opening, this is a risk factor for recurrent otitis media and barotrauma under conditions such as flying and diving.

Patulous Eustachian Tube and Assessment

A patulous ET is abnormally open at rest, which can cause discomfort because of autophony (hearing one's own voice and breathing) that coincides with breathing. When patients present with complaints about discomfort because of hearing their own voice, breathing, or chewing, a patulous ET should be suspected. Patulous ET can be evaluated using immittance tests performed during breathing tasks. McGrath and Michaelides (2011) compared results of endoscopy and physician examination for 25 patients (8 to 82 years) referred for suspected patulous ET to 10 control patients. Admittance fluctuations greater than 0.07 mL during breathing tasks were found in 75% of ears with patulous ET whereas none of the control ears exhibited fluctuations during breathing. Thus, this study demonstrated a clear difference in ears with and without patulous ET on immittance testing.

Sensitivity and Specificity of Tympanometry

In order to truly understand the clinical usefulness of any diagnostic test, studies are needed of the test's performance in various populations at high and low risk for the disease of interest. Depending on the protocol, tympanometry has variable sensitivity to OME in children. It is important to note that the below studies examining test performance of pneumatic otoscopy have used experienced otoscopists who have received specific training and have been validated or compared to other expert otoscopists. Most OM is diagnosed by primary care physicians. In many cases, clinicians who use otoscopy to diagnose OME do not use pneumatic otoscopy and have not been validated against experienced otoscopists. For otoscopy to reach high levels of sensitivity and specificity, pneumatic otoscopy must be performed after ear canal cleaning by a highly experienced clinician. Because of these practical considerations, tympanometry is very useful as an alternative, especially when pneumatic otoscopy is not done by an experienced clinician. Performance of two tympanometry screening measures was assessed by Roush et al. (1992) in 374 ears of 3- to 4-year-old children in a preschool program against the gold standard of pneumatic otoscopy by an experienced, validated otoscopist. A procedure based on TPP less than -200 daPa or absent acoustic reflexes was compared with a proposed protocol, later published (ASHA, 1997). The procedure using TPP showed high sensitivity (95%), but low specificity (65%). The ASHA procedure had high sensitivity (84%) and specificity (95%), with a positive predictive value of 69% and a negative predictive value of 98%.

Nozza et al. (1992, 1994) studied six different combinations of static admittance, gradient, and acoustic reflexes in two related studies. In the first study (1992), two groups of children were evaluated. One group ($n = 61$, aged 1 to 8 years) received tympanostomy tubes and thus was at high risk for OME. The second group of children ($n = 77$, aged 3 to 16 years) attended an allergy clinic and was unselected with regard to otitis media history, thus was low risk. For the high-risk group, sensitivity (90%) and specificity (86%) were highest for gradient combined with acoustic reflexes. Gradient combined with static admittance also produced relatively high sensitivity (83%) and specificity (87%). In the low-risk group, sensitivity was 78% for all protocols except ipsilateral acoustic reflex alone (sensitivity = 88%) and gradient or static admittance <0.1 mmho (sensitivity = 67%). Gradient + ipsilateral reflex and gradient + static admittance performed equally well for specificity (99%). Positive predictive value was higher for gradient + static admittance (88%) than it was for gradient + ipsilateral reflex (78%). In a second study (Nozza et al., 1994), a group of children with recurrent or chronic OME ($n = 171$, aged 1 to 12 years), who were scheduled for myringotomy and tubes, received otoscopy by a validated otoscopist and

tympanometry by a certified audiologist. The prevalence of OME in this group was 55%. Eleven criteria were evaluated for sensitivity and specificity. Best overall performance was found for TW or Y_{tm} combined with pneumatic otoscopy (sensitivity and specificity = 80%) or for TW alone greater than 275 daPa (sensitivity = 78%, specificity = 82%). The ASHA (1997) protocol showed high sensitivity (95%), but poor specificity (24%). These various studies demonstrate that the population and choice of cutoff criteria affect test performance greatly. Combinations of criteria, such as static admittance and TW or gradient and static admittance, perform better than single criterion. Static admittance (Y) alone has poor sensitivity but good specificity, depending on the cutoff criteria selected. Ipsilateral reflex or TW combined with Y provides good overall test performance, as does otoscopy combined with TW. Static admittance needs to be combined with pneumatic otoscopy, width, gradient, or ipsilateral acoustic reflexes to improve sensitivity.

Shahnaz and Polka (1997) compared standard and multifrequency tympanometry to diagnose otosclerosis. They provided guidelines and normative data for interpreting tympanometric data obtained using the Virtual 310 multifrequency tympanometry system. Tympanometric measures were compared in 68 normal ears and 14 subjects with surgically confirmed otosclerosis. Two traditional measures, Y and TW, were derived from a standard single-component 226-Hz tympanogram. Seven additional measures were obtained from multifrequency tympanometry, including resonant frequency (RF) and frequency corresponding to an admittance phase angle of 45° ($F45^\circ$). Although Y tended to be lower and TW tended to be narrower in otosclerotic ears, there were no statistically significant differences between normal and otosclerotic ears. Test performance analysis showed that Y and TW were performing at chance levels and did not distinguish normal from otosclerotic ears. Shahnaz et al. (2009) also tested 62 normal-hearing adults and 28 patients diagnosed with otosclerosis. They reported that no measure obtained using standard low-frequency tympanometry was able to distinguish otosclerotic ears from normal ears, consistent with previous studies.

Calibration of Acoustic Immittance Systems

ANSI/ASA standard S3.39 (1987, R2012) specifies standards for acoustic immittance instruments. Calibration cavities should be provided with the immittance system with volumes of 0.5, 2.0, and 5.0 cm³. The calibration cavities should be hard walled, cylindrical, and acoustically nonporous and provide a hermetic seal with supplied probe tips. For ipsilateral acoustic activators, the acoustic output should be measured in a standard HA-1 (2-cm²) coupler connected to a sound level meter, frequency counter, and harmonic distortion analyzer.

TYMPANOGRAM STANDARD FORMAT

The ANSI standard specifies many variables that are important for consistent tympanometry results. Various measurement units (mmho, kohm, mm mercury) have been used, so the ANSI S3.39 standard specifies uniform methods to label and scale the x and y axis of the tympanogram to allow for uniformity and easier correspondence between different instruments and clinics. The standard 226-Hz probe tone is referenced to, an acoustic admittance value of $10^{-8} \text{ m}^3/\text{Pa s}$ (1 acoustic mmho), which corresponds to an acoustic admittance value of 10^8 Pa s/m^3 (1 acoustic kohm). An acoustic kohm equals the acoustic immittance of a 1-cm^3 volume of air at sea level, when barometric pressure equals 101 Pa (760 mm Hg) and temperature equals 20°C . These various units (mmho, kohm, mm Hg) have been used, so the ANSI S3.39 standard specifies uniform methods to label and scale the x - and y -axes of the tympanogram to allow for uniformity and easier correspondence between different instruments and clinics.

The tympanogram should be plotted with the probe ear indicated. The tympanogram may display compensated or baseline middle ear admittance relative to specified pressure (compensated or baseline) or it may display total peak admittance, including the ear canal admittance (compensation or baseline off). In either case, the compensation method and pressure used for baseline (e.g., +200, -400 daPa, or ambient) should be noted. The vertical or y -axis label should read: Acoustic admittance $10^{-8} \text{ m}^3/\text{Pa s}$ (1 acoustic mmho) or acoustic admittance of an equivalent volume of air (cm^3) or both. The label on the horizontal or x -axis should read: Air pressure (daPa) [1 daPa = 1.02 mm H₂O]. Both the x - and y -axes should be linear. Negative air pressure values (below ambient) are scaled to the left of 0 daPa and positive air pressure values (above ambient) are plotted to the right.

For a probe frequency of 226 Hz, the scale aspect ratio should be 300 daPa equal to 1 acoustic mmho (1 cm^3). The scale aspect should remain the same if the total quantity in acoustic admittance is increased or decreased relative to the height of the measured tympanogram or if the recorded pressure range is changed.

SCREENING TYMPANOMETRY

Screening is designed to identify individuals who are at high risk for a given disorder or condition from among the general population with no apparent symptoms. The cost versus benefit of any screening program must be justified, ensuring that benefits outweigh cost. The ASHA (1997) Guidelines for Audiologic Screening endorses the identification of school children at risk for hearing impairment that may adversely affect education, health, development, or communication as an expected outcome for hearing-screening programs. Coordinated hearing and middle-ear screening managed by school systems can play an important role in the identification of children with middle-ear malfunction that provides

the medical community with important information on the presence of chronic OME so that appropriate management options can be determined. Because the largest number of children will be identified through mass screening in pre-school and elementary school hearing-screening programs, it is likely that the initial suspicion of chronic OME that significantly affects hearing will come from the school hearing screening rather than from the medical home. For this reason a coordinated effort among school screening programs and the medical community will result in the optimum management for students with OME (American Academy of Audiology [AAA], 2011; ASHA, 2004).

Most programs combine audiometric screening with tympanometric screening to detect both hearing loss and middle-ear disorders (AAA, 2011; ASHA, 2004). High-risk populations should be screened because of the higher risk of OME and hearing loss and the greater potential for negative impact on development and medical status. High-risk groups include children in Head Start preschools and Early Childhood Special Education (such programs are common in the United States), children with autism, developmental delay, speech–language delay, craniofacial anomalies, or syndromes associated with CHL, Native American or Canadian ethnicity, and children in day care settings. Children with family histories of chronic OME are also at high risk.

Tympanometry screening can be done by healthcare providers such as nurses, physicians, physician assistants, and speech–language pathologists. Support personnel trained and supervised by an audiologist can be used to carry out large-scale screening programs. Applicable state licensure laws and institutional policy should be consulted to determine credentialing requirements for support personnel. Tympanometry screening can be completed in any clean, well-lit space of sufficient size for a chair, the tympanometer, child and examiner, and parent, if applicable. Access to a sink or other hand hygiene and power supply is needed. Handheld screening instruments can run on rechargeable batteries, so testing at bedside in hospitals and clinics is also possible. A sound-treated booth is not necessary because the probe stimuli are presented at levels above ambient noise with insert or supra-aural earphones.

The AAA Childhood Hearing Screening Guidelines (2011) recommend the following procedures for tympanometry screening:

1. Calibrate tympanometry equipment daily.
2. Tympanometry should be used as a second-stage screening method following failure of puretone or OAE screening.
3. Use defined tympanometry screening and referral criteria: A ≥ 250 -daPa TW is the recommended criterion. If it is not possible to use TW, then <0.2 -mmho static admittance can be used as the criterion. A final choice for failure criterion is a negative pressure of >200 to 400 daPa; however, it is not appropriate to use this criterion alone to elicit a referral.

4. Young child populations should be targeted for tympanometry screening.
5. Use results of puretone or OAE and tympanometry rescreening to inform next steps.
6. Rescreen with tympanometry after a defined period, after failing the immediate puretone rescreening, and in 8 to 10 weeks for children failing puretone or OAE screening and tympanometry.

Because of the transient nature of otitis media and the need to minimize overreferrals, screening protocols for middle-ear disorders have recommended to rescreen for abnormal tympanometry results before a medical referral (AAA, 2011). The rationale for the length of the period between initial mass hearing screening and rescreening is based on information known about spontaneous resolution of transient MEE. Although MEE in children is prevalent, especially for the preschool population, it often resolves spontaneously without treatment. Based on an evidence-based review, AAA (2011) guidelines recommend that if both puretone and tympanometry screening is failed on the day of screening, children should be rescreened. The rescreening period should occur at a minimum of 8 weeks after the initial screening date and no later than 10 weeks after failing hearing screening to allow temporary middle-ear conditions to resolve.

Tympanometry in Newborns and Infants

Tympanograms recorded from newborn infants are often very different from those obtained from older infants, children, and adults mainly because of ear canal flaccidity in newborns. In neonate ears with confirmed middle-ear disease, 226-Hz tympanograms may not provide accurate diagnostic information. In addition, the variability of 226-Hz tympanometry in young infants because of the presence of M-shaped or notched patterns casts doubt on the

clinical utility of these measures for newborns (Hunter and Margolis, 1992; Paradise et al., 1976; Sprague et al., 1985). For these reasons, 226-Hz tympanometry is not an effective test for middle-ear measurement in newborns.

The earliest tympanometric recordings from neonate ears were made with single-component instruments that used a 220-Hz probe tone and “arbitrary compliance units” (Bennett, 1975; Keith, 1973). These studies reported a frequent occurrence of double-peaked tympanograms. Later studies recorded resistance and reactance tympanograms at two probe frequencies, 220 and 660 Hz (Himelfarb et al., 1979; Sprague et al., 1985). Overall, these studies have shown that the newborn ear is highly resistive and has low negative reactance, suggesting a significant mass effect that offsets the stiffness of the middle-ear system. These effects are probably related to developmental differences between infant ear canals and middle ears relative to those of older children and adults. Anatomical and physical differences in the infant ear, ear canal wall flaccidity (Holte et al., 1991), smaller ear canal and middle-ear space, TM thickening, presence of middle-ear fluid and mesenchyme in some ears, and a more horizontal orientation of the TM with respect to the axis of the ear canal, are the most likely contributors (Eavey, 1993; Ruah et al., 1991).

Evidence has accumulated that tympanometry using a higher probe tone frequency (e.g., 1,000 Hz) is more sensitive to middle-ear status, compared with 226-Hz tympanometry, in infants less than 4 to 6 months old. Some studies have reported normative data for a variety of young ages, and some have investigated test performance of specific 1,000-Hz admittance criteria in predicting OAE screening results. Table 9.3 provides tympanometry normative data for infants and toddlers for 226 and 1,000-Hz probe tones.

Using a shape classification technique, Baldwin (2006) compared admittance tympanometry results at 226, 678, and 1,000 Hz between young infants (mean = 10 weeks) classified

TABLE 9.3

Normative Data for Tympanometry (226- and 1,000-Hz Probe Tones) in Infants and Children

Study	Age	Probe Frequency (Hz)	Y_{tm} 5–95 Percentiles (mmho)	Tympanic Width (daPa)
Margolis et al. [2003]	Birth to 4 wks	1,000	0.60–4.3 [–400 tail]	NA
Shahnaz et al. [2008]	32 wks gestational age	1,000	0.10–1.50 [+250 tail] 0.53–2.31 [–400 tail]	NA
Kei et al. [2003]	1–6 days	1,000	Right ears 0.39–2.28 [+200 tail]	Right ears 56.6–154
	1–6 days	1,000	Left ears 0.39–1.95 [+200 tail]	Left ears 46.1–144.2
Roush et al. [1995]	6–12 mos	226	0.20–0.50 [+200 tail]	102–234
	12–18 mos	226	0.20–0.60 [+200 tail]	102–204
	18–24 mos	226	0.30–0.70 [+200 tail]	102–204

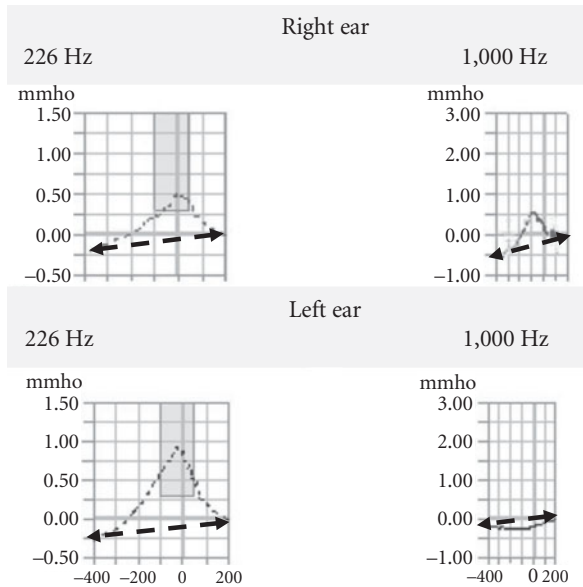

FIGURE 9.8 Tympanograms measured at 226 and 1,000 Hz in a newborn infant with a normal and disordered middle ear for the right and left ears, respectively. [Modified from Zhiqi L, Ku Y, Zhiwu H. [2010]. Tympanometry in infants with middle ear effusion having been identified using spiral computerized tomography. *Am J Otolaryngol.* 31, 96–103.]

as having either normal or disordered middle-ear function, based on a combination of air- and bone-conduction auditory brainstem response (ABR) results and behavioral assessments. The tympanograms were organized using the traditional visual classification scheme discussed earlier (Jerger, 1970; Lidén, 1969) and an alternative method proposed by Marchant et al. (1986). The alternative method for classifying 1,000-Hz tympanograms provided the best results, with sensitivity of 0.99 and specificity of 0.89. The alternative method simply requires identification of the positive and negative Y tympanogram “tails” and drawing (visually or in reality) a line between the two points. Tympanograms measured at 226 and 1,000 Hz in a newborn infant with a normal middle ear as determined by CT scan in the right ear are shown in the left and right panels of Figure 9.8, respectively (Zhiqi et al., 2010). A tympanogram tracing falling above the dashed line connecting the tympanogram tails is suggestive of a normal middle ear, whereas a tracing falling below the line would be suggestive of middle-ear dysfunction. These plots show that 1,000 Hz is diagnostic in the left ear, whereas 226 Hz is not.

MULTIFREQUENCY, MULTICOMPONENT TYMPANOMETRY

Multifrequency, multicomponent tympanometry (MFT) expands on conventional 226-Hz tympanometry through

the use of more than one probe tone frequency, typically ranging from 226 to 2,000 Hz, and measurement of more than one acoustic immittance component (e.g., admittance (Y_a), conductance (G_a), susceptance (B_a), and phase angle (ϕ_a)). A strength of MFT is the ability to identify both quantitative and qualitative changes in immittance components across frequency to obtain a more detailed view of the admittance characteristics of the middle ear than is possible with only a single-frequency or single-immittance component.

The qualitative hallmarks of MF tympanograms for adults with normal middle-ear function are the systematic and predictable tympanometric patterns that result with changes in frequency. Early work by Colletti (1975) demonstrated a systematic change in tympanometric shape from the well-known single-peaked tympanogram, to a slight notched peak shape, followed by a tympanogram with a deeper notched peak, eventually progressing to a “M”-shaped tympanogram. Examples of systematic changes in tympanogram morphology are shown in Figure 9.9. Each panel in Figure 9.9 represents uncompensated tympanograms for different immittance components and demonstrates the relationships between changes in frequency and tympanogram morphology; tympanogram shape becomes more varied and complex as frequency increases. Note, that whereas the tympanograms for each immittance component follow a similar sequence of morphologic change, the frequencies

FIGURE 9.9 Uncompensated multiple frequency conductance [G_a], susceptance [B_a], admittance [Y_a], and phase angle [ϕ_a] tympanograms recorded from a 40-year-old man with normal middle ear function.

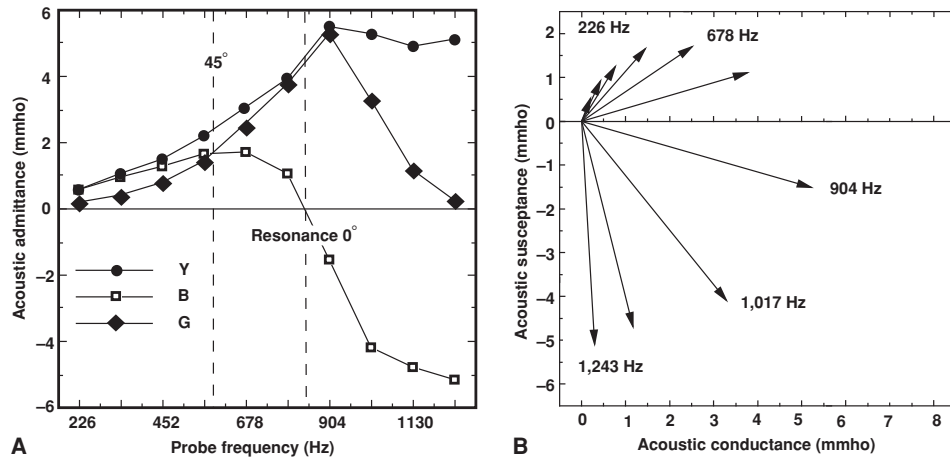

FIGURE 9.10 Peak-compensated static acoustic admittance calculated from the normal multiple frequency tympanograms in Figure 9.9. Peak $200B_{tm}$ [open squares], $200G_{tm}$ [filled diamonds], and $200Y_{tm}$ [closed circles] are plotted in rectangular format as a function of probe frequency in [A]; the rectangular admittance values corresponding to phase angles of 45° and 0° are indicated by dashed lines. Rotation of the admittance vector as a function of probe frequency is plotted in polar format in [B].

at which notching begins and the extent to which changes in tympanogram morphology occur vary by immittance component. Identification of frequencies at which some of the characteristic changes in tympanogram morphology occur can provide useful diagnostic information.

The tympanograms shown in Figure 9.9 present a much more complicated picture than is portrayed by single-frequency, single-component tympanograms. Fortunately, there are several ways to analyze and interpret the information presented in Figure 9.9. Recall the discussion earlier in the chapter regarding the calculation of peak-compensated static acoustic admittance (Y_{tm}) with 226-Hz tympanometry; Y_{tm} is derived by simply finding the peak to tail (+200 daPa) amplitude of the admittance tympanogram. This same procedure can be applied to the group of tympanograms in Figure 9.9, with the note that when a notch or trough is present, the trough to tail amplitude is measured. The results are shown in Figure 9.10A where Y_{tm} for three tympanometric components (Y_a , B_a , and G_a) is plotted as a function of frequency (Hz). Plots for each component present with a similar monotonically rising magnitude (mmho) from 226 through approximately 550 Hz. The dashed line at approximately 550 Hz represents the frequency at which the amplitudes of B_a and G_a are equal or when the admittance phase angle (ϕ_a) is at 45° . As frequency increases, the magnitudes of Y_a and G_a continue to increase until both begin to decrease at approximately 900 Hz, with G_a decreasing more rapidly, but neither falling below 0 mmho. Alternatively, B_a follows a significantly different path above 550 Hz and crosses 0 mmho at approximately 850 Hz, then continues to -5 mmho at 1,243 Hz. The point at which B_a crosses 0 mmho is denoted by a dashed line at approximately 850 Hz and represents middle-ear resonance, or the point at which mass and stiffness susceptance are equal. Identifying the

extent to which mass and stiffness influence the acoustic response properties of the middle ear can provide important clues regarding the state of the middle ear. For example, positive B_a would indicate that an ear is in a stiffness-dominated state, whereas negative B_a would indicate that a middle ear is in a mass-dominated state.

Figure 9.10B shows an alternative plotting scheme for data from Figure 9.10A. In this case, the vectors (arrowed lines of varying length) represent the admittance magnitude (algebraic sum of B_a and G_a) by frequency, with an orientation or angle determined by ϕ_a . Similar to the plot in Figure 9.10A, estimation of RF and contributions of mass and stiffness can be determined from Figure 9.10B. For vectors above zero, phase angle is positive and would therefore be considered stiffness controlled; below zero, phase angle is negative and would therefore be considered mass controlled. The plot in Figure 9.10B highlights the importance of knowing the ϕ_a ; without phase angle, it is not possible to determine the “direction” of the vector, or therefore, the frequency at which resonance occurs or if a middle ear is mass or stiffness dominated. The information presented in Figure 9.10B suggests that middle-ear resonance occurs at a frequency between 791 and 904 Hz. An alternative to calculating and/or plotting data obtained from MFT is to rely on the information that is obtained through the morphologic changes in the tympanograms themselves.

The Vanhuyse Model

During the same period of time when Colletti’s (1975) early work was published, a group of nuclear physicists, at an otolaryngologist’s request, were trying to explain the underlying cause of a series of complex tympanometric shapes obtained from a patient. A physicist in the group suspected

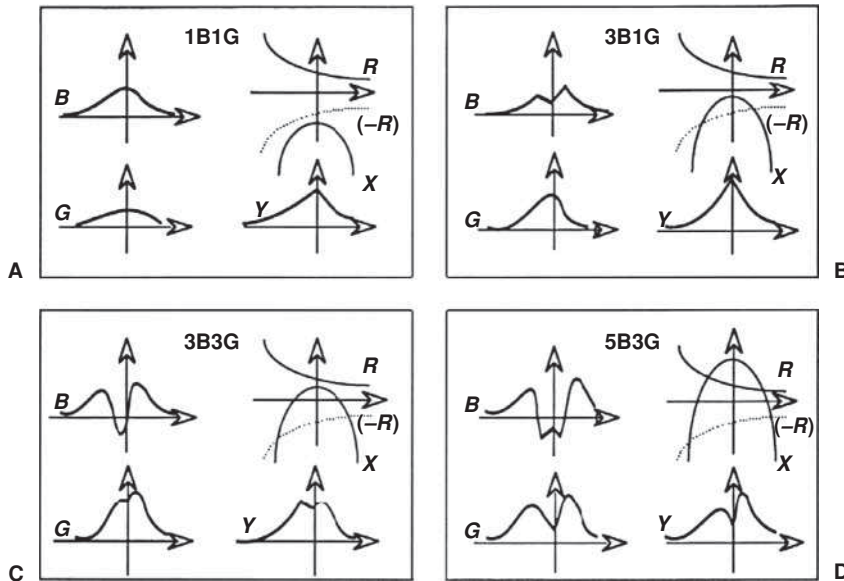

FIGURE 9.11 A model proposed by Vanhuysse et al. (1975) shows patterns of susceptance [B], conductance [G], resistance [R], reactance [X], and admittance [Y] tympanograms. [A–D] depict the interaction of resistance and reactance and the effects on B, G, and Y tympanograms in a healthy adult ear, beginning with what would be expected for low-frequency probe tone in [A] to progressively higher frequencies in [B–D]. [Adapted from Hunter LL, Shahnaz N. (2014) *Acoustic Immittance Measures: Basic and Advanced Practice*. San Diego, CA: Plural Publishing, reprinted with permission.]

a simple explanation based on the interaction of the impedance components of resistance and reactance and quickly presented a model that accounted for the different tympanometric patterns. This model, first presented in publication by Vanhuysse et al. (1975), has become one of the most important contributions to the understanding of multifrequency tympanometry. The Vanhuysse model, as it has come to be known (Figure 9.11, Hunter and Shahnaz, 2014), is based on the assumption of the changes in the shapes of resistance and reactance as a function of ear canal pressure. The model in Figures 9.11A, 9.11B, 9.11C, and 9.11D depicts the interaction of resistance and reactance in a healthy adult ear, beginning with what would be expected for low-frequency probe tone in Figure 9.11A to progressively higher frequencies in Figures 9.11B, 9.11C, and 9.11D. The influence of the interaction of resistance and reactance on susceptance (B_a), conductance (G_a), and admittance (Y_a) is also shown in each subfigure. The model is divided into categories based on the number of positive and negative peaks, or extrema, in the susceptance and conductance tympanograms. For example, in Figure 9.11A, the “BG” tympanograms, as they have come to be known, each have one peak or extrema and would be classified as 1B1G tympanograms. The complexity of the BG tympanogram morphology increases as resistance (R) and reactance (X) interact, changing from a 1B1G pattern, to a 3B1G pattern in Figure 9.11B, and so forth. Resistance (R) is assumed to decrease monotonically as a function of negative to positive change in air pressure, as shown in the upper right hand corner of Figures 9.11A to 9.11D. On the other hand, reactance (X) is a single-peaked function, symmetric around ambient ear canal pressure, also shown in the upper right hand corner of panels A through D. Although single-frequency, single-component tympanograms can be interpreted using the Vanhuysse model, employing this model for interpreting tympanograms at multiple frequen-

cies and with multiple components is more useful since more complexity in tympanometric shape is typically seen at higher probe frequencies and with individual admittance components. For example, note that the admittance tympanograms (Y_a), located in the bottom right hand corner of panels A to D, present with essentially only two patterns (a 3Y pattern) as resistance and reactance interact. The BG tympanograms on the other hand are more sensitive to the interactions of resistance and reactance, which is reflected in the more complex tympanometric patterns as frequency increases (e.g., a 5B3G pattern in Panel D). The Vanhuysse model’s depiction of the effects of the interaction of resistance and reactance on susceptance (B_a), conductance (G_a), and admittance (Y_a) led to the use of this model as the dominant strategy for interpreting MFT data.

Resonant Frequency

The primary diagnostic utility of MFT is found in the ability to determine whether the middle ear is characterized by an RF that is typical or higher than normal, such as with otosclerosis, or lower than normal, such as with ossicular discontinuity. Examination of both quantitative and qualitative changes in tympanogram morphology can provide clues regarding the RF of the middle ear. Although different qualitative methods of estimating RF have been suggested, a simple and accurate method involves examining the point at which the notch in the susceptance tympanogram approximates the plane of the positive tail of the tympanogram (Hunter and Margolis, 1992). Figure 9.12A shows an example of the notch in a susceptance tympanogram equal to the magnitude of the plane of the positive tail (illustrated with the horizontal line); this pattern is indicative of middle-ear resonance. Figures 9.12B and 9.12C represent the admittance characteristics of the same

FIGURE 9.12 Susceptance [B] and conductance [G] tympanograms representative of a middle ear at resonance [A], a middle ear that is stiffness dominated [B], and a middle ear that is mass dominated [C]. [Wiley TL, Fowler CG. [1997] *Acoustic Immittance Measures in Clinical Audiology. A Primer*. San Diego, CA: Singular Publishing.

middle ear measured at a frequency below RF and a frequency above RF, respectively. The tympanograms represented in Figure 9.12 were obtained in the same manner in which conventional single-frequency tympanograms are obtained by holding frequency constant and sweeping pressure in a positive to negative direction (e.g., a sweep-pressure procedure).

To truly make the information in Figure 9.12 useful it is necessary to know the frequency at which the tympanograms were obtained. The important clinical question would be: Is the frequency at which the susceptance notch crosses the plane of the positive tail above or below the range in which a normal RF is expected? Mean middle-ear RF for adult ears ranges from approximately 1,100 to as high as 1,800 Hz. If the BG tympanogram presented in Figure 9.12A was observed at a probe frequency within the normal range for middle-ear RF, this result would suggest normal middle-ear function. If middle-ear resonance was identified at a much lower frequency, outside the normal range such as 500 Hz, this would be consistent with a mass-dominated pathology; a resonance identified at a much higher frequency such as beyond 1,800 Hz may suggest the possibility of a stiffness-dominated pathology. A quantitative way of estimating RF includes a sweep-frequency approach where the difference between B at a tympanogram tail (either positive or negative) and B at peak pressure (e.g., ΔB) is plotted as a function of frequency; the frequency at which ΔB approaches 0 (0 mmhos) is considered the middle-ear RF (see Hunter and Shahnaz, 2014). It is important to note that the range of RF observed in ears with normal middle-ear function is quite large and data from some studies show a range that is skewed toward the upper frequencies; some studies report an upper limit of normal at or close to 2,000 Hz. The large range of normal for RF and the potential “ceiling” effect observed in some normative data lessen the clinical utility of MFT in detecting pathologies that produce stiffening effects (Shanks et al., 1993). Although the frequency resolution over which MFT data can be obtained varies by equipment manufacturer, it seems that increasingly options for MFT tests are limited to three frequencies (e.g., 226, 678, and 1,000 Hz).

Some equipment allows for a quantitative approach for estimating RF that does not require the clinician to make a judgment based on visual classification of tympanogram morphology. For example, some Grason Stadler systems (GSI-33 and Tymptstar) with MFT capabilities can obtain a sweep-frequency MFT recording that estimates the B_a tympanogram peak (or notch) to tail difference (e.g., ΔB) across a range of frequencies; for sweep-frequency recordings, ear canal pressure is held constant and frequency is changed. The point at which a ΔB value of 0 is obtained (e.g., 0 mmhos, or the point where mass and stiffness are equal and phase angle is 0) is identified as middle-ear RF.

Low Resonant Frequency

Pathologies that typically result in abnormally low RF and abnormal tympanogram morphology include ossicular discontinuity and external otitis. For example, Figure 9.13 represents the effects of ossicular discontinuity on BG tympanograms. First, it is obvious that the tympanogram morphology is significantly different than what

FIGURE 9.13 A susceptance [B] and conductance [G] tympanogram representative of a middle ear with ossicular discontinuity. [Wiley TL, Fowler CG. [1997] *Acoustic Immittance Measures in Clinical Audiology. A Primer*. San Diego, CA: Singular Publishing.]

is expected from a normal middle ear (re: BG tympanograms in Figure 9.12). In addition, because the frequency at which these BG tympanograms were obtained (678 Hz) is below the normal limits for RF, and the B_a notch extends well below the plane of the positive tail, it can be concluded that this middle ear is mass dominated and is operating at a low RF; RF is potentially far below 678 Hz, since the notch extends significantly below the plane of the positive tail. Also, notice the wide notching for both B_a and G_a tympanograms (peak-to-peak difference on the x -axis of approximately 150 daPa). This wide-notch configuration is another tympanogram quality consistent with ossicular discontinuity. Figure 9.14 shows MFT for a 9-year-old boy with recurrent OME and a thickened, retracted right eardrum. The left ear had a normal appearance, with 226-Hz tympanograms normal in both ears (see inset). In this case, the BG tympanograms at 500 Hz shows notching in the right ear for B (susceptance) and appears normal for the left ear. Examination of the changes in BG tympanograms as frequency increases suggests that RF is about 500 Hz in the right and just above 710 Hz in the left. At 500 Hz in the right ear, a 3B3G pattern is apparent, showing mass domination. Thus, the multifrequency tympanograms clearly show abnormal patterns that are not found in the 226-Hz admittance tympanograms.

High Resonant Frequency

Pathologies that create a middle-ear system dominated by stiffness can result in abnormal tympanogram morphology and RF that exceeds the normative range. Because stiffening

pathologies have the effect of reducing the mobility of the TM and low-frequency stimuli are less affected by increased stiffness, BG tympanograms from stiffness-dominated ears are generally more flat, with fewer peaks. For stiffness-dominated ears, as frequency increases, changes in tympanogram morphology may occur and may progress to a point indicative of resonance; however, RF may be beyond the upper limits of the immittance device, so RF may not be identified. Figure 9.15A illustrates the stiffening effects of partial OME on BG tympanograms. Note that although the tympanograms in Figure 9.15A exhibit peaks that are more widely spaced than normal, similar to the BG tympanograms in Figure 9.13, their amplitudes are greatly reduced. Figure 9.15B demonstrates a BG tympanogram pattern for an ear completely filled with effusion; in this case the middle ear is dominated by extreme stiffness and no tympanometric movement is detected.

Several studies have investigated the potential utility of MFT to detect otosclerosis. Ogut et al. (2008) obtained conventional and MFT data from 28 ears with surgically confirmed otosclerosis and 100 ears with normal middle-ear function. Using a static acoustic admittance criterion of ≤ 0.3 mmhos (for 226-Hz tympanometry) to classify an ear as disordered, sensitivity and specificity values of 40% and 98% were obtained. For RF with a criterion of $\geq 1,025$ Hz, sensitivity and specificity values of 80% and 82%, respectively, were reported; a sweep-frequency method to identify ΔB was used to estimate middle-ear resonance. Other studies have reported improved test performance for detecting otosclerosis when using the frequency most closely approximating a 45° admittance phase angle (Shahnaz and Polka, 1997); phase angle of 45° is defined as the point at which the admittance contributions of B_a and G_a are equal (see Figure 9.10A).

Although some results from the studies mentioned previously suggest that MFT is more sensitive to otosclerosis than single-frequency tympanometry, a systematic review of the literature examining the diagnostic accuracy of MFT in identifying the presence or absence of otosclerosis suggested that criterion references of RF or phase angle of 45° (F_{45°) are not strong predictors of otosclerosis (Sanford et al., 2012). Specifically, Sanford et al. (2012) identified three studies that met strict inclusion criteria and had suitable data for the systematic review. Based on sensitivity and specificity data from each study, likelihood ratios (both positive and negative ratios) and 95% confidence intervals were computed. Whereas the high proportion of positive likelihood ratios in the 95% confidence interval range suggested that RF might be potentially useful in ruling out otosclerosis, the low proportion of negative likelihood ratios suggested that RF and a phase angle of 45° are weak predictors of otosclerosis.

The primary clinical assets of MFT are the ability to assess the relative contributions of mass and stiffness of the middle ear and to help identify middle-ear RF. However,

FIGURE 9.14 The 226-Hz admittance tympanograms and multifrequency tympanograms for a 9-year-old boy with recurrent otitis media with effusion and a thickened, retracted right eardrum.

one limitation associated with MFT tests is the restricted range of probe frequencies (<2,000 Hz), which could limit identification of RF in some cases (Shanks et al., 1993). In addition, the more complicated multifrequency tympanometric response patterns are often difficult for clinicians to interpret, and the normative range of RF is fairly wide (Margolis and Goycoolea, 1993). However, MFT test results, in conjunction with other audiometric test findings, can be used to provide more information regarding middle-ear

function than would be available from a single audiometric test interpreted in isolation.

WIDEBAND ACOUSTIC IMMITTANCE

Imagine interpreting audiometric test findings from a patient using only the information from the audiogram at 250 Hz. With this limited amount of information it would

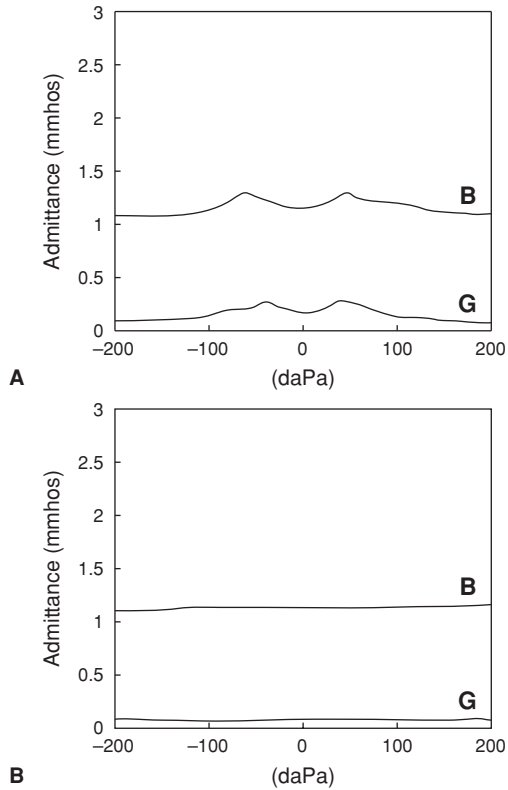

FIGURE 9.15 Susceptance [B] and conductance [G] tympanograms representative of a middle ear with partial otitis media with effusion [A] and an ear completely filled with effusion [B]; in the latter case, no tympanometric movement is detected. [Wiley TL, Fowler CG. (1997) *Acoustic Immittance Measures in Clinical Audiology. A Primer*. San Diego, CA: Singular Publishing.]

be difficult to comprehensively characterize the patient's auditory sensitivity. However, for decades, audiologists have relied on tests that use single or a limited range of frequencies to describe middle-ear function. Although conventional single- and multifrequency tympanometry have been and continue to be useful tests of middle-ear status in adults and children presenting with a variety of middle-ear disorders, a broadband measure of middle-ear function provides a more comprehensive view of the middle ear's acoustic response properties over a wide range of frequencies. Wideband acoustic immittance (WAI) tests provide this broadband view of middle-ear function and are showing promise as powerful tools for evaluating middle-ear status (Feeney and Keefe, 2012).

PRINCIPLES AND CALIBRATION OF WAI

WAI responses have several desirable qualities. Most importantly, WAI tests utilize stimuli (clicks or simultaneously

presented puretones) with broad frequency spectra (usually 250 to 8,000 Hz) to assess middle-ear status, whereas for conventional tympanometry, generally only a single puretone is used. The capability to assess a broad frequency range allows for improved understanding of how the middle ear is functioning across the range of frequencies important for human hearing. Second, unlike admittance tympanometry, WAI measurement results are relatively independent of the location of measurement in the ear canal; this allows for a direct measure of middle-ear function without as much concern for ear canal effects.

WAI measurement theory takes advantage of the fact that when sound is presented to the external ear canal some of the sound is absorbed by the middle ear and transferred into the inner ear, whereas some of the sound is reflected back along the ear canal. The application of a rigorous calibration technique facilitates reliable measurement of the absorbed (or reflected) sound.

The most common calibration routine reported in the literature involves the calculation of the Thevenin source impedance and source pressure associated with the transducers within the WAI probe (Keefe et al., 1992; Liu et al., 2008; Voss and Allen, 1994). This process typically involves making acoustic pressure measurements within a set of at least two rigid cylindrical cavities that are similar in diameter to the ear; different sets of cavities, which approximate the average ear canal diameter for adults and infants, are used. Once the Thevenin parameters of the WAI probe assembly are known, the same probe and stimulus used in calibration can be applied to an unknown system (e.g., the human ear canal) and pressure measurements can be made. The pressure measurements made in the ear canal are then compared to the characteristic impedance of the ear canal using standard transformations to derive the pressure reflectance coefficient, R , which is then squared to derive the energy/power reflectance, \mathfrak{R} (Keefe et al., 1992). Absorbance is calculated as $1 - \mathfrak{R}$ as a function of frequency and represents the proportion of sound power absorbed by the middle ear. Use of this calibration routine and data transformation overcomes the problems introduced with standing waves for frequencies above 2,000 Hz, as encountered with conventional impedance measurements (Stinson et al., 1982). Therefore, if negligible sound is absorbed by the ear canal, which is generally assumed in adult ears, WAI measured at the plane of the probe tip is essentially the same as if the measurement was taken next to the TM.

WIDEBAND ACOUSTIC IMMITTANCE MEASUREMENTS

The umbrella term, WAI, covers a variety of acoustic measurement types, such as energy or power reflectance, absorbance, conductance, and admittance. The variety of measurement types derived from WAI data provide alternative perspectives on how the transfer of acoustic information

FIGURE 9.16 Wideband absorbance data, plotted as a function of frequency [kHz], from an adult with normal middle-ear function.

is handled by the middle ear. Whereas the term wideband reflectance has been used regularly to describe this emerging measurement tool, in this chapter, we will focus primarily on the quantity of absorbance and use the term WAI when referring, generally, to this family of WB ear canal-based measurements (Feeney et al., 2013). Whereas absorbance is simply 1 minus power reflectance, absorbance is better suited for some WAI analysis techniques (Liu et al., 2008) and the peak-shaped absorbance function bears resemblance to conventional tympanometry morphology. Currently, two audiologic device manufacturers provide commercially available systems capable of making WAI measurements (Mimosa Acoustics, Champaign, IL and Interacoustics, Assens, Denmark).

Unlike tympanometry measurements, WAI data can be obtained at ambient ear canal pressure. An ambient WAI test, which takes just 1 to 2 seconds to complete, provides a broad spectral view of middle-ear function. As evidenced

in Figure 9.16, WB absorbance changes as a function of frequency and ranges from 1, meaning much of the acoustic power is absorbed, to 0, meaning little of the acoustic power is absorbed. Higher amounts of absorbance occur in the mid-frequency range (750 to 4,000 Hz) with relatively less absorbance in both the low and high frequencies. A growing body of work has described WAI for infants, children, and adults with normal middle-ear function (Hunter et al., 2013; Kei et al., 2013; Shahnaz et al., 2013) and with middle-ear disorders (Nakajima et al., 2013; Prieve et al., 2013).

Wideband Tympanometry

Just as the addition of ear canal pressure sweeps increased the usefulness of early work with admittance measurements in adults and children, it was hypothesized that WAI measurements would reveal more developmental effects and be more diagnostically useful if they were obtained in the presence of ear canal pressure changes (Keefe and Simmons, 2003; Margolis et al., 1999; Piskorski et al., 1999; Sanford et al., 2009). WAI data obtained in the presence of ear canal pressure sweeps (e.g., WB tympanometry) are presented in Figure 9.17; the WB tympanogram provides a multidimensional representation of middle-ear function with absorbance plotted as a joint function of frequency and pressure. Because the pressure sweep used in WB tympanometry is similar to that used in conventional tympanometry, it is possible to extract both WB and traditional single-frequency tympanometry measurements in a single measurement of approximately 7 seconds. Currently, the Titan system (Interacoustics, Assens, Denmark) is the only FDA-approved device capable of measuring both ambient and tympanometric WAI.

FIGURE 9.17 Wideband tympanogram data [absorbance], plotted as a function of frequency [kHz] and pressure [daPa], from an adult with negative tympanometric peak pressure, but otherwise normal middle-ear function. Tympanometric peak pressure is located at approximately -100 daPa [denoted with the *dashed line*]; the *solid black line* denotes absorbance at 0 daPa.

FIGURE 9.18 Wideband absorptance data, plotted as a function of frequency (kHz), from an adult with negative tympanometric peak pressure, but otherwise normal middle-ear function; these data were extracted from the wideband tympanogram presented in Figure 9.17. Absorbance at 0 daPa is denoted by the *solid line* and absorbance at tympanometric peak pressure is denoted by the *starred line*.

The WB tympanogram in Figure 9.17 is from an adult with mild, negative TPP, as evidenced by the peak of the response located at approximately -100 daPa (dashed line). The solid black line denotes absorptance at 0 daPa and represents how the middle ear is operating at atmospheric pressure. The ability to assess the middle ear at TPP, relative to ambient conditions, may provide useful diagnostic information, especially in situations where excess middle-ear pressure, often the more lateral pathology, may be obscuring the presence of another middle-ear disorder (Margolis et al., 1999). Figure 9.18 shows WB absorptance data (extracted from the WB tympanogram in Figure 9.17), plotted at ambient pressure (solid line) and at TPP (starred line). Note that absorptance at ambient pressure in the low frequencies is decreased (relative to absorptance at TPP) because of negative middle-ear pressure. Because absorptance at TPP represents an estimate at which the middle ear is most efficient at transferring acoustic power, evaluation of absorptance data at TPP may be of interest.

Effects of Ear Disorders on Wideband Acoustic Immittance

A number of studies have reported changes in WAI responses in the presence of middle-ear dysfunction including otitis media with fluid (Beers et al., 2010; Ellison et al., 2012; Feeney et al., 2003; Piskorski et al., 1999), otosclerosis (Nakajima et al., 2012; Shahnaz et al., 2009; Voss et al., 2012), excess middle-ear pressure (Beers et al., 2010), perforation of the TM (Feeney et al., 2003; Nakajima et al., 2012; Voss et al., 2012), and ossicular discontinuity (Feeney et al., 2003; Voss et al., 2012).

Excess middle-ear pressure results in increased stiffness of the TM and a systematic decrease in absorptance with increasing negative TPP across the majority of measured frequencies (Beers et al., 2010). Figure 9.19 shows the effects of increased middle-ear stiffness from fluid behind the TM on absorptance (data replotted from Feeney et al., 2003). Specifically, small increases in absorptance occur across low to mid-frequencies, with sharp peaks occurring between 4,000 and 6,000 Hz. A completely different pattern is observed for the ears with TM perforations (Figure 9.19, see right panel), with absorptance as high as 1 in the low frequencies and nonmonotonic patterns above 1,000 Hz. Voss et al. (2012) demonstrated the effect of TM perforation size on WAI for cadaveric ears, showing that smaller perforations resulted in the largest effects; Voss et al. (2012) suggested that resonance effects created by hole in the TM may be the dominant factor responsible for these effects.

Ellison et al. (2012) assessed the accuracy of WAI in predicting MEE in a group of 44 children (median age = 1.3 years) with surgically confirmed OME; an age-matched group of 44 children (median age = 1.2 years) with normal pneumatic otoscopic findings and no history of middle-ear surgery or ear disease was used as the control group. Ellison et al. (2012) found that absorptance was reduced in ears with MEE compared to ears from the control group. In addition, whereas WAI measurement types (absorbance and admittance magnitude) were the best univariate predictors of MEE, a predictor combining absorptance, admittance magnitude, and phase was the most accurate overall. Results from this study suggest that absorptance is sensitive to MEE,

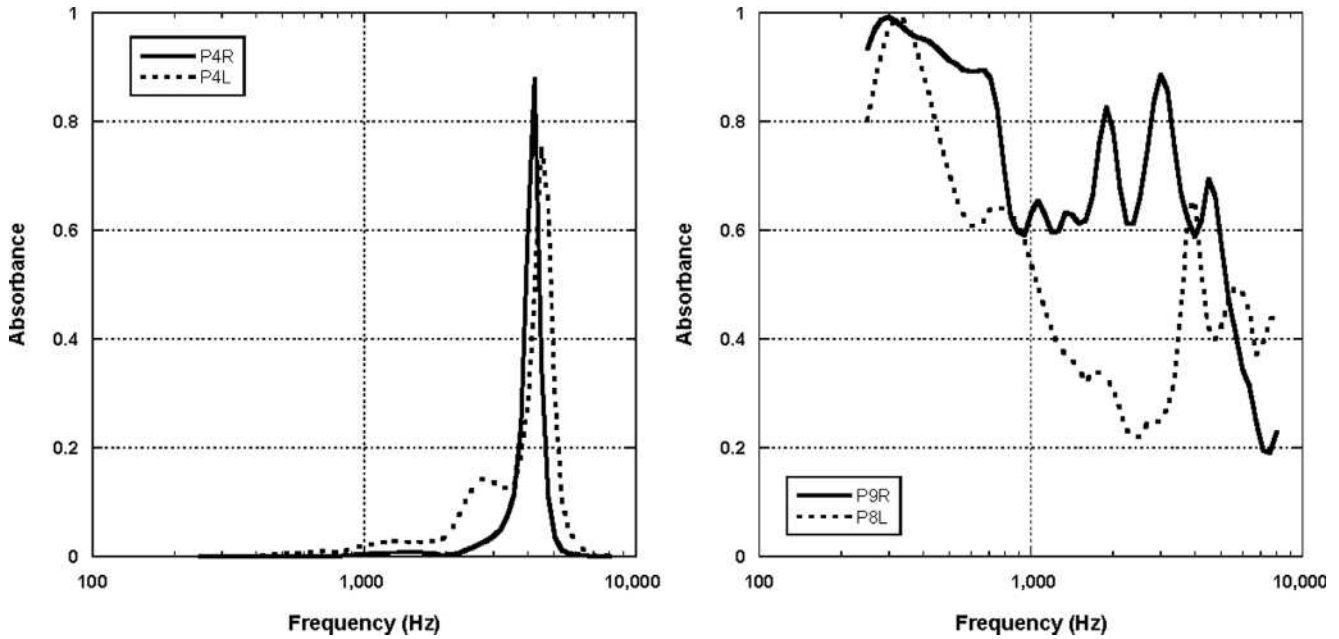

FIGURE 9.19 Wideband absorbance data, plotted as a function of frequency [Hz], from an adult with otitis media with effusion in both ears (**left panel**) and from two adults with tympanic membrane perforations (**right panel**). Replotted from Feeney MP, Grant IL, Marryott LP [2003].

and WAI measurements are accurate predictions of MEE in young children.

Sanford and Brockett (in press) obtained WAI data from 20 ears with suspected OME (sOME), 19 ears with PE tubes, and 15 ears with negative TPP (ranging from -115 to

-275 daPa); mean WAI data are presented in Figure 9.20. Ears with sOME presented with reduced absorbance across a majority of frequencies (250 to 8,000 Hz) with more significant reduction in absorbance and narrowing of the absorbance peak from 1,000 to 5,000 Hz. The presence of

FIGURE 9.20 Wideband absorbance data, plotted as a function of frequency [Hz], from children with suspected otitis media with effusion [sOME], negative tympanometric peak pressure [TPP], and pressure equalization tubes [PE tube]. The shaded region represents the 10th to 90th percentiles for absorbance for 0.5-7 year-old children with normal middle-ear function (N = 59 ears; mean age of 1.8 yrs., unpublished data from Boys Town National Research Hospital). Recreated figure using data from Sanford CA, Brockett JE. (in press) article is still In Press Characteristics of wideband acoustic immittance in ears with middle ear dysfunction. *J Am Acad Audiol*.

PE tubes creates an additional absorbance peak in the low frequencies, perhaps because of the resonance effect of the PE tube. Changes in WAI for ears with negative TPP are less significant than those with OME and PE tubes; for ears with negative TPP, the general trend is for decreased absorbance below 2,000 Hz, with a mixture of decreased and increased absorbance above 2,000 Hz.

Work by Shahnaz et al. (2009) demonstrated statistically significant differences in power reflectance below 1,000 Hz for individuals with surgically confirmed otosclerosis compared with a group of individuals with normal middle-ear function. However, the authors noted that the range of variability for power reflectance for otosclerotic ears overlapped considerably with the power reflectance in the normal middle-ear group; this overlapping variability would make it difficult to detect the presence of otosclerosis on an individual case-by-case basis.

Nakajima et al. (2012) presented interesting WAI findings from individuals with superior semicircular canal dehiscence (SCD). Although the site of lesion for SCD is not in the middle ear, the “third window” created by the dehiscence in the semicircular canal allows energy to leave the inner ear via the dehiscence, which can result in a decreased impedance at the oval window. For six ears with SCD, Nakajima et al. (2012) noted a consistent notching pattern in the power reflectance close to 1,000 Hz. These results suggest that WAI may be a useful tool to help diagnose SCD.

Predicting Conductive Hearing Loss

Whereas increased TW and decreased Y_{tm} are sometimes associated with CHL, conventional tympanometric characteristics are not accurate predictors of CHL. Results from a number of studies suggest that WAI tests may be accurate predictors of CHL (Keefe et al., 2012; Keefe and Simmons, 2003; Piskorski et al., 1999; Prieve et al., 2013). Building on work by Piskorski et al. (1999) and Keefe and Simmons (2003), Keefe et al. (2012) tested the hypothesis that WAI accurately predicts CHL in young children suspected of having OME. The reference standard for identification of CHL was air–bone gaps (ABGs) at octave frequencies from 250 to 4,000 Hz, based on behaviorally measured audiometric thresholds. Absorbance and conventional 226-Hz tympanometric measurements were obtained from 25 children (36 ears aged 3.5 to 8.2 years) with CHL and 23 children (44 ears aged 2.6 to 8.2 years) with normal hearing. For WAI measurements, a likelihood ratio was calculated (using the average mean and standard deviation of WAI responses across frequency, weighted more heavily where differences in WAI between the OME and control groups were greater) to predict hearing status (e.g., CHL or normal). The area under the receiver operating characteristic curve (AUC) was calculated using criterion ABGs of ≥ 20 , 25, and 30 dB. WAI and conventional tympanometric predictors were evaluated for individual octave frequencies and for a range of frequen-

cies (250 to 4,000 Hz) at which a CHL was present. Results showed WB absorbance as the best overall predictor of CHL with AUC values ≥ 0.97 . These results support the hypothesis that WAI tests are accurate predictors of CHL in children, offering improved test performance for predicting CHL relative to conventional tympanometric measurements.

Effects of Maturation and Aging

Understanding maturational and aging-related changes in the middle ear and their effects on transfer of sound power through the middle ear is important for our understanding of developmental processes in the auditory system and for the development of clinical norms for hearing and middle-ear assessment. These changes may also impact the interpretation of ABR tests and to a greater extent OAE measurements, which depend on both forward and reverse transfer of sound power through the middle ear.

Several studies have examined WAI responses in the newborn period (Aithal et al., 2013; Hunter et al., 2010; Sanford et al., 2009) with aims of examining developmental effects on WAI or comparing WAI measurements from ears that either passed or were referred on newborn hearing tests, such as OAEs. WAI data from these studies of infants in the newborn period are in general agreement and the overall shape and magnitude of the WAI data are similar. However, studies involving infants ranging in age from just a few days and into childhood have revealed significant age-related differences in WAI (Keefe et al., 1993; Werner et al., 2010) and results suggest that dramatic changes in WAI occur throughout infancy. Figure 9.21, containing replotted data from Keefe et al. (1993), shows the most dramatic changes in absorbance occurring during the first year of life; however, differences in absorbance persist beyond 12 months of age. Sanford et al. (2009) and Hunter et al. (2010) reported test performance results for WAI and 1,000-Hz tympanometry in terms of ability to predict newborn hearing-screening outcomes based on DPOAE screening outcomes. For large numbers of ears, both studies showed that WAI had high sensitivity and specificity for predicting DPOAE screening outcomes and outperformed 1,000-Hz tympanometry.

Relative to WAI data from newborns, a limited number of studies have evaluated WAI data from toddlers, young children, and adolescents and results are inconsistent with respect to identification of significant age-related differences in WAI (Beers et al., 2010; Hunter et al., 2008). Beers et al. (2010) compared WAI data from children ranging in age from 5 to 7 years to WAI data from adult subjects ranging in age from 22 to 32 years and found a significant difference in WAI for frequencies ranging from 310 to 1,250 Hz. However, Hunter et al. (2008) examined WAI data from children aged 6 months to 4 years and reported a lack of significant differences across age, other than for high frequencies. Other studies have reported WAI data for children with normal middle-ear function. Ellison et al. (2012) reported

FIGURE 9.21 Wideband absorbance data, plotted as a function of frequency [Hz], from infants (1, 3, 6, 12, and 24 months) and adults. [Replotted data from Keefe DH, Bulen JC, Arehart KH, Burns EM. [1993] Ear-canal impedance and reflection coefficient in human infants and adults. *J Acoust Soc Am.* 94, 2617–2638 data.]

WAI data for 44 children with a median age of 1.2 years and Keefe et al. (2012) reported WAI data for 26 children with a mean age of 5.5 years. A comparison of the overall shape and magnitude of the WAI data from both studies reveals similar results for the 1- and 5-year-old children; however, WAI data from both groups are somewhat different compared to adult WAI data. Although reasons for these differences are not clear, differences in equipment and calibration methods may be contributing factors. Although the specific maturational influences on WAI data in young children have not been pinpointed, postnatal increases in middle-ear cavity volume, which continues throughout childhood, may be an influence (Anson and Donaldson, 1981). Furthermore, Eby and Nadol (1986) reported that mastoid bone dimensions increase in growth spurts, the first occurring between birth and approximately 7 years of age and the second occurring between ages 11 and 15 years.

It is believed that the TM and middle ear undergo anatomical and physiological changes with advancing age, which cause an increase in middle-ear stiffness (Ruah et al., 1991). Feeney and Sanford (2004) examined 226-Hz tympanometry and WAI in a group of 40 young adults (18 to 28 years) and a group of 30 older adults (60 to 85 years). Whereas the 226-Hz admittance tympanometry data from the two groups were not different, there were significant age effects observed for the absorbance data. Specifically, the older group exhibited a comparative increase in absorbance for frequencies ranging from 800 to 2,000 Hz and a decrease at approximately 4,000 Hz. These results suggest a decrease in middle-ear stiffness as a function of age; these findings are contrary to what would be expected based on the anatomical studies cited above.

Conclusions

An important part of translating WAI techniques to clinically useful tests is to identify alternative ways of analyzing the large amount of data obtained with WAI measurements. Whereas a *qualitative*, pattern recognition approach may be informative in individual cases, *quantitative* analysis techniques will be important for more accurate interpretation of WAI measurements. Although strategies to simplify large, multivariate data sets to univariate predictors have shown promising results (Hunter et al., 2010; Keefe et al., 2012; Sanford et al., 2009; and others), additional approaches, with goals of making data analysis and interpretation relatively straightforward, should improve the clinical utility of WAI tests. In addition, investigations should seek to identify key WAI characteristics for both normal and disordered ears in an effort to develop middle-ear tests with high sensitivity and specificity. Work is also needed to construct normative databases for a variety of age groups since age-related differences in ambient and tympanometric WAI have been reported. With new WAI technology and equipment options becoming available, the development of clinically friendly features will be an important factor for advancements in research and clinical utility of WAI measurements.

FOOD FOR THOUGHT

In this chapter, we have covered principles that govern middle-ear function and how it can be measured clinically. If one could apply a known force directly to different parts of the ear such as the TM, the ossicles, or the oval window,

it would be possible to determine precisely how effectively each of these parts of the ear is able to respond to the applied force. This would theoretically provide exact measures of the impedance properties of each part of the ear. However, it must be appreciated that none of these anatomical components operate in isolation to transmit sound energy. The outer ear and middle ear represent a functionally connected mechanical system, and so changes in impedance for one part affect the function of the entire system. Using acoustic immittance measurements, we are able to indirectly infer the function of the entire middle-ear system by applying a known force to the input of the system, at the plane of the TM, and then measuring how that force is altered. If we measure this input sound compared to the resultant sound as a function of frequency, we can gain an appreciation for how the middle ear reacts in a dynamic way across the speech frequency range. These measures can then be compared to other functional measures, such as audiometry and OAEs, to determine possible pathology and functional impact.

Single-frequency tympanometry using a single low-frequency probe tone and measuring admittance with qualitative type interpretation (A, B, and C types) has been the standard practice in audiometry for over 50 years. This simplified procedure has persisted for so long because it is straightforward, quick, and able to detect OME with reasonable accuracy. Gaining additional diagnostic sensitivity and specificity through more sophisticated stimuli and measurement may be desirable.

The primary clinical assets of MFT are the ability to assess the relative contributions of mass and stiffness of the middle ear and to help identify middle-ear RF. Some of the challenges associated with MFT tests include equipment constraints, which limit the upper frequency range to 2,000 Hz, which could limit identification of RF in some individuals (Shanks et al., 1993). In addition, the more complicated multifrequency tympanometric response patterns are often difficult for clinicians to interpret and the frequency range of what is currently considered normal is fairly wide (Margolis and Goycoolea, 1993). However, MFT test results, in conjunction with other audiometric test findings, can be used to provide more information regarding middle-ear function than would be available from either test interpreted in isolation.

Results from studies using commercial WAI systems are demonstrating greater diagnostic accuracy relative to traditional middle-ear measurement techniques; however, more studies of diagnostic accuracy are needed. It is our hope that future generations of audiologists will be able to make use of these advanced techniques and contribute to the literature regarding their clinical utility. Here are some thoughts we should be aware of and try to answer:

1. Discuss how single-frequency tympanometry differs from multi-frequency and wideband tympanometry, including any evidence that sensitivity is improved with

the addition of multiple frequencies or broad-band stimuli.

2. Describe how tympanometry changes with development from newborn to childhood age ranges, and how this affects sensitivity of tympanometry to middle ear effusion.
3. How does increased stiffness affect tympanometry shape and resonant frequency, and what conditions are primarily due to increased stiffness?

Acoustic Stapedius Reflex Measurements

M. Patrick Feeney and Kim S. Schairer

INTRODUCTION

Metz (1952) measured middle ear impedance and found that it increased when a loud sound was presented to the opposite ear. He hypothesized that the increased impedance was because of middle ear muscle reflexes (MEMR) which stiffened the middle ear system. Metz reported patterns of reflexes in individuals with normal hearing, cochlear hearing loss, and hearing loss due to otosclerosis and vestibular schwannoma. He reported that MEMR thresholds were similar between ears with normal hearing and ears with mild to moderate hearing loss and loudness recruitment (presumably a cochlear site of lesion, e.g., **Ménière** disease). In contrast, no recruitment or reflex was observed in ears with acoustic neuromas (retrocochlear site of lesion) or otosclerosis (middle ear site of lesion). Since Metz's initial observations, MEMR tests have become a standard component of the clinical test battery (1) to cross-check behavioral results, and (2) in conjunction with other test results, to differentiate among middle ear, cochlear, retrocochlear and even non-auditory sites of lesion (e.g., superior semicircular canal dehiscence).

Anatomy and Acoustic Stapedius Reflex Pathways

The two middle ear muscles are the tensor tympani and the stapedius. The body of the tensor tympani muscle is located in a canal above the Eustachian tube in the anterior-medial wall of the middle ear. The tendon stretches from the body of the tensor tympani muscle to the manubrium of the malleus. When the muscle contracts, the tendon pulls the malleus anteriorly and medially, which stiffens the ossicular chain and tympanic membrane (TM). This muscle is innervated by cranial nerve V which is also called the trigeminal nerve. The tensor tympani may contract in response to tactile stimulation or as a startle response to loud unexpected sounds. However, the tensor tympani does not typically contribute to the MEMR measured clinically in humans.

The stapedius muscle is the smallest skeletal muscle in the human body, and it is the main contributor to the MEMR measured clinically in humans. Therefore, in this chapter, the response will be called the acoustic stapedius

reflex (ASR). The body of the stapedius muscle is located in the pyramidal eminence, or small bony protrusion, on the posterior wall of the middle ear. The tendon stretches anteriorly from the body of the stapedius muscle to the posterior surface of the neck of the stapes. The stapedius muscle is innervated by the motor branch of cranial nerve VII which is also called the facial nerve. When an intense sound is presented to the ear, the stapedius muscle contracts and pulls the head of the stapes posteriorly toward the muscle body, which causes an increase in stiffness of the ossicular chain and the TM. The stiffening causes a decrease in admittance of sound into the middle ear that can be measured by a probe in the ear canal, and this is the basis of clinical ASR measurements. The stapedius reflex also can be activated by vocalizations, chewing, yawning, and tactile stimulation.

The ASR is a bilateral response which means that when an activating stimulus is presented to one ear the stapedius muscle contracts in both ears. Therefore, the ASR may be measured in the same ear in which the activating stimulus is presented (ipsilateral conditions) or in the opposite ear (contralateral conditions). There are four overlapping pathways of the reflex arc, including two ipsilateral and two contralateral pathways (Borg, 1973; Lyons, 1978). One ipsilateral pathway is represented by the black arrows in Figure 10.1 and includes the ipsilateral ear canal, middle ear, cochlea, VIIIth nerve, ventral cochlear nucleus (VCN), medial superior olivary complex (MSO), motor nucleus of the facial nerve (MN VII), VIIth nerve, and stapedius muscle. The second ipsilateral pathway includes a connection between the VCN and the ipsilateral MN VII. One contralateral pathway represented by gray arrows in Figure 10.1 includes the middle ear, cochlea, VIIIth nerve, VCN, and MSO on the side of the activating stimulus, and the MN VII, VIIth nerve, and stapedius muscle on the contralateral side. The second contralateral pathway includes a connection between the ipsilateral VCN and the contralateral MSO which connects with the MN VII.

As the intensity of the eliciting stimulus increases, the amplitude of the ASR response increases, and an example of this response growth measured with a clinical immittance system is shown in Figure 10.2. The latency of the acoustic reflex varies by activator (the stimulus used to induce the ASR), but in general it is around 100 ms which reflects the travel time

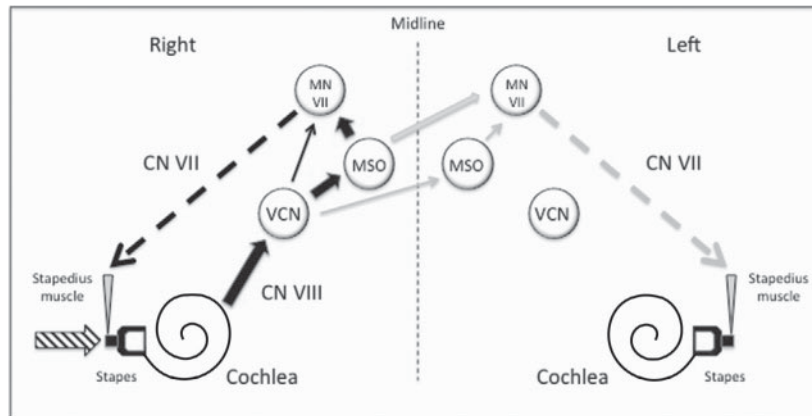

FIGURE 10.1 Right ipsilateral and right contralateral acoustic stapedius reflex pathways are shown as if facing the patient. The activator stimulus (*striped arrow*) is presented to the right ear canal. The pathway is through the right middle ear and cochlea to the VIIIth cranial nerve [CN VIII]. From that point, the right ipsilateral reflex arc (*black arrows*) consists of the ventral cochlear nucleus [VCN], medial superior olivary complex [MSO], and motor nucleus of the VIIth cranial nerve [MN VII], which results in efferent stimulation (*dashed black arrow*) of the stapedius muscle via the VIIth cranial nerve [CN VII]. A second ipsilateral path goes directly from the VCN to the MN VII. The right contralateral reflex arc (*gray arrows*) is simultaneously activated from the ipsilateral VCN to the ipsilateral MSO, to the contralateral MN VII, which results in efferent stimulation (*dashed gray arrow*) of the contralateral stapedius muscle via the CN VII. A second path goes from the ipsilateral VCN to the contralateral MSO, and the remaining pathway.

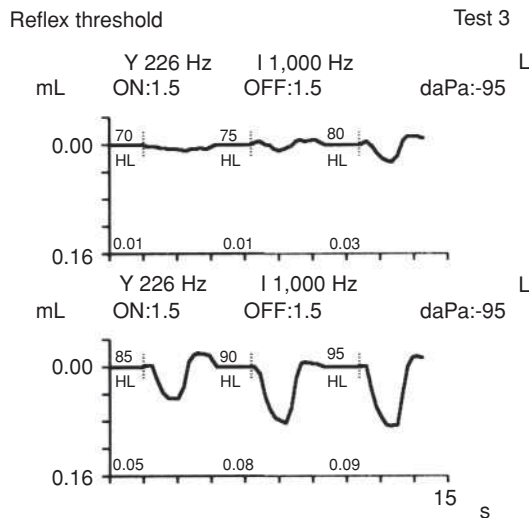

FIGURE 10.2 Acoustic stapedius reflex [ASR] response growth in an adult human ear with normal middle ear function and hearing in the left ipsilateral condition elicited by a 1,000-Hz activator [226-Hz probe tone] at levels of 70 to 95 dB HL. Response amplitude is plotted in mmho as a function of time in seconds, with three activator levels on the top row and three activator levels on the bottom row. The numbers at the bottom of each plot ranging from 0.01 to 0.09 are the amplitudes. ASR is not elicited by 70- or 75-dB HL activators. However, from 80 to 95 dB HL the ASR is present and the amplitude increases as the activator level increases.

of the signal from the cochlea through the pathway to the stapedius muscle, and when the response is being clinically measured, the latency includes the inherent delay of the measurement system (e.g., Qui and Stucker, 1998). ASR increased latencies have been reported in ears with retrocochlear disorders such as vestibular schwannomas (e.g., Clemis and Samo, 1980) and it has been suggested that latency may be useful in separating cochlear from retrocochlear sites of lesion. However, ASR latency is not routinely measured clinically; rather amplitude is usually measured to establish threshold.

Theories of Functional Significance

There are two main theories about the functional significance of the ASR. First, it was thought that the ASR reduces the amount of sound pressure that reaches the cochlea, and therefore it has a protective effect from high-level sounds (e.g., Brask, 1979). For example, temporary threshold shifts (TTS) in hearing were observed after intense stimulation on the affected side of listeners with Bell palsy during an episode of facial paralysis, but no TTS (or less TTS) was observed on the unaffected side or on the affected side after recovery from an episode (Brask, 1979). The main problems with this theory are that the ASR (1) is not fast enough to protect the cochlea from high-level transient sounds and (2) the ASR can fatigue and thresholds may increase in the presence of high-level, long-duration sounds (e.g., Gerhardt and Hepler, 1983). In contrast, Borg et al. (1982) reported ASR-mediated resistance from fatigue in the presence of long-duration industrial noise. Therefore, the protective effect (or lack thereof) is not entirely clear and, if present, may

depend on the frequency response, duration, and level of the sound to which listeners are exposed.

The second theory is that the ASR provides humans with an advantage for understanding speech in noise because lower frequencies are attenuated relative to higher frequencies when the stapedius muscle contracts. For example, Aiken et al. (2013) reported that listeners with stapedius tendons that were transected during stapedotomy had poorer speech discrimination scores in moderate levels of noise in comparison to listeners with intact ASR, but that this benefit did not persist for high levels of noise. It is not clear whether the effect provides protection from upward spread of masking (i.e., lower frequencies masking higher frequencies) at high speech levels in quiet. Some authors have reported no “rollover,” or worsening in speech discrimination scores with increases in stimulus level, in individuals with Bell palsy (e.g., Phillips et al., 2002), whereas other authors have reported significant rollover (e.g., Wormald et al., 1995). For a more detailed discussion of the theories of functional significance, see Borg et al. (1984).

Relevance to Clinical Practice

ASR threshold and decay tests can be included in a test battery, along with tympanometry, otoacoustic emissions (OAEs), and behavioral puretone and speech tests, to differentiate among middle ear, cochlear, and retrocochlear sites of lesion. ASR threshold also can be used as a cross-check with the behavioral audiogram to increase confidence in the diagnosis of hearing loss in young children with whom behavioral results may be questionable, and in older children and adults who may present with false or exaggerated hearing loss. Finally, the ASR thresholds can be used in cochlear implant assessments to verify function of the device and to set minimum or maximum stimulation levels in young children who cannot provide reliable threshold and loudness information. ASR thresholds are typically obtained with multiple puretone activators and with ipsilateral and contralateral stimulation. The pattern of thresholds across conditions is examined and compared with puretone behavioral thresholds and speech recognition scores. The procedure for obtaining ASR thresholds is described in the next section, and patterns of ASR thresholds that can be associated with a variety of underlying pathologies are described in the section on disorders.

MEASUREMENT OF ASR THRESHOLD

Terminology

Two stimuli are currently used for clinical measurement of the ASR. The *probe* is a puretone that is presented continuously to the ear in which the response is to be measured. In early clinical equipment and studies the probe tone was 220 Hz. In current equipment, the standard probe tone fre-

quency for children approximately 6 months of age through adulthood is 226 Hz presented at 85 dB SPL (70 dB HL) (ANSI S3.39). A low-frequency probe tone is advantageous due to reduced interaction between the probe and the activator (see below) in ipsilateral test conditions in which both the probe and activator are presented in the same ear. The 220- or 226-Hz probe tones are well separated from higher-frequency activators. Despite this benefit of lower frequency probe tones, higher probe tone frequencies are required to increase the probability of observing an ASR in newborns and infants (see the Gender and Age Effects section).

ANSI (2012) refers to the high-level acoustic stimulus that elicits the ASR as simply “stimulus.” However, “stimulus” can be considered a generic term (e.g., the probe is a stimulus), therefore, to be clear in this chapter the term *activator* will be used to refer to the stimulus used to induce the ASR. Activators that are used in clinical measurements include 500-, 1,000-, 2,000-, and 4,000-Hz puretones and broadband noise (BBN) of 1 to 2 seconds in duration. Although 4,000-Hz activators are often available on test equipment, this activator has relatively less diagnostic value because it is often elevated or absent in ears with normal hearing (Gelfand, 1984). Thresholds are lower for BBN than for puretone activators (e.g., see Wiley et al., 1987 normative data in Table 10.1). Activator levels are typically available in 5-dB steps and should be limited in level, particularly for ASR decay tests, due to potential for temporary or permanent threshold shift (see the ASR Decay section).

During an ASR test, the *admittance* (Y_a) of the 226-Hz probe tone is continuously monitored. Admittance is the ease with which acoustic energy is admitted into the middle ear as estimated at the lateral plane of the TM. When the activator is presented, the stapedius muscle contracts, which stiffens the ossicular chain and TM, which creates a reduction in admittance of the probe tone at the TM. Therefore, the ASR is measured as a decrease in admittance of the probe tone at the TM when the activator is presented.

TABLE 10.1

Contralateral and Ipsilateral ASR Thresholds in dB HL for Puretone and BBN Activators in Young Adults with Normal Hearing (Wiley et al., 1987)

	Contralateral		Ipsilateral	
	Mean	SD	Mean	SD
500 Hz	84.6	6.3	79.9	5.0
1,000 Hz	85.9	5.2	82.0	5.2
2,000 Hz	84.4	5.7	86.2	5.9
4,000 Hz	89.8	8.9	87.5	3.5
BBN	66.3	8.8	64.6	6.9

SD, standard deviation.

Although current clinical measurements of the ASR are plotted as decreases in admittance when the activator is presented, early measurements were often plotted as increases in impedance.

Instrumentation

ASR measurements should be completed using equipment that is calibrated to the ANSI S3.39 (2012) Specifications for Instruments to Measure Aural Acoustic Impedance and Admittance (Aural Acoustic Immittance). The equipment is the same as used for tympanometry and consists of a physical probe assembly (not to be confused with the probe tone stimulus) that is coupled to the ear with a small ear tip to create a hermetic seal. The instrument should have a manometer to monitor pressurization of the ear canal with an air pump, two speakers (one for the probe and one for the activator) and a microphone to measure the sound pressure level of the probe tone stimulus in the ear canal. An example probe assembly for an ipsilateral measurement is shown in Figure 10.3 (from Feeney and Sanford, 2008). Diagnostic equipment will have an additional cable and transducer through which an activator can be presented to the contralateral ear. The data should be plotted as admittance in mmho on the Y-axis and time in seconds on the X-axis. Diagnostic immittance equipment may have multiple activators, probe frequencies, and ipsilateral and contralateral selections. Screening immittance equipment may only have the ability to present an ipsilateral activator at a single frequency and level.

FIGURE 10.3 Components of a tympanometer probe assembly. The pressure pump varies the air pressure in the ear canal as monitored by the manometer. The pump is used to hold pressure in the ear canal at or near tympanometric peak pressure (TPP) during acoustic stapedius reflex [ASR] tests. One receiver is used to present the probe tone that is continuously monitored by the microphone during tympanometry and ASR tests. The second receiver is used to present the reflex activator to the same [ipsilateral] ear as shown in the figure. A cable is required to deliver the activator to the opposite ear for contralateral ASR tests [not shown]. [From Feeney MP, Sanford CA. [2008] Middle-ear measurement. In: Madell J, Flexer C, eds. *Pediatric Audiology: Diagnosis, Technology, and Management*. New York: Thieme; pp 115–122.]

Methodology

The ASR is measured in the ear canal as a decrease in admittance, and therefore it should be measured at the pressure at which the admittance is the greatest, or tympanometric peak pressure (TPP). ASR thresholds may be higher if estimated at pressures above or below TPP (e.g., Martin and Coombes, 1974). The ASR is considered to be present if the admittance at TPP decreases by a criterion amount when the activator is presented. The criterion amount will depend on the manufacturer specifications, the normative data used, and the state of the patient. ASR thresholds have been found to be repeatable in adult ears with normal hearing and hearing loss (e.g., Forquer, 1979) and in newborns who passed a hearing screening (Kei, 2012; Mazlan et al., 2009).

The ASR test conditions are described based on the ear to which the activator is presented (ANSI, 2012). The four test conditions (left and right, ipsilateral and contralateral) are described in Table 10.2. In a typical test battery for a new patient, all four conditions are presented and the pattern of reflexes across conditions is examined. Different patterns can be associated with different underlying pathologies (see the section on disorders in this chapter). However, ipsilateral and contralateral conditions have their own relative advantages. Contralateral conditions have the advantages of (1) being sensitive to crossed pathways, and therefore mid-brainstem pathologies; (2) being less susceptible to artifact because the activator and probe stimuli are presented through separate transducers to the two ears; and (3) having more normative data available. Ipsilateral conditions have the advantages of (1) being sensitive to middle ear effects because the probe and activator are presented to the same ear; (2) ease of use in young children and other individuals who are difficult to test because it requires only one ear at a time; and (3) no concern for collapsed ear canals (for systems in which a supra-aural earphone is used to present a contralateral activator).

During manual ASR threshold estimation, the probe tone is presented continuously and the activator is manually presented in 5-dB steps either from higher to lower levels or

TABLE 10.2

Description of Stimulus Presentation Conditions for Ipsilateral and Contralateral ASR Measurements

Condition	Activator Ear	Probe Ear	Ear in Which ASR is Measured
Right contralateral	Right	Left	Left
Left ipsilateral	Left	Left	Left
Left contralateral	Left	Right	Right
Right ipsilateral	Right	Right	Right

from lower to higher levels. In controlled experiments, no significant differences were found between ASR thresholds obtained with ascending and descending approaches (e.g., Wilson, 1979), although lower thresholds can be observed on occasion in practice with a descending approach. The lowest level at which an activator elicits a criterion change in admittance is the ASR threshold for that activator. In a typical threshold search, the criterion change in admittance in the presence of the activator is 0.02 or 0.03 mmho, depending on the selected normative data, and the response should be time-locked to the onset of the stimulus (e.g., not associated with patient movement, swallowing). The response should be repeatable at the level defined as threshold with at least two presentations of the activator. Moreover, a response should be present (with possible growth of the admittance change) for an activator 5 dB above threshold as long as that does not exceed 105 dB HL. As activator levels increase, the amount of change in admittance will increase, although it may seem “upside down” because the measurement is actually a decrease in admittance. An example of ASR response growth to a 1,000-Hz activator is shown in Figure 10.2, with no ASR at 70 or 75 dB HL, and ASR responses of increasing size from 80 to 95 dB HL (0.03 to 0.09 mmho). Saturation of the response is often observed at higher levels in which increased activator levels elicit ASR responses, but the response magnitudes do not change. An example threshold search is shown in Figure 10.4 for an ipsilateral condition with a 1,000-Hz activator. Note that the ASR threshold test was completed at TPP which was -105 daPa. In this example,

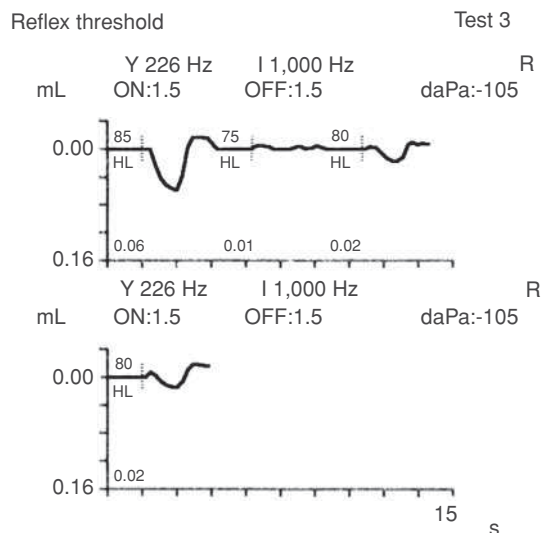

FIGURE 10.4 Acoustic stapedius reflex [ASR] threshold in an adult human ear with normal middle ear function and hearing in the right ipsilateral condition for a 1,000-Hz activator [226-Hz probe tone]. Data are represented as in Figure 10.2. The ASR is absent at 75 dB HL, repeatable at 80 dB HL, and grows in amplitude at 85 dB HL. ASR threshold in this example is 80 dB HL.

threshold is 80 dB HL, with two responses of at least 0.02 mmho amplitude at 80 dB HL, no response at 75 dB HL, and growth (i.e., an ASR response of larger magnitude, 0.06 mmho) at 85 dB HL. It should be noted that although an objective criterion is used (0.02 or 0.03 mmho), the determination of whether or not the reflex is a true reflex and not artifact is based on a subjective examination by the tester.

Automated ASR tests may be available in both screening and diagnostic equipment. In screening equipment, the ASR test may be limited to ipsilateral, single-frequency (usually 1,000 Hz), single-level (90 or 95 dB HL), single presentation tests and the outcome is either pass or fail. Diagnostic equipment may have the same type of screening procedure, and in addition, they may have the ability to store user defined threshold estimation procedures. However, inclusion of an ASR test in hearing screening is not recommended (ASHA, 1990) due to contribution of absent ASRs to high false-positive and medical over-referral rates (e.g., Roush and Tait, 1985). Sells et al. (1997) suggest that the high referral rate found in previous studies may be related to the simultaneous presentation of the activator and probe in the ipsilateral screening mode of the tympanometer. The authors argued that outcomes may be improved by using a system that uses multiplexing (alternating presentation of the probe and activator) and, therefore, ipsilateral ASR would be appropriate for screening procedures.

Normative Data

ASR thresholds should be about 70 to 90 dB above behavioral air conduction thresholds at corresponding activator frequencies in ears with normal hearing (e.g., Metz, 1952). These general guidelines are predicated on the assumption that the ear canal is clear and middle ear function is normal. If the peak static acoustic admittance is very high, for example in an ear with a monomeric TM, the baseline admittance may be unstable. “Monomeric” refers to a spot on a TM that may be thin, or missing one or two of the normal three layers, due to repeated ear infections and/or perforation. This artifact of an unstable baseline may make it difficult if not impossible to observe the small changes in admittance that are associated with ASR activation. DiGiovanni and Ries (2007) found improved detection of the ASR in ears with high peak static acoustic admittance by setting ear canal pressure to -50 daPa relative to TPP.

Normative data for MEMR tests with a 226-Hz probe tone are available for normal hearing young adults in the ipsilateral and contralateral conditions for 500-, 1,000-, 2,000-, and 4,000-Hz puretones and for BBN (Table 10.1, data from Wiley et al., 1987). ASR threshold for a BBN activator is typically lower than for puretone activators, and threshold is often lower in ipsilateral than contralateral conditions. If normative data are used in a clinic, then the same procedures used in the study must be used in the clinic. One way to use the normative data is to consider MEMR thresholds above

the mean plus two standard deviations to be “abnormal.” Another approach is to use the 90th percentile of normal data as the cutoff for abnormal ASRs. This issue is revisited in the section on disorders.

Normative data for MEMR thresholds as a function of behavioral puretone hearing thresholds are not available for ipsilateral conditions, but there are data available for contralateral conditions (Gelfand et al., 1990; Silman and Gelfand, 1981). The 10th, 50th, and 90th percentiles for ASR thresholds for 500-, 1,000-, and 2,000-Hz activators from Gelfand et al. (1990) are shown in Figure 10.5. The main trend is

FIGURE 10.5 Acoustic stapedius reflex [ASR] threshold 10th, 50th, and 90th percentiles in dB HL as a function of behavioral threshold in dB HL for activators of 500 Hz [top], 1,000 Hz [middle] and 2,000 Hz [bottom] in adult ears with normal middle ear function. [Gelfand, 2009, pp 203; adapted from Gelfand SA, Schwander T, Silman S. [1990] Acoustic reflex thresholds in normal and cochlear-impaired ears; effects of no-response rates on 90th percentiles in a large sample. *J Speech Hear Disord.* 55, 198–205.]

that median ASR threshold remains constant as behavioral threshold increases up to thresholds of about 50 dB HL. Above that level, ASR threshold increases as behavioral threshold increases. The 90th percentiles of ASR thresholds from Gelfand et al. (1990) and Silman and Gelfand (1981) are shown in tabular form in Table 10.3. If activator levels are restricted to 105 dB HL to protect hearing, the behavioral threshold above which a “no response” for ASR would be expected may be different for different activator frequencies. For example, in the Silman and Gelfand data, if a limit of 105 dB HL activator level is imposed, the highest associated behavioral threshold for a 500-Hz activator is 65 dB HL, whereas the highest behavioral threshold for a 1,000-Hz activator is 55 dB HL. The cutoffs are also slightly different between the Silman and Gelfand versus Gelfand et al. data.

Clinical Considerations

GENDER AND AGE EFFECTS

There are no significant effects of gender (Gelfand et al., 1990; Osterhammel and Osterhammel, 1979). However, there are two effects of age on ASR thresholds. First, ASR thresholds in adults increase with age for BBN activators beginning around 44 years of age (Silverman et al., 1983), and increase with age above 50 years for puretone activators above 2,000 Hz (Wilson and Margolis, 1999).

Second, higher probe tone frequencies must be used to increase the probability of observing an ASR in newborns and young infants. Weatherby and Bennett (1980) used probe frequencies from 200 to 2,000 Hz and found that probe frequencies from 800 to 1,800 Hz were associated with the lowest contralateral BBN ASR thresholds in newborns. McMillan et al. (1985a) tested newborns with 500-, 1,000-, 2,000-, and 4,000-Hz ipsilateral and contralateral activators, and found that the ASR was observed overall three times more often with the 660-Hz probe tone than with the 220-Hz probe tone. Sprague et al. (1985) reported that the ASR was observed more often with a 660-Hz probe in comparison to a 220-Hz probe in neonates for ipsilateral and contralateral conditions with 1,000-Hz and BBN activators. McMillan et al. (1985b) found similar results in older children 2 weeks to 12 months of age using the same activators and probe tone frequencies, with a higher rate of identification obtained with the 660-Hz probe than the 220-Hz probe. Although the normative database is still developing, contemporary ASR instruments with 1,000-Hz probe tones for infant tympanometry and ASR testing are currently available.

Normative data are available for adults with normal hearing for ipsilateral ASR thresholds (Wiley et al., 1987), and as a function of hearing loss for contralateral activators (Gelfand et al., 1990; Silman and Gelfand, 1981). However, because behavioral thresholds are not available for newborns, normative data are restricted to infants from well-baby nurseries who are assumed to have low risk for hearing

loss or infants who have passed a newborn hearing screen. Kankkunen and Liden (1984) used a 660-Hz probe tone and ipsilateral 500-, 1,000-, 2,000-, 4,000-Hz and BBN activators in neonates and in preschool children with normal hearing and sensory/neural hearing loss. In neonates, the mean BBN ASR threshold was 57 dB HL and the mean ASR threshold across tonal activators was 85 dB HL. For separating ears with normal hearing from ears with hearing loss, they reported sensitivity for tonal activators of 58% and specificity of 89% (66% and 86%, respectively, for BBN activators). The authors cautioned that children with hearing loss may be missed when using ASR thresholds to predict hearing loss. Mazlan et al. (2009) reported mean ASR thresholds of 76 and 65 dB HL for ipsilateral activators of 2,000 Hz and BBN, respectively, using a 1,000-Hz probe tone in infants who passed an auditory brainstem response (ABR) and OAE screen. Kei (2012) used a 1,000-Hz probe tone and ipsilateral activators of 500, 2,000, and 4,000 Hz and BBN and reported 95th percentiles of 95, 85, 80, and 75 dB HL, respectively. Both Mazlan et al. and Kei reported that ASR thresholds were reliable across repeated tests.

In summary, the ASR can be elicited in infants with thresholds that are comparable to adults if a higher probe tone frequency is used. By 6 months of age, a 226-Hz probe tone can be used for tympanometry and ASR measurement.

For neonates, normative data are available for 660-Hz probe tone and ipsilateral tonal and BBN activators (Kankkunen and Liden, 1984) and 1,000-Hz probe tone with ipsilateral tonal and BBN activators (Kei, 2012; Mazlan et al., 2009). Normative ASR data are not available for infants between the neonatal period to 6 months of age when a 226-Hz probe tone can be used, and normative ASR data are not available for neonates and young children for ASR threshold as a function of hearing loss.

PHARMACOLOGICAL EFFECTS

Elevated ASR thresholds have been reported with alcohol (Borg and Moller, 1967), barbiturates and chlorpromazine, an antipsychotic drug (Simon and Pirsig, 1973). It is not in the audiologist's scope of practice to determine whether pharmacological effects are associated with elevated or absent ASR in a given patient, but it would be helpful to document the patient's current medications for consideration in further testing (e.g., ABR) or in a report to the otolaryngologist if the patient is referred.

ASR DECAY

The ASR decay test can be completed in cases in which retrocochlear involvement is suspected. Indicators of retrocochlear

involvement include asymmetrical puretone behavioral thresholds, asymmetrical word recognition scores or scores that are poorer than expected given puretone thresholds, unilateral tinnitus, report of dizziness, and absent or elevated ASR (in which case the decay test cannot be completed). An abnormal amount of decay, which means that the reflex cannot be sustained, is often associated with retrocochlear site of lesion.

The 226-Hz probe tone is used with a 500- or 1,000-Hz activator for the standard ASR decay test. Higher activator frequencies are not used because decay can be observed even in normal ears. The ipsilateral or contralateral activator is presented for 10 seconds at 10 dB above the ASR threshold for the activator. The activator should elicit a reflex and a decrease in admittance should be observed that is essentially constant for the entire 10 seconds. In ears with VIIIth nerve disorders, “abnormal” or “positive” decay is observed, meaning the amplitude of the reflex decreases by half its initial magnitude in less than 10 seconds (Jerger et al., 1974b). Figure 10.6 shows

FIGURE 10.6 Examples of normal and abnormal acoustic stapedius reflex [ASR] decay results. Percent of ASR magnitude at stimulus onset is plotted as a function of time in seconds. The stimulus [A] is presented for 10 seconds and in a normal response [B], the ASR activates and maintains nearly 100% of the initial magnitude for the entire 10 seconds. The magnitude of the response in example [C] decreases from the initial magnitude by less than 50% and it is also considered normal. Positive ASR decay, or abnormal ASR decay, is shown in [D] in which the response magnitude decreases by more than 50% of the initial magnitude. [From Gelfand SA. [2009] Chapter 10: The acoustic reflex. In: Katz J, Medwetsky L, Burkard R, Hood L, eds. *Handbook of Clinical Audiology*. 6th ed. Philadelphia: Lippincott Williams & Wilkins.]

an example of normal responses (negative decay) in rows b and c, and positive decay of more than 50% in 10 seconds in row d. The reflex decay (RD) is interpreted with reference to the activator ear. If decay is measured in the left contralateral condition, with the activator presented to the left ear and the reflex measured in the probe/right ear, and decay is positive, it means the test is positive for possible retrocochlear pathology in the left ear.

The ABR is used more often today to identify patients with possible retrocochlear involvement. By comparison, the acoustic RD test is more convenient because it can be done with the diagnostic immittance equipment, it is faster, and it requires fewer supplies relative to the ABR which requires another piece of equipment, takes about 30 to 45 minutes, and requires skin preparation pads, electrodes, and electrode wires. However, the RD test has three disadvantages with regard to identification of retrocochlear involvement. First, the test often cannot be completed because ASR is absent or elevated to the point that 10 dB sensation level (SL) re: ASR threshold cannot be presented for the decay test. Second, it has poorer sensitivity/specificity than the ABR for retrocochlear disorders. Finally, temporary and permanent threshold shifts have been reported with high-level activators (Arriaga and Luxford, 1993; Hunter et al., 1999).

USE OF ELECTRICALLY EVOKED ASR IN PATIENTS WITH COCHLEAR IMPLANTS

The ASR can be used in patients with cochlear implants to assess device function and to predict lower or upper stimulus levels of the electrical dynamic range of the electrodes. The stimuli are presented directly to the internal electrodes in the cochlea. The external ear canal, middle ear, and hair cells of the inner ear are bypassed because the VIIIth nerve is directly stimulated. The electrical ASR is recorded using standard clinical immittance equipment and the test can be done intra-operatively during implant surgery or in the audiologist's office during mapping visits. During mapping visits, the ASR can be used to confirm function of the implant in very young children who cannot provide reliable behavioral responses. ASR thresholds have been shown to occur at 70% to 80% of a listener's electrical dynamic range for a given electrode (e.g., Battmer et al., 1990). Levels for each electrode (e.g., “M” levels or most comfortable levels) may be set at some value relative to ASR threshold in children, for example, who can provide limited (or no) information about loudness comfort (e.g., Caner et al., 2007; Hodges et al., 1999), although caution must be taken due to the large subject variability observed within and across studies. ASR may not be recorded in all ears, including ears with ossification of the cochlea related to meningitis (for a review, see Hodges et al., 2003, p. 83). The electrically

evoked ASR is also susceptible to, or may be affected by, middle ear status of the probe ear including otitis media, ventilation tubes, excessive peak static acoustic admittance, and otosclerosis.

ACOUSTIC REFLEXES AND DISORDERS

Acoustic Reflex Thresholds

Various otologic disorders will result in ASR thresholds that are outside the normal range or may be present when expected to be absent. All of these objective outcomes can contribute substantially to the audiologic diagnosis. In this section we will review the expected patterns of ASR threshold responses for a range of pathologies and audiometric patterns.

We will assume that the probe stimulus used to monitor changes in middle ear function induced by the ASR is a 226-Hz tone as stipulated in the ANSI S3.39 standard. For a specific set of measurements, the ear with the 226-Hz probe will be referred to as the probe ear. A basic framework for evaluating ASR threshold responses in the presence of various disorders is to consider the pattern of responses for ipsilateral and contralateral reflex activator stimulation. By convention as described in the ANSI standard, ASR thresholds are named by reporting the ear to which the reflex activator stimulus was presented (right or left) combined with a reference to the probe configuration: Ipsilateral for an activator stimulus presented to the probe ear and contralateral for an activator presented to the opposite ear. For a probe-right condition when a 1,000-Hz tone was presented to the left ear and varied in level to obtain the ASR threshold, we would refer to the reflex threshold as a Left (activator ear) Contralateral (reference to the probe being in the opposite ear) reflex threshold. If we leave the probe in the right ear, but now present the 1,000-Hz activator tone to the right ear, we would call such an ASR threshold a Right Ipsilateral reflex threshold.

The patterns of ipsilateral and contralateral ASR thresholds can be conveniently displayed by using a chart as in Figure 10.7. The chart is organized by Probe ear as if you are facing the patient with the results for the probe in Right ear in the left column and the results for the probe in the Left ear in the right column. The top row of results is for ipsilateral reflex thresholds, thus with the Probe in the Right ear the top left circle indicates results for the R(ight) Ipsilateral reflex threshold. The bottom row is for Contralateral reflex thresholds, so with the probe in the Right ear and the activator in the Left ear we have a L(eft) Contralateral reflex threshold which is indicated by the circle on the bottom left, and so on. The legend at the bottom of the graph shows the symbols for a reflex threshold within normal limits (open circle), elevated (shaded circle) and absent (black circle).

FIGURE 10.7 The basic configuration for reporting ipsilateral and contralateral reflex threshold results for a given activator stimulus. The chart is organized by Probe ear as if you are facing the patient with the results for the probe in Right ear in the left column and the results for the probe in the Left ear in the right column. The *first row* of results is for ipsilateral reflex thresholds, so with the Probe in the Right ear the *top left circle* indicates results for the R(ight) Ipsilateral reflex threshold. The *bottom row* is for Contralateral reflex thresholds, so with the probe in the Right ear and the activator in the Left ear we have a L(eft) Contralateral reflex threshold which is indicated by the *circle on the bottom left*, and so on. The legend at the bottom of the graph shows the symbols for a reflex threshold within normal limits (*open circle*), elevated (*shaded circle*) and absent (*black circle*).

HEARING LOSS OF COCHLEAR ORIGIN

As discussed previously, based on the normative data in Table 10.3 for listeners with normal hearing, the 90th percentile of ASR thresholds is 95- to 100 dB HL. Sensory/neural hearing loss of cochlear origin results in median ASR thresholds in the normal range (i.e. ≤ 95 dB HL for 500-, 1,000-, and 2,000-Hz tones) for levels of hearing loss approximately ≤ 60 dB HL (Gelfand et al., 1990). Although some individuals (10th percentile, Figure 10.5) will have ASR thresholds in the normal range with even a severe hearing loss (≥ 70 dB HL), the trend is for puretone thresholds above 60 dB HL to result in median reflex thresholds >95 dB HL. The 90th percentile of ASR thresholds increases as a function of cochlear hearing loss from 95 to 105 dB HL for 30 dB HL puretone thresholds to 105 to 115 dB HL for 60 dB HL puretone thresholds (Table 10.3). Note that to prevent high levels of sound exposure many centers will restrict the upper limit of reflex activator stimulus to 105 dB HL, and thus report an absent reflex if the ASR is not observed at 105 dB HL. As can be seen from Table 10.3 many listeners with cochlear hearing loss greater than 60 dB and at the 90th percentile of ASR thresholds will have absent reflex thresholds at 105 dB HL.

FIGURE 10.8 Shown is a pattern of elevated reflex thresholds with activator in the Left ear [shaded circles] due to a sensory/neural hearing loss of 50 dB HL at 1,000 Hz. The reflex thresholds for stimulation of the normal right ear are within normal limits [open circles]. See audiogram in Figure 10.9.

Figure 10.8 shows the expected ASR threshold results for the case of normal hearing in the right ear and a cochlear hearing loss in the left ear of 50 dB HL at 1,000 Hz (see audiogram in Figure 10.9). The top row shows that the L(eft) Ipsilateral reflex threshold is elevated and the bottom row shows that the L(eft) Contralateral reflex threshold (probe in the right ear and activator in the left ear) is elevated. This diagonal pattern of elevated reflexes was referred to as a “sound effect” by Hannley (1986) because reflexes are abnormal whenever the *sound* (activator) is presented to the affected ear.

ASR thresholds would be expected to be absent at the upper limit of the activator when stimulating an ear with a profound cochlear hearing loss (≥ 90 dB HL). Figure 10.10 shows the expected ASR threshold results at 1,000 Hz for a right profound sensory/neural hearing loss and a left moderately-severe sensory/neural hearing loss of 65 dB HL (see audiogram in Figure 10.11). Figure 10.10 shows two diagonal patterns of reflex threshold results: elevated thresholds for ipsilateral and contralateral stimulation of the left ear at 1,000 Hz, and absent thresholds for ipsilateral and contralateral stimulation of the right ear. The abnormal pattern

FIGURE 10.10 Results for an asymmetrical hearing loss of cochlear origin. The puretone threshold shows a moderately severe loss of 65 dB HL on the left at 1,000 Hz, and a profound loss of 105 dB HL of cochlear origin on the right. The pattern of elevated reflex thresholds with activator in the Left ear [shaded circles] is combined with the pattern of absent reflexes at the upper limits of stimulation due to the profound cochlear hearing loss at 1,000 Hz on the right [black circles]. See audiogram in Figure 10.11.

of elevated/absent reflexes are related to the ear receiving the activator sound. Thus, this can be thought of as a sound effect for both ears due to the cochlear hearing loss.

FACIAL NERVE PARALYSIS

When measuring ASR thresholds, the opposite of a sound effect is a probe effect. This occurs when the ASR is abnormal for an ear whenever the probe is in that ear. This is due to a failure to properly *measure* the acoustic reflex threshold in an ear. The classic case of a probe effect is cranial nerve VII paralysis such as Bell palsy (idiopathic facial nerve palsy). If the site of the inflammation of the VIIth nerve that is causing the paralysis is proximal to (closer to the brain than) the innervation of the stapedius muscle, the muscle will likely not contract due to the paralysis and thus a reflex cannot be *measured*, even though the activator stimulus may be sufficiently intense to activate the reflex arc. If the site of the inflammation of the VIIth nerve is distal to (further from the brain than) the innervation of the stapedius muscle, the stapedius muscle will likely not be affected, even in the presence of facial paralysis (Alford et al., 1973). This ASR result provides diagnostic information about the site of the lesion causing the paralysis. Bell palsy may also result in abnormal reflex adaptation in the affected ear (Silman

FIGURE 10.12 ASR results are for a patient with normal hearing bilaterally with a right Bell palsy. The ASR threshold results at 1,000 Hz are absent in both conditions where the probe is in the Right ear, and present in both cases where the probe is in the Left ear. The reflex threshold is absent with the probe in the right ear because the reflex cannot be measured due to the dysfunctional stapedius muscle.

et al., 1988). The ASR can be used to monitor the eventual return of function in the case where the site of lesion is proximal to the innervation of the stapedius and the ASR is initially absent. However, assessment for the determination of the need for surgical intervention may require the use of electroneurography and electromyography (Gantz et al., 1999).

Figure 10.12 shows the results of ASR threshold testing at 1,000 Hz for a case of right Bell palsy with an absent reflex with the probe in the right ear, for both the right ipsilateral reflex test and left contralateral reflex test. This patient’s audiometric data are shown in Figure 10.13 and are within normal limits except for the reflex pattern. Hannley (1986) referred to this probe-effect pattern as a vertical pattern because the absent reflexes were in one vertical column corresponding to the probe ear with the abnormality.

CONDUCTIVE HEARING LOSS

When a measurement probe is inserted in an ear with a conductive hearing loss (CHL) or mixed hearing loss, even a slight conductive component may result in an absent reflex threshold. Jerger et al. (1974a) reported that with an

FIGURE 10.14 ASR results for a 500-Hz activator frequency for a patient with normal cochlear function but with a left serous otitis media resulting in a 20-dB air–bone gap at 500 Hz. Reflexes are absent on the left when it functions as a probe ear since the small change in admittance caused by the reflex is masked by the stiffness and mass changes induced by the serous fluid in the middle ear. However, when stimulating the left ear for the contralateral reflex threshold, a reflex is obtained at an elevated level of 105 dB HL. See audiogram in Figure 10-15.

average air–bone gap of only 5 dB in the probe ear, 50% of subjects had an absent reflex threshold. Thus, similar to the case of facial nerve paralysis, a CHL results in a probe effect, an inability to measure a reflex with the probe in an ear with CHL. The small change in admittance induced by the reflex is masked by the conductive component. In addition to the probe effect, a sound effect may exist when trying to stimulate an ear with a conductive component to achieve a contralateral reflex threshold since the CHL attenuates the level of the activator by the degree of CHL. This may result in normal, elevated or absent contralateral reflex threshold depending on the size of the air–bone gap. For example, Jerger et al. (1974a) reported that when an ear with a CHL was the activator ear for the contralateral reflex threshold, the reflex threshold was absent in 50% of cases with average air–bone gaps ≥ 27 dB HL. Figure 10.14 shows the results of a reflex test at 500 Hz for a patient with left serous otitis media and a 20 dB air–bone gap at that frequency (audiogram in Figure 10.15). The reflex is absent with the probe in the left ear due to the conductive component (probe effect). However, the left contralateral reflex threshold was elevated due to the CHL, but was not eliminated (sound effect). The dB sensation level of the activator was sufficiently high to induce an ASR at a high presentation level. A greater degree of conductive component on the left would have resulted in an absent left contralateral reflex. Bilateral CHL of a significant degree may result in a bilateral probe effect, and thus absent reflexes bilaterally (Figure 10.16, audiogram in Figure 10.17).

A TM perforation or pressure equalization tube in the TM may result in only a slight change in puretone threshold in the low frequencies when measured with standard headphones (but see Voss et al., 2000 for inaccurate results obtained when an insert phone is used in an ear with a perforation). However, this condition when using a 226-Hz probe tone, results in the measurement of a cavity volume including the ear canal and middle ear rather than admittance at the TM. Because the stapedius muscle contraction does not appreciably alter the cavity volume being measured, a probe effect exists for the involved ear. This would result in a reflex pattern like that shown in Figure 10.12 for Bell palsy with absent reflexes in the probe ear. Mixed hearing loss with a significant conductive component results in a probe effect in the involved ear, and may result in an elevated or absent contralateral reflex if that ear is the activator ear. For greater degrees of sensory/neural loss the contralateral reflex threshold for the activator ear would be elevated due to the cochlear component plus the conductive component and would, therefore, likely be absent.

CENTRAL NERVOUS SYSTEM DISORDERS

Retrocochlear and Brainstem Disorders

Vestibular Schwannoma

A vestibular schwannoma (acoustic neuroma) is a slow growing benign tumor that most commonly develops in the Schwann cells on the vestibular branch of CN VIII and causes destruction of neural tissue as it grows. The growth pattern of these tumors is not well understood, but the mean growth rate is between 1 and 4 mm per year with up to 75% of these tumors showing no appreciable growth rate, but with some exceptional growth rates over 18 mm per year (Nikolopoulos et al., 2010). Magnetic resonance imaging (MRI) is the definitive diagnostic tool for detection of vestibular schwannomas. These tests are typically ordered based on the presence of an asymmetrical sensory/neural hearing loss. Such MRI scans are typically positive in about 1% to 3% of cases (Newton et al., 2010). ABR testing has been reported to be as effective as MRI for larger tumors (>1 cm) but is not as effective as MRI for smaller tumors (Fortnum et al., 2009).

ASR thresholds in ears with vestibular schwannomas are likely to be elevated or absent. Thus, suspicion for a retrocochlear lesion is raised when the reflex threshold exceeds the normal range for the degree of hearing or is absent. The 90th percentile of ASR thresholds for a given hearing threshold for normal hearing or cochlear hearing loss (Table 10.3) may be used to determine if the reflex threshold is elevated. Even with puretone thresholds in the 0- to 10-dB HL range, as high as 50% of subjects with retrocochlear lesions may have been reported to have absent reflexes (Jerger et al., 1974b); however, these data were likely based on a larger average tumor size than that observed in patients seen currently given the improvements in tumor detection

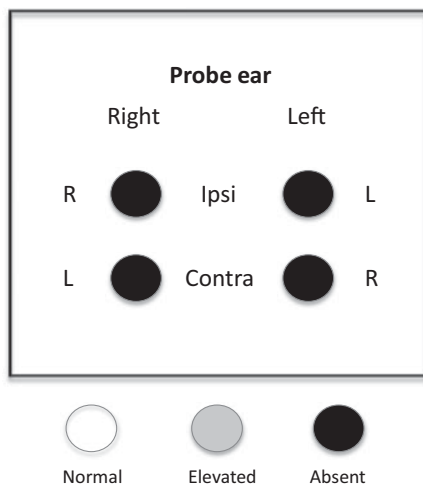

FIGURE 10.16 ASR results for a 500-Hz activator frequency for a patient with bilateral serous otitis media resulting in a bilateral conductive hearing loss at 500 Hz with an air-bone gap of 30 dB. Reflexes are absent in both ears as the result of a bilateral probe effect.

with MRI. Thus, although ASR thresholds may not be a sensitive test for detecting small vestibular schwannomas, positive findings of absent or elevated ASR thresholds, especially in patients with asymmetrical hearing loss, raise the index of suspicion for retrocochlear pathology.

The results for a prototypical retrocochlear finding of ASR thresholds for a case of left vestibular schwannoma are shown in Figure 10.18 for a 1,000-Hz activator tone (audiogram in Figure 10.19). The ASR thresholds are within normal limits when the activator is presented to the right ear for ipsilateral and contralateral stimulation. However, with only a 10 dB increase in threshold at 1,000 Hz on the left compared to the right, the ASR is absent for both left ipsilateral and contralateral stimulation. Hunter et al. (1999) conducted a retrospective analysis of 56 cases of acoustic neuroma compared to 108 adults with hearing loss of cochlear origin. They examined the sensitivity and specificity of the presence or absence of a 1,000-Hz ipsilateral reflex threshold for subjects in these groups whose 1,000-Hz puretone threshold was ≤ 70 dB HL, ≤ 50 dB HL or no exclusion for threshold. The

FIGURE 10.17 Audiometric results for the patient with ASR results at 500 Hz in Figure 10.16.

FIGURE 10.18 Results for an asymmetrical sensory/neural hearing loss in a patient with a left vestibular schwannoma. The puretone thresholds show a mild to moderate sensory/neural hearing loss on the right with a threshold of 40 dB HL at 1,000 Hz. There is a moderate to severe sloping sensory/neural hearing loss on the left with a threshold of 50 dB HL at 1,000 Hz. The ASR is absent with stimulation of the left ear at 1,000 Hz for both ipsilateral and contralateral stimulation, which is not expected with a 50-dB HL threshold.

best test performance was found for reflex threshold with a cutoff criterion of >90 dB HL with a true positive rate of 68% and false-positive rate of 46%. Puretone asymmetry at 1,000 Hz provided a better test when considering all hearing losses with >10 dB puretone asymmetry yielding a true positive rate of 93% and a false-positive rate of 32%. This suggests that ASR thresholds alone may not be as useful as puretone threshold asymmetry for suspicion of vestibular schwannoma.

Auditory Neuropathy Spectrum Disorder

Auditory neuropathy/auditory dyssynchrony or auditory neuropathy spectrum disorder (ANSD) is a form of hearing impairment in which neural transmission in the peripheral auditory system is impaired and for which there is often normal cochlear outer hair cell function and present otoacoustic emissions (Starr et al., 2000). Berlin et al. (2005) reviewed the records of 136 patients from a database of 257 subjects with ANSD who had normal otoacoustic emissions and were tested with acoustic reflexes. None of these subjects showed normal reflexes at all frequencies tested and only three subjects had reflexes at 95 dB HL or lower, but not at all frequencies. All of the other subjects had reflex thresholds that were absent or were observed at levels above 100 dB HL. The authors urged that, for perinatal hearing

screening programs based solely on otoacoustic emissions, ASR thresholds should be tested to help rule out ANSD.

Extra-axial Brainstem Disorders

Tumors such as meningiomas, arising from the lining of the brain, that are located in the cerebellar pontine (CP) angle of the brainstem may exert pressure on CN VIII fibers. This type of extra-axial (outside the brainstem itself) lesion would result in a sound effect similar to an acoustic neuroma (Figure 10.18) (Jerger & Jerger, 1975). However, a meningioma may exist in the CP angle and not cause auditory symptoms if the CN VIII fibers are not compromised.

Intra-axial Brainstem Disorders

Lesions occurring within the brainstem (intra-axial) may affect the ASR thresholds if the reflex pathways are compromised (Gelfand, 1984; Jerger & Jerger, 1977). If the crossed fibers are compromised, a pattern as shown in Figure 10.20 (audiogram in Figure 10.21) may exist, which Hannley (1986) referred to as the “horizontal pattern” in that the contralateral reflexes were affected, but the ipsilateral reflexes were normal, thus absent reflexes occurred in a horizontal

FIGURE 10.20 ASR results for a 1,000-Hz activator are shown for a patient with an intra-axial brainstem lesion. This horizontal pattern indicates that the brainstem is compromised at the point of nerve fiber crossover, thus rendering the contralateral reflexes absent, but leaving the ipsilateral reflexes intact.

pattern. However, Cohen and Prasher (1988) reported that it was not uncommon in intra-axial brainstem lesions to have abnormal reflexes for both ipsilateral and contralateral stimulation. They referred to this as a “full house” pattern, which was observed along with abnormal ABR results bilaterally.

Demyelinating and Cortical Disorders

Reflex thresholds, reflex magnitude and temporal characteristics such as rise time and onset latency may be useful in the assessment of patients with multiple sclerosis (MS), a demyelinating disease (Jerger et al., 1986; Keith et al., 1987). However, Wiegand and Poch (1988) reported that in patients who are asymptomatic for the disease, ASR rise time and onset latency may not be a useful screening tool for MS.

ASR thresholds do not appear to be greatly affected by cortical disorders. For example, Gelfand and Silman (1982) reported on ASR thresholds in 14 patients with documented brain lesions including head trauma, stroke and anoxia who also had auditory processing deficits as confirmed by evaluations from speech language pathologists. All subjects had

ASR thresholds consistent with their hearing loss when compared to individuals with normal hearing or sensory/neural loss who did not have cortical disorders. Downs and Crum (1980) reported on several cases of low ASR thresholds in patients with documented brain damage, with a suggestion that a release from central inhibition could have been responsible for the reduced ASR thresholds. However, this finding is not supported by other studies (Gelfand, 1984; Gelfand & Silman, 1982).

SUPERIOR CANAL DEHISCENCE

A dehiscence of the superior semicircular canal may result in symptoms of vertigo, oscillopsia, or disequilibrium in response to sound or changes in ear pressure (Minor et al., 1998). Patients with superior canal dehiscence (SCD) may also experience elevated puretone air conduction thresholds and enhanced bone conduction threshold in the involved ear as the dehiscence acts as a third window for the inner ear, which can lower the cochlear input impedance and shunt sound pressure away from the cochlea resulting in an

FIGURE 10.22 ASR results at 500 Hz for a subject with a right conductive hearing loss. Given the degree of air-bone gap one would expect absent reflexes with the probe in the right ear. However, this is a case of superior canal dehiscence with a normal middle ear. The presence of the reflexes helps distinguish this case from otosclerosis, which would have a similar hearing loss but absent reflexes.

air conduction hearing loss that appears to be conductive in nature (Rosowski et al., 2004). In some patients the only presenting symptom for SCD may be “conductive” hearing loss in the involved ear with larger air–bone gaps in the low frequencies and no vestibular symptoms, which mimics otosclerosis (Merchant et al., 2007; Mikulec et al., 2004).

The ASR threshold is one test that can help to distinguish SCD from otosclerosis; the presence of acoustic reflexes at normal levels with the probe in the involved ear is an indication that the middle ear is not the source of the “conductive” hearing loss. These patients may also present with low thresholds for vestibular evoked myogenic potentials (VEMP) (Banerjee et al., 2005; Zuniga et al., 2013). Figure 10.22 shows the ASR result at 500 Hz for a patient with a mild CHL in the low frequencies on the right (audiogram in Figure 10.23). Note that ASR thresholds are within normal limits in the presence of the conductive loss for ipsilateral and contralateral stimulation. This paradoxical ASR finding is part of the pattern of findings that aid in the diagnosis of SCD along with low VEMP thresholds and radiological evidence (see also Chapter 20 in this volume on VEMP results in SCD).

FUNCTIONAL HEARING LOSS

As indicated above, median ASR thresholds are expected to be within normal limits for cochlear hearing loss ≤ 60 dB HL, so for suspected functional losses in this range ASR thresholds will not provide objective evidence to support the suspicion. In these cases, especially for losses in the upper end of this range, objective evidence provided by otoacoustic emissions may prove to be more useful (see Chapter 19 this volume). Tonal ASR thresholds occurring below the admitted puretone threshold are an obvious red flag for functional hearing loss. However, the question remains, how low is too low if the ASR threshold occurs at a low sensation level above the puretone threshold? Gelfand et al. (1990) suggested using published 10th percentiles of ASR thresholds at 500, 1,000 and 2,000 Hz (lower curves in Figure 10.5) as cutoff values for determining the likelihood of functional hearing loss. ASR thresholds falling below 10th percentile values for a given level of hearing loss are considered suspect for functional hearing loss. Gelfand (1994) found this 10th percentile approach to successfully identify about 85% of 74 ears with functional hearing loss having admitted thresholds ≥ 60 dB HL at all three frequencies, while maintaining a false-positive rate for 50 ears with true sensory/neural hearing loss between 5% and 7%.

Acoustic Reflex Adaptation

The acoustic reflex adapts when constantly evoked for a period of time. This relaxation of the reflex results in the admittance change induced by the ASR returning to baseline or decaying over time. Adaptation of the reflex occurs in normal hearing subjects depending on the duration of exposure. There is a frequency dependence of this effect that increases in adaptation with frequency, for example, at 4,000-Hz RD for tones presented at 10 dB above reflex threshold decays to 50% of maximum in less than 10 seconds in subjects with normal hearing (Anderson et al., 1969; Wilson et al., 1984). Anderson et al. (1969) proposed using a criterion RD of 50% of original amplitude in 5 seconds at 500 and 1,000 Hz as a criterion for abnormal RD and an indication for retrocochlear site of lesion. Other studies have suggested looking for a decay of 50% within a 10-second window (Jerger et al., 1974b; Olsen et al., 1981). Hirsch and Anderson (1980a, 1980b) recommended looking at adaptation at 500 and 1,000 Hz as a graded finding as follows:

RD⁺⁺⁺ if the reflex amplitude declines $\geq 50\%$ in 5 seconds at 500 and 1,000 Hz. This is positive sign of retrocochlear lesion.

RD⁺⁺ if the reflex amplitude declines $\geq 50\%$ in 5 seconds at 1,000 Hz but not 500 Hz. This is a questionable sign of retrocochlear lesion.

RD⁺ if the reflex amplitude declines $< 50\%$ within 5 seconds at 500 and 1,000 Hz. This is not a significant retrocochlear sign.

Since the proposed method of determining RD depends on an activator presentation for 5 to 10 seconds at 10 dB above the ASR threshold it calls into question the resultant high level of sound exposure during the test. Hunter et al. (1999) reported on a case of hearing loss that was caused by the RD testing in a patient whose ASR threshold at 1,000 Hz was 110 dB HL. RD testing was conducted at 120 dB HL for 10 seconds in each ear and resulted in permanent threshold shift at 1,000 Hz of 20 to 30 dB. A similar finding was reported by Arriaga and Luxford (1993). Hunter et al. recommend a maximum safe presentation level for RD stimuli of 115 dB SPL, but suggested that manufacturers include an in-the-ear measure of SPL for activator presentation to help account for inter-patient variability in real-ear stimulus presentation levels.

New Methods of Measuring the ASR Threshold

Several recent studies have investigated new methods of measuring the ASR threshold. Neumann et al. (1996) utilized standard otoacoustic emissions recording techniques to measure ASR threshold. In this method the probe stimulus and activator stimulus are one and the same. Two identical 100 ms tone bursts were presented with a 10 ms inter-stimulus interval with a repetition rate of one per second. Since the latency of the ASR is on the order of 100 ms, it was assumed that the first tone burst was not affected by an ASR that might have been elicited by the tone; however, the second 100 ms tone burst would be affected by stapedius muscle contraction. The difference in microphone response for the two tone bursts averaged across a number of presentations was taken as a measure of the ASR. The level of the tones was varied until a difference between the two tones was reliably detected. This method allowed for an ASR threshold for normal hearing subjects to be detected at a level 8 dB lower than traditional methods. In addition, for 5 out of 10 subjects with sensory/neural hearing loss, the new method was able to detect an ASR when the ASR was absent for traditional methods.

Several studies have used wideband acoustic immittance (WAI) to measure the ASR threshold (see Schairer et al., 2013 for a review). For an introduction to WAI, see Chapter 9 by Hunter and Sanford in this volume. Feeney and Keefe (1999) were the first to report on this method for measuring contralateral reflex thresholds using a WAI system developed by Keefe et al. (1992). In that study 40 ms wideband chirps were presented at ambient pressure as the probe stimulus and 1,000- or 2,000-Hz contralateral tones were used as reflex activator stimuli for three subjects. The tones were varied in level ± 8 dB relative to the clinical ASR threshold in 2-dB steps. WAI obtained during the baseline measurement in quiet was subtracted from the WAI obtained during the presentation of the contralateral activator stimulus. The study demonstrated that the ASR could

be measured using this technology and that the ASR threshold appeared to be as much as 8 dB lower using the WAI method. The same method was used by Feeney and Keefe (2001) but with a white noise contralateral activator. Measurements on seven subjects revealed lower ASR thresholds by about 18 dB with the WAI method using statistical tests of the magnitude and shape of the shift across frequency in WAI to detect the ASR threshold.

A statistical method was also used by Feeney et al. (2003) to measure the contralateral reflex threshold for 1,000- and 2,000-Hz tones for 34 adults with normal hearing. The average reflex thresholds measured with this method were 12 and 14 dB lower than for a clinical method for the 1,000- and 2,000-Hz tones, respectively. Feeney et al. (2004) used the method to develop an ipsilateral wideband test using a 4,000-Hz activator and wideband probe. In this study the WAI method resulted in ASR thresholds that were 3 dB lower than with a clinical method.

Schairer et al. (2007) developed an automated system to use WAI to measure ipsilateral ASR thresholds using a wideband click as the probe presented alternately with 1,000- and 2,000-Hz tones or BBN activators. They reported ASR thresholds to be from 2.2 to 9.4 dB below clinical ASR thresholds depending on the activator stimulus. An automated WAI method for assessing ASR thresholds in newborns was recently reported by Keefe et al. (2010). In that study a combination of WAI middle ear tests and ASR thresholds predicted newborn hearing screening outcomes.

Although these new methods have resulted in lower ASR thresholds than clinical tests, which may result in the measurement of the ASR in a greater proportion of patients, more research is needed to evaluate the methods for various ages and with various degrees and types of hearing loss.

CONCLUSIONS

The ASR test battery is an established part of the clinical armamentarium of the audiologist. No other test in the toolbox can provide more information about a variety of components that contribute to the human auditory system: Middle ear, cochlea, CN VIII, brainstem, CN VII, and stapedius muscle. A normal ASR test can help confirm normal function in any of these components, whereas an abnormal ASR test can help point to a lesion. The addition of ASR test results with other physiological and behavioral tests provides unique information that strengthens the test battery and provides a cross-check of results.

ACKNOWLEDGMENTS

FOOD FOR THOUGHT

1. A patient with a suspected right vestibular schwannoma has been referred to you for a hearing evaluation. What symptoms might the patient report? What results might you see on a standard clinical test battery, including puretone thresholds, speech discrimination scores, and immittance (specifically, what ASR pattern would you expect)? What special tests would you recommend and why? Assume that a right vestibular schwannoma was eventually diagnosed and the neurotologist recommended surgical removal of the tumor which would likely result in loss of most or all of the hearing on the right side. What amplification options would be appropriate for the patient after the surgery? (Assume two scenarios, one in which the hearing in the left ear is normal, and one in which there is moderate hearing loss in the left ear).
2. You are opening your own private practice, and you need to define your immittance test battery protocol. Assume that you will test patients from newborns to adult. What test equipment would you purchase? Define the age-specific probe tones, activators, and normative data that you would use (and identify conditions for which normative data may not be available). Think about your report templates—how will describe your results for ASR present when expected, present when not expected, etc.?
3. You are unable to obtain behavioral test results for a 3-year-old child, except for speech awareness at 40 dB HL in the sound field. She is very cooperative for the physiological test battery and has normal otoacoustic emissions in one ear, absent in the other, and normal tympanometry bilaterally at 226 Hz. What additional information about this child could you obtain with ipsilateral and contralateral ASR thresholds? If the ipsilateral and contralateral ASR thresholds were normal at 1,000 Hz, would you consider the child to have normal hearing? Why or why not?

Introduction to Auditory Evoked Potentials

Robert Burkard and Manuel Don

INTRODUCTION

The seventh edition of the Handbook of Clinical Audiology includes eight chapters specifically dealing with auditory-evoked potentials (AEPs). The chapters range from the very short latency response components using electrocochleography (EcochG) to long-latency responses. These responses vary in terms of generators, time epochs, stimulus, and response dependencies, as well as clinical applications. However, they share a number of commonalities, in terms of the use of differential amplification and time-domain signal averaging to observe a response that is small when compared to the magnitude of the background electroencephalographic (EEG) activity. The present chapter will (1) present a brief overview of the central auditory nervous system from eighth nerve through brainstem; (2) provide a brief overview of the various AEPs, and their clinical applications; (3) present an introduction to the instrumentation and principles underlying the acquisition of AEPs; (4) review the normative aspects of the auditory brainstem response (ABR) as an introduction to the clinical applications of the ABR presented in Chapters 13, 14, and 16; and (5) describe two relatively new techniques, involving novel stimulus manipulations, designed to improve the ABR for site-of-lesion testing and for hearing screening/threshold estimation.

THE EIGHTH NERVE AND AUDITORY BRAINSTEM

For threshold estimation, it is not very important to know the generators of a particular AEP peak. In contrast, for such clinical applications as site-of-lesion testing (see Chapter 13), or intraoperative monitoring (see Chapter 16), knowledge of the generators of a particular peak can be invaluable. Early work focusing on the ABR peak generators (e.g., Buchwald and Huang, 1975) used lesion studies in animals (cats) and related the loss of peaks or changes in amplitude to the level of the lesion. This led to a mapping of a given ABR peak to a specific generator. This mapping was problematic for two reasons. First, other than for the first peak (generated by the eighth nerve), multiple regions of the auditory nervous system are activated in a temporally overlapping fashion, making a one-to-one mapping of peak to genera-

tor impossible. Second, even though in the animal studies it was often possible to identify the dominant contributor to a given peak, the generalization to humans was confounded by the unusually long auditory nerve in humans compared to other mammals (Moller, 1994). Despite these difficulties, our current knowledge of ABR peak generators allows us to make useful clinical decisions for site-of-lesion testing, as well as to interpret changes in the ABR during intraoperative monitoring.

The auditory nerve, one branch of the vestibulocochlear (eighth) cranial nerve, projects from the hair cells to the cochlear nuclei (CN). According to Spoendlin (1972), 90% to 95% of auditory nerve fibers are type I fibers, and 5% to 10% are type II fibers. Type I afferent dendrites innervate inner hair cells (IHCs), whereas type II afferents innervate outer hair cells (OHCs). Type I fibers are bipolar and heavily myelinated, whereas type II afferents are sparsely myelinated and are pseudomonopolar (i.e., the axon and dendrites arise from a common neurite arising from the cell body, and then the two processes split and project in different directions). The cell bodies of both type I and type II auditory peripheral afferents are contained in the spiral ganglion. Based on number alone, it is clear that IHCs and type I afferents deliver most of the auditory information to the central auditory nervous system. The auditory nerve passes through the internal auditory meatus of the cochlea, and upon entering the posterior fossa, it projects to the lateral aspect of the brainstem, near the pontomedullary junction. These fibers bifurcate and terminate in the CN of the caudal pons. There are three divisions of the CN: The anteroventral cochlear nucleus (AVCN), the posteroventral cochlear nucleus (PVCN), and the dorsal cochlear nucleus (DCN). Each of these nuclei is tonotopically organized (i.e., each subnucleus has a map relating place to a specific best or characteristic frequency). Best or characteristic frequency is the frequency to which that unit responds at the lowest sound pressure level. Indeed, a tonotopic organization is a characteristic of many auditory nuclei. Each of the various subnuclei of the CN has unique anatomical cell types, unique electrophysiological response patterns, and unique connections. Auditory nerve fibers are uniform in cell type (mostly type I afferents) and present fairly uniform response properties (sustained responses showing adaptation, but differing in terms of best frequency

and spontaneous discharge rate). However, at the level of the CN such homogeneity is no longer seen. Multiple cell types are present in the CN, with input from various structures. Similarly, response characteristics vary greatly, reflecting, among other things, differing membrane properties and combinations of excitatory and inhibitory input. The details of these response properties go well beyond the scope of the present review. Detailed reviews of the anatomy and physiology of the auditory nervous system can be found in Webster et al. (1992) and Popper and Fay (1992).

The three subnuclei of the CN have major projections (called acoustic striae) to more rostral regions of the brainstem: The dorsal acoustic stria arises from the DCN and projects to the contralateral inferior colliculus (IC). The ventral acoustic stria projects from the AVCN to the superior olivary complex (SOC) bilaterally. The intermediate acoustic stria projects from the PVCN to the ipsilateral SOC. The SOC is composed of multiple subnuclei. The periolivary nuclei are integral to the descending auditory system, which projects to the OHCs or the type I afferents beneath the IHCs via the crossed and uncrossed olivocochlear bundles. This descending system is involved in the suppression of otoacoustic emissions (OAEs) (see Chapter 19). In terms of the ascending system, three SOC subnuclei are of importance: the medial superior olive (MSO), the lateral superior olive (LSO), and the medial nucleus of the trapezoid body (MNTB). The SOC is where inputs from both ears first converge. Information from the contralateral and ipsilateral CN projects to medial and lateral dendritic tufts of the MSO, respectively. Single-unit responses from the MSO show similar tuning curves from both ears, suggesting convergence of excitatory input from similar best frequency regions from the right and left CN. For example, the right LSO receives direct input from the right CN, whereas input from the left CN crosses midline to the right MNTB, and then to the right LSO. There is evidence that the input from the MNTB is inhibitory. Both MSO and LSO are tonotopically organized. The SOC clearly adds binaural processing to the monaural CN input.

From the SOC, the major output is via the lateral lemniscus (LL). There are two subnuclei of the LL: the dorsal nucleus of the LL (DNLL) and the ventral nucleus of the LL (VNLL). The LL terminates in the IC. The IC are on the dorsal aspect of the midbrain and appear as a pair of protuberances just below the paired superior colliculi. There are several subnuclei of the IC, but the main division is the central nucleus. The central nucleus of the IC is tonotopically organized, with a laminar arrangement. You can visualize the isofrequency (same frequency) laminae like the layers of an onion, with each layer of onion having a narrow range of best frequencies. The other regions of the IC have units with broader tuning curves, making determination of their frequency organization complicated. These other divisions appear to respond to not only auditory input, but also to somatosensory and visual inputs.

Now that we know something about the auditory nerve and brainstem, we can briefly provide a listing of the primary generators of the various ABR peaks. The human ABR is composed of a series of up to seven vertex-positive peaks that occur within 10 ms of stimulus onset to moderate-level click stimuli in adults. The first five peaks have received the most attention scientifically and clinically. Based largely on the studies performed by Moller and Jannetta during intraoperative monitoring, we can assign the following peak generators: Wave I arises from the distal auditory nerve, Wave II arises from the proximal eighth nerve, Wave III is primarily generated by the CN, Wave IV appears to be generated by the SOC, Wave V (the peak) appears to emanate from the LL, whereas the trough following Wave V comes predominantly from the IC (Moller, 1994).

AN OVERVIEW OF AUDITORY-EVOKED POTENTIALS

If you were to simultaneously measure the responses from all auditory nervous system structures following presentation of an acoustic stimulus, you would record activity in the cochlea, auditory nerve, auditory brainstem, thalamus, and auditory cortex. Multiple brain regions would be activated at the same time. However, it would be true that, generally speaking, the more caudal structures in the auditory nervous system would have shorter onset latencies than the more rostral structures. This latency increase for more rostral structures is the result of the finite action potential conduction velocity and the delay as the activity passes through chemical synapses. Although we have no noninvasive way of recording from these various auditory nuclei directly, it is possible to record a series of responses from the scalp (using noninvasive surface electrodes) which have latencies ranging from one one-thousandth to several tenths of a second. A millisecond (one-thousandth of a second) and a microsecond (one-millionth of a second) will be convenient time units. Microvolts (one-millionth of a volt) will be convenient amplitude units. Because of the progressive latency increase of responses from more rostral auditory structures, it is popular to classify AEPs by their response time following the onset of a transient stimulus (e.g., a click).

EcochG refers to the responses from the cochlea and auditory nerve, using a recording electrode located in close proximity to the inner ear. Two responses arise from the hair cells: the cochlear microphonic (CM) and the summing potential (SP) (Dallos, 1973; Davis, 1976). Each has a very short latency (1 ms or so), which is basically the delay from stimulus onset to hair cell excitation. The CM has the same waveform as the stimulus, and so a 2,000-Hz toneburst will produce a CM with spectral energy primarily at 2,000 Hz. The SP is a direct current (DC) response, which continues for the duration of the eliciting stimulus. The response from the acoustic portion of the eighth cranial nerve is

called either the whole-nerve action potential (WNAP) or the compound action potential (CAP). The first two negative peaks of the CAP are labeled N_1 and N_2 . Unlike the CM and SP, which continue for the duration of the stimulus, the CAP occurs at stimulus onset (and sometimes offset). Many AEPs (CAP, ABR, middle latency response: MLR, slow vertex potential: SVP) are responsive to the stimulus onset. The CAP has a latency that is roughly 1 ms longer than the CM or SP, which is the result of the synaptic delay from hair cell depolarization to the onset of auditory nerve fiber discharge. Unlike the other AEPs, the EcochG responses are typically NOT measured with scalp electrodes, but rather from electrodes placed in the ear canal, on or near the tympanic membrane, or on the promontory or round window of the inner ear (see Chapter 12).

The ABR includes a series of five to seven peaks arising from auditory nerve and brainstem structures (Moller, 1994), occurring within 10 ms of the onset of a moderate-intensity click stimulus in otologically, audiological, and neurologically intact adults. Most investigators label the peaks with capital Roman numerals (I through VIII), following the convention established by Jewett and Williston (1971). An ABR from a normal adult is shown in Figure 11.1. The ABR is, without question, the most clinically useful AEP at the present time. It can be used for estimating hearing

FIGURE 11.1 An example of the human ABR. Waves I, III, and V are labeled. [Reprinted from Burkard R, Secor C. (2002) Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. Baltimore, MD: Lippincott, Williams & Wilkins; pp 233–248, with the permission of Lippincott Williams & Wilkins.]

threshold (Chapter 14) and differential diagnosis of peripheral and central abnormalities (Chapter 13) and for intraoperative monitoring (Chapter 16).

MLRs are typically recorded over a time window of 80 to 100 ms. Generators are thought to include thalamus and auditory cortex (Chapter 17; Kraus et al., 1994; Moller, 1994). Unlike EcochG and ABR, the MLR appears to be affected by subject variables such as attention and arousal. Peak-labeling nomenclature varies somewhat with investigator, but the polarity of the peak is typically indicated by a capital P or N (positive or negative), subscripted by small-case early letters of the alphabet (e.g., P_a and N_b). The earliest MLR peaks may be labeled P_o and N_o . AEP responses occurring beyond ~75 ms are collectively called the SVP or late component responses. These responses are most commonly labeled with a capital N or P, to indicate peak polarity and subscripted with an Arabic number indicating which SVP peak of that polarity it is (e.g., P_1 is the first positive SVP peak). Alternatively, an Arabic number indicating average peak latency may be used as a subscript. For example, N_{200} would be the negative peak with a mean latency of approximately 200 ms. The SVP is affected by attention and arousal (see Chapter 18). The term event-related potential (ERP) is used when referring to long-latency responses that are strongly dependent on the attention and arousal of the subject (Kraus and McGee, 1994). Innovative paradigms have been developed to study ERPs. One commonly used paradigm is the oddball paradigm. In its simplest application, the oddball paradigm involves the use of two different stimuli, one that occurs frequently and another that occurs infrequently. Responses to the frequent stimulus are averaged in one memory array, whereas the responses to the infrequent stimuli are averaged in a second memory array. Often, there are differences in the responses to the frequent and infrequent stimuli, with these differences depending on whether the subject is attending to the stimuli or not. Differences can also be due to the acoustical differences between the rare and frequent stimuli, an effect that can be controlled by using the same stimuli as both the “frequent” and the “rare” stimulus in different runs. If attending, there is an additional response called the P_3 or P_{300} response to the infrequent stimulus. Thus, the P_{300} can be used to evaluate the effects of attention on the ERP response. Differences to the rare and frequent stimuli can also be seen in the response known as the mismatch negativity (MMN), and this occurs even when the subject is not actively attending to the stimuli. Both the P_{300} and the MMN are discussed in Chapter 18.

A relative newcomer to the family of AEP responses is the auditory steady-state response (ASSR). This response represents a sustained response and can be elicited by trains of clicks, noisebursts, or tonebursts, as well as amplitude-modulated (AM) and/or frequency-modulated (FM) stimuli. This response has been extensively investigated in recent years (see Chapter 15).

CLINICAL APPLICATIONS OF AEPs

There are a number of well-established clinical uses of AEPs. First, AEPs can be (and are) used for hearing screening and to estimate hearing thresholds of difficult-to-test populations. The ABR is currently the most popular AEP for hearing screening and threshold estimation in the United States (see Chapter 14). However, in recent years there has been a lot of interest in applying the ASSR to the problem of threshold estimation (see Chapter 15). EcochG is more invasive than the ABR (or ASSR), especially if a transtympanic electrode is used, whereas the middle and long-latency responses have the disadvantage of being at least somewhat dependent on attention and arousal (see Chapters 17 and 18). There are clear advantages (in terms of expense and time) in using OAEs rather than ABRs (or, perhaps, ASSRs) for hearing screening. However, OAEs appear to be less than optimal for threshold estimation, and OAEs in isolation will not allow identification of those patients with auditory neuropathy (see Chapters 14 and 19).

AEPs are also used for site-of-lesion testing. For example, the ABR is useful for differentiating conductive, sensory, and retrocochlear disorders (see Chapter 13). Recent studies have revealed a clinical entity termed “auditory neuropathy” (Hood, 1998; Starr et al., 1996). Subjects with auditory neuropathy often have abnormal or missing ABRs, missing acoustic reflexes, normal OAEs but missing contralateral suppression of OAEs, and speech discrimination (especially in noise) that is commonly poorer than predicted by the threshold audiogram. These patients show no evidence of CNS lesions by conventional imaging modalities. The diagnosis is made based on the unusual pattern of audiologic results (including OAEs and AEPs), not on diagnostic imaging procedures. Auditory neuropathy is discussed in more detail in Chapter 12.

AEPs (primarily EcochG and ABR) are also used for intraoperative monitoring (see Chapter 16). For intraoperative monitoring, the patient’s baseline responses are used as the basis for monitoring changes in inner ear/auditory nerve and/or brainstem function during surgery. Degrada-tions in the response (such as increases in peak latency and/or decreases in amplitude) are used to warn the surgeon that damage is being done to the auditory system, thus giving the surgeon the opportunity to modify their procedures to preserve auditory and/or neural function.

The above list of clinical uses of AEPs is not exhaustive, but does reflect the most common uses of AEPs in clinical audiology today. AEPs are now being used in the mapping of cochlear implants in the pediatric population. It is likely that ERPs such as the P_{300} and the MMN will find a place in the diagnosis and perhaps in the efficacy of treatment of such complex clinical entities as central auditory processing disorder.

THE TECHNICAL DETAILS

It is necessary to present an acoustic (or perhaps an electrical) stimulus to elicit an AEP. To record the AEP, the electrical response must be recorded from the human scalp (or, for EcochG, from the ear canal, tympanic membrane, or round window/promontory). Electrodes serve as the interface between the scalp (or ear) and the electronic instrumentation. Because AEPs are small in amplitude, we must use special amplifiers (called bioamplifiers) to make these signals large enough for further signal processing. It is also common to get rid of undesirable electrical activity by the use of filtering. Finally, the scalp-recorded electrical activity must be converted into a binary format so that it can be utilized by a digital computer. The device that accomplishes this transformation is an analog-to-digital converter (ADC). Once in binary form, the data can be manipulated by a digital computer. This manipulation can include additional filtering (called digital filtering), the elimination of responses deemed to be too noisy (called artifact rejection), and a synchronization of stimulus onset and response recording that we will refer to as time-domain signal averaging. In the sections that follow, we will consider electrodes, bioamplifiers, filters, artifact rejection, analog-to-digital conversion, and time-domain signal averaging. We will also consider the stimuli used to elicit AEPs.

Response Recording

In the clinic, surface (scalp) electrodes and an electrolytic paste or gel typically serve as the interface between the biologic world (the scalp) and the electrical world (the bioamplifier input). Needle electrodes can also be used: These are placed subdermally (under the skin), and the ions present in your body fluids facilitate the transfer of the electrical signal from the tissue to the electrode. Various types of electrodes, both disposable and reusable, are commercially available. Some are special purpose, but most are usable for a variety of recording situations. The locations of electrode placement have been standardized by the development of the international 10–20 system (Jasper, 1958). For the international 10–20 system, left scalp locations are subscripted with odd numbers, whereas right scalp locations are subscripted with even numbers. Here we will briefly review those scalp locations commonly used for AEP recordings. The labels for the left and right mastoid are A_1 and A_2 , respectively. F_{pz} is the nasion (bridge of the nose), O_z is the middle of the occipital lobe, and F_z is the middle of the forehead. The vertex (Cz) is halfway between nasion and inion, and midway between the ear canals.

A critical step when applying electrodes is the scalp preparation. Cleaning the scalp by abrasion, using alcohol or other skin-preparation materials, removes dead skin and oils (see Chapter 46 for further information on infection control).

You should measure the interelectrode impedance following electrode application, using either the impedance-testing function that comes packaged with commercially available AEP systems or using a handheld portable electrode impedance meter. Low electrode impedances are desirable (some sources state 5 k Ω or less), but it is sometimes difficult to achieve such low electrode impedances. For example, if you use a tympanic membrane electrode, it is often impossible to achieve a low electrode impedance. High electrode impedance increases the noise floor of the recording and will often result in an increased magnitude of the line frequency and its harmonics (60 Hz and its harmonics in the United States; 50 Hz and its harmonics in Europe and elsewhere). For differential recordings, which are used in most AEP applications, differences in interelectrode impedances can compromise the minimization of common-mode noise (see below).

Three electrodes are used for each recording channel when using a differential bioamplifier. The three leads are referred to as the noninverting, inverting, and the common leads. The noninverting lead is sometimes called the positive or the active lead. The inverting lead is often referred to as the negative or the reference lead. The common lead is sometimes called the ground. In a differential amplifier, the voltages seen by the noninverting and the inverting leads are relative to the common electrode. Another term for voltage is the potential difference, telling us that the voltage of one lead must be expressed relative to the voltage of a second lead. For differential amplification, the voltage from the inverting-common channel is subtracted from the voltage of the noninverting-common channel. Indeed it is this subtraction (or voltage difference) that is the basis of the term “differential amplification.” Following this voltage subtraction, the remainder is amplified. Differential amplification substantially reduces noise that is common to the inverting and noninverting leads. This noise, in fact, is called common-mode noise. Why is this useful? Let us imagine that we are recording in a room with a lot of 60-Hz electrical activity (e.g., from the lights). This 60-Hz line noise will often be of similar magnitude and phase at the noninverting and inverting leads. This voltage that is “common” to both of these leads will be “subtracted” prior to amplification. The common-mode rejection ratio (CMRR) is a value that tells us how well “common-mode” activity is eliminated. Let us say we have a bioamplifier gain (V_{out}/V_{in}) of 100,000. If we put 10 μ V into the noninverting lead and short the inverting lead (or vice versa), we essentially eliminate the differential amplification, producing a monopolar or single-ended bioamplifier, whose output would be 1 V (1,000,000 μ V). If we now apply the same 10 μ V into both the inverting and noninverting leads of a differential amplifier, because of the subtraction process used in differential amplification, the output voltage is much smaller, let us say 10 μ V. To calculate the CMRR, you divide the differential voltage by the single-ended voltage, and you can convert

this to a decibel value by taking 20 times the base 10 logarithm of this ratio:

$$\begin{aligned} \text{CMRR} &= 20 \log_{10}(1,000,000 \mu\text{V}/10 \mu\text{V}) \\ &= 20 \log_{10}(100,000) = 100 \text{ dB} \end{aligned}$$

The larger the dB value, the better the CMRR.

Anywhere from 1 to 256 (or more) bioamplifier channels can be used for AEP recordings. In most clinical applications, a small number of channels are used, perhaps 1 to 4. For ABR recordings, it is common to use two recording channels, called the ipsilateral montage and the contralateral montage. For left ear stimulation, the ipsilateral channel might be vertex (noninverting), left mastoid (inverting), and forehead (common), whereas the contralateral channel would be vertex (noninverting), right mastoid (inverting), and forehead (common).

The Digital World

At the heart of evoked potential instruments is a digital microprocessor. However, the bioamplifier output (discussed above) is a continuous (analog) voltage. The analog voltage coming out of the bioamplifier must be converted into a digital form, via a process called analog-to-digital conversion.

Figure 11.2 shows an analog representation of a sinusoid. An analog signal has a voltage value at all moments in time. For example, there is a signal at 1.5 ms and at 1.5001 ms. Also, the voltage can assume any value within a specified voltage range (e.g., ± 1 V). For example, the signal can have a voltage of 5 mV and 4.99999 mV. When our analog voltage is converted to a digital format, only a finite number of voltage values can be recorded, and we can only sample the voltage at specific time intervals. We will describe these sampling processes below, but first we will describe the base 2 (or binary) number system.

BINARY NUMBER SYSTEM

In our base 10 (or decimal) number system, each place can represent 10 different values (0 through 9). In the base 2 or binary number system, each place can represent only two values: 0 or 1. In the base 10 system, the rightmost (integer) number is multiplied by 10^0 , with the exponent increasing by 1 for each number as we move to the left. The reader who is not familiar with exponents should refer to Speaks (1996). Although we do not think about this much, the number 25 can be described as

$$25 = (2 \times 10^1) + (5 \times 10^0)$$

In a binary number, the rules are the same, except that we can only use 1s and 0s. What is the decimal equivalent of the binary number 1000111?

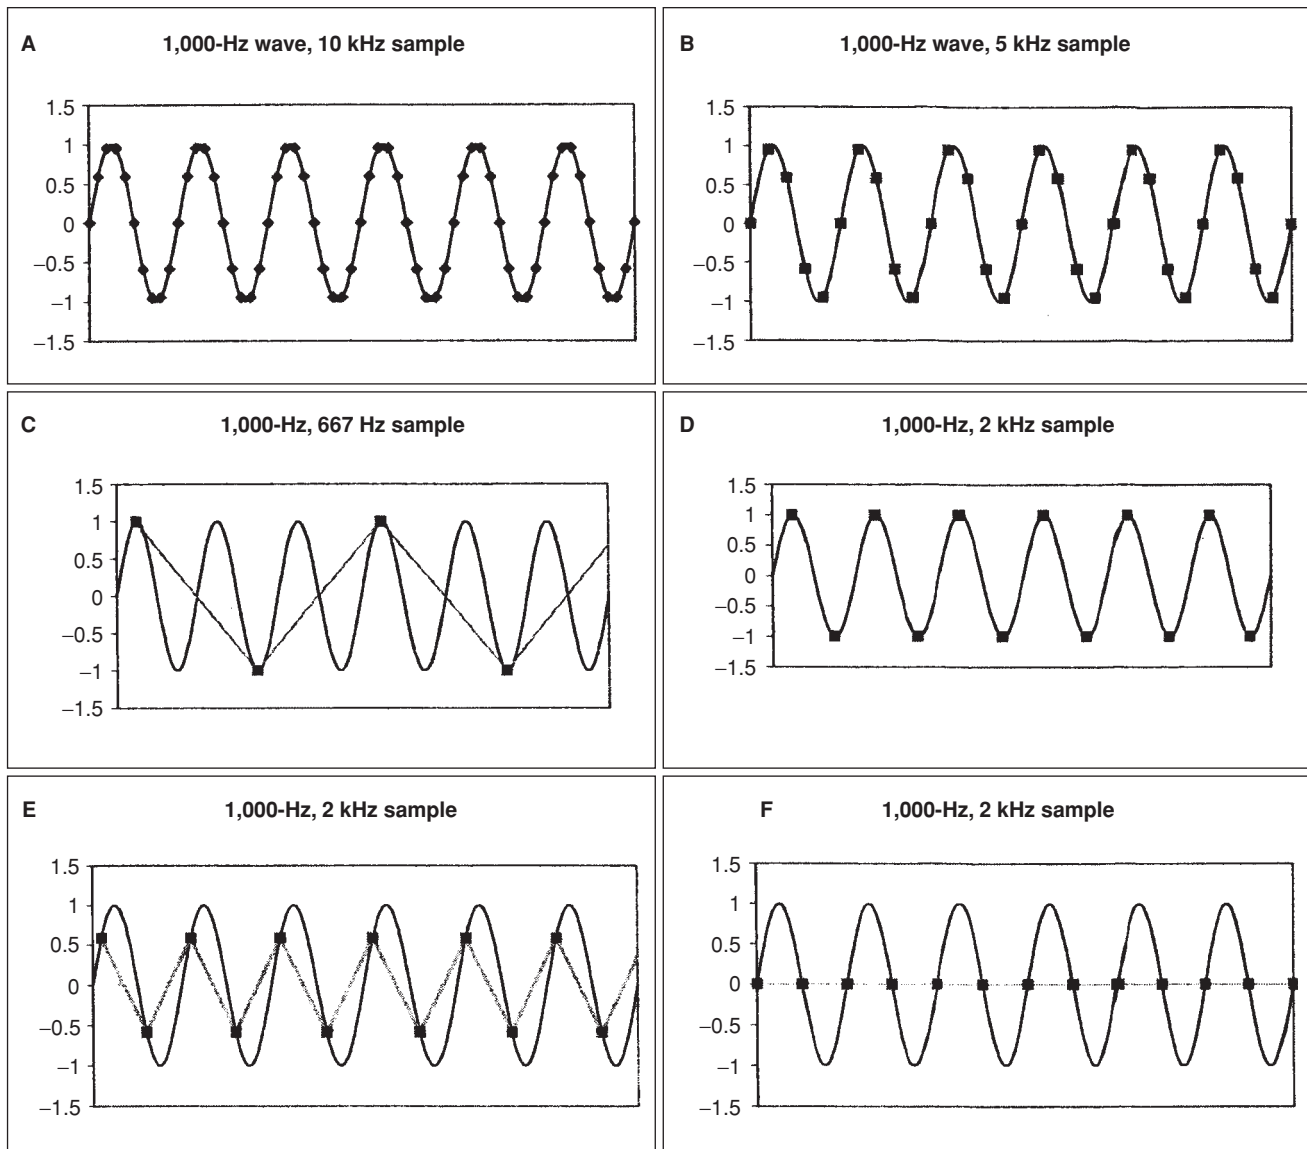

FIGURE 11.2 An analog representation of a sinusoid is shown. The time window shown represents 5 ms. Each subfigure shows an analog representation of a 1,000-Hz sinusoid, sampled at 10,000, 5,000, 667, 2,000, 2,000, and 2,000 Hz, respectively. [Reprinted from Burkard R, Secor C. [2002] Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. Baltimore, MD: Lippincott Williams & Wilkins; pp 233–248, with the permission of Lippincott Williams & Wilkins.]

$$\begin{aligned}
 1000111 &= (1 \times 2^6) + (0 \times 2^5) + (0 \times 2^4) + (0 \times 2^3) \\
 &\quad + (1 \times 2^2) + (1 \times 2^1) + (1 \times 2^0) \\
 &= 64 + 0 + 0 + 0 + 4 + 2 + 1 = 71
 \end{aligned}$$

As you can see, the rules of binary numbers are the same as those of decimal numbers, except that we can only use 0s and 1s. If each binary digit (called a bit) can only represent two values, then we need to use more than one bit to represent numbers greater than 1: In our example above, the two-place number 71 in decimal is represented in binary by the seven-place number 1000111. We refer to each of these binary places as a bit, and hence 1100010 is a seven-bit binary num-

ber. An n -bit binary number can assume 2^n values. Thus, a seven-bit number can assume 2^7 or 128 values. The smallest value this seven-bit number can assume is 0 (0000000), whereas the largest is 127 (1111111 = $64 + 32 + 16 + 8 + 4 + 2 + 1 = 127$). When we need to represent a greater number of possible values in the binary system, we must increase the number of bits.

ANALOG-TO-DIGITAL CONVERSION

An ADC is a device that changes the continuous activity of the real world (such as brain wave activity) into the binary coding used in the digital world. For practical reasons, it is

impossible to sample an infinite number of values. When we convert analog signals into a digital format we cannot sample the signal at all possible times, and we must round off the amplitude values. Thus, with analog-to-digital conversion, we lose information, but we gain the versatile processing capabilities of the digital computer.

The amplitude “round off” mentioned above is known as quantization. When the amplitude of a continuous (analog) signal is “rounded off” in the digital world, there is often a difference between the original analog value and the digital value. This difference is called quantization error. The magnitude of this quantization error is affected by a number of factors. One of these factors is the dynamic range of the ADC. The dynamic range is the largest voltage that can be accurately digitized. Let us say your ADC has a dynamic range of ± 1 V. A second factor in determining quantization error is the number of bits of the ADC. Let us assume that we have a ± 1 V dynamic range and a 12-bit ADC. A 12-bit ADC provides 4,096 (e.g., 2^{12}) possible values. As the total voltage range is 2 V (from -1 to $+1$ V) and a 12-bit ADC encodes 4,096 values, the resolution of this system is (with x = number of bits):

$$\begin{aligned} \text{ADC resolution} &= \text{voltage range}/2^x = 10\text{ V}/2^{12} = 12\text{ V}/4,096 \\ &= 0.000488\text{ V} = 0.488\text{ mV}. \end{aligned}$$

In this example, the resolution between two sequential points is 0.488 mV. The quantization error becomes relevant when we want to separate out amplitudes that are less than this ADC resolution. Assuming that the ADC rounds down to the largest value it has exceeded, the smallest nonzero amplitude this ADC can encode (called the least significant bit, LSB) must be more negative than -0.488 mV or more positive than $+0.488$ mV. You are probably wondering how this might be a useful resolution, as all EEG activity is quite a bit less than half a millivolt, and hence all electroencephalogram (EEG) voltages would round off to zero. For example, let us assume that off-the-scalp EEG voltage for a subject is ± 50 μV (± 0.05 mV) and your evoked potential amplitude is 1 μV . How close will you estimate this value in the proposed digital system? Without amplification (as stated above) because 1 μV is less than the quantization range of ± 0.488 mV, you will estimate the amplitude as 0 mV. The quantization error in estimating the peak EEG amplitude in this case is 1 μV (1 μV to 0 μV) and produces a significant estimation error. How do you reduce this unacceptable error? First, we could use an ADC with more bits. Sixteen-bit ADCs are currently available at a reasonable cost. This would produce a resolution of $2\text{ V}/2^{16} = 2,000\text{ mV}/65,536 = 0.0305\text{ mV}$, or 30.5 μV . With this 16-bit system, 1 μV is still digitally approximated as 0 μV , again giving a quantization error of 1 μV . In other words, this did not help one bit (bad joke, but after all, this is digital electronics we are talking about here). One can get 24-bit ADCs, which provide in excess of 16 million values (16,777,216). In this case, the

digital approximation is $2\text{ V}/2^{24}$, with a resolution of ~ 0.12 μV ; the digital approximation is this example would be 0.96 μV , with a resulting quantization error of 0.04 μV —a much more acceptable “round-off” error.

An alternative to using a very high resolution ADC (above) is to provide bioamplifier gain. All commercially available evoked potential systems provide variable bioamplifier gain. With the use of a bioamplifier, we can amplify the signal of interest so that it occupies most of the ADC voltage range, and in doing so we improve the amplitude resolution of our digital system. For our ± 1 V ADC range with 10-bit resolution, let us amplify the signal by 10,000 times. In this case, the full-scale off-the-scalp voltage that the ADC can resolve is $2\text{ V}/10,000 = 0.002\text{ mV}$ (note that this equals a total specified EEG range of ± 100 μV). Because this 0.2 mV range is encoded by the 10-bit ADC (representing 1,024 values), our off-the-scalp resolution is now $0.2\text{ mV}/1,024 = 0.195$ μV and our digital estimate of the 1 μV peak amplitude is 0.975 μV , with an error of 0.025 μV . To summarize, we can reduce quantization error using several strategies: reduce the ADC voltage range, increase the number of bits of the ADC, and/or increase bioamplifier gain.

The second limitation of a digital system arises because we sample the continuous analog response at periodic time intervals. The solid line in Figure 11.2A shows a 1,000-Hz analog sine wave. The dots represent the results of digitally sampling this 1,000-Hz sine wave every 0.1 ms. This is called the sampling period. The inverse of the sampling period is the sampling frequency ($1/0.1\text{ ms} = 1/0.0001\text{ s} = 10,000\text{ Hz}$). Figure 11.2B shows the same 1,000-Hz sine wave, but now sampled half as often: every 0.2 ms. If we visually connect the dots, we can visualize a signal that follows the periodicity of the sine wave. If we sample even less frequently, let us say every 1.5 ms (Figure 11.2C), we no longer adequately resolve the period of this sine wave. We now see a sine wave with a longer period (i.e., a lower frequency) than our analog 1,000-Hz sine wave. Digitally sampling an analog signal at too large a sampling period (or too low a sampling frequency) results in an inaccuracy in the estimate of the frequency of the analog signal. This inaccurate (false) frequency is referred to as an aliased frequency. The process leading to this false or inaccurate frequency is called aliasing. The Nyquist theorem can be used to avoid aliasing. According to the Nyquist theorem, to avoid aliasing, we must have a sampling frequency that is greater than twice the highest frequency in the analog signal that we are digitizing. The lowest digitization (sampling) frequency that can be used to accurately represent the frequency of a given analog signal is called the Nyquist rate. In our example, from Figure 11.2, we must sample at just above 2,000 Hz to adequately represent our 1,000-Hz sine wave. Figure 11.2D shows what might happen if we digitize at exactly 2,000 Hz (i.e., at exactly twice the frequency of the analog signal). In this case, when the sampling occurs at or near the peaks of the sine wave, we can resolve the frequency of the sine

wave. Although this sine wave looks more like a triangular wave, the frequency does appear appropriate. Figure 11.2E shows the same 2,000-Hz sampling frequency, but now the sampling times are slightly shifted in time from that shown in Figure 11.2D. You can see that the frequency of the 1,000-Hz sine wave is accurate, but the peak amplitude is underestimated. Figures 11.2D and 11.2E show that sampling at exactly twice the frequency of the analog signal can adequately resolve the frequency of interest. Why, then, does the Nyquist theorem state that the sampling frequency must be just above twice the highest frequency in the analog signal? This is answered by referring to Figure 11.2F, where the 1,000-Hz sine wave is digitally sampled at 2,000 Hz, but now these sample times occur at the zero crossings, and not at or near the peaks. This produces a flat line (i.e., a 0-Hz signal). As this 0-Hz frequency is clearly different (lower) than the analog signal frequency of 1,000 Hz, this example demonstrates aliasing. To avoid aliasing, we must sample at a little more than twice the highest frequency in our signal. It is wise to sample at two times the Nyquist rate (i.e., four times the highest frequency in the analog signal of interest), just to err on the side of caution. Using an example relevant to AEP work, if we know our ABR has substantial energy from 100 to 3,000 Hz, then the Nyquist rate is just above 6,000 Hz, and this sampling rate will be adequate to prevent aliasing. If we double the Nyquist rate, then the desired sampling frequency is ~12,000 Hz.

Now we know that using a sampling frequency that is too low can result in aliasing. Are there any problems with using a very high sampling frequency? Using a sampling frequency that is well above that needed to prevent aliasing will result in larger data files. This is most easily understood by a numerical example. We want to obtain an ABR for an infant, and we know that we should look at a response time window (time epoch) of 20 ms. Assuming there is little energy at 1,500 Hz or above in an infant ABR. In this example, the Nyquist rate is just above 3,000 Hz, and if we double this to prevent aliasing, we should digitize at ~6,000 Hz (a sampling period of 167 μ s). If we sample every 167 μ s, then we will have 120 data points in our 20-ms time window:

$$\begin{aligned} \text{Response time epoch} &= \{\text{sampling period}\} \\ &\times \{\text{number of data points}\}. \end{aligned}$$

This can be rewritten as

$$\text{Number of data points} = \{\text{response time epoch}\} / \{\text{sampling period}\}$$

Plugging our numbers from the example into this equation yields

$$\text{Number of data points} = 20 \text{ ms} / 167 \mu\text{s} = 120 \text{ data points}$$

We would only need to store 120 data points for this ABR waveform. If we doubled the sampling frequency (i.e., four times the Nyquist rate) this would require a sampling period of 83.5 μ s, and a grand total of 240 data points in our memory array. Now let us sample as fast as we can. We construct a digitizer that can sample at 1 GHz (a billion samples per second). A 1 GHz sampling frequency is a sampling period of 1 ns, or 0.001 μ s. The number of points in our evoked potential memory array would be 20 ms = 20,000 μ s / 0.001 μ s = 20,000,000 data points. You would fill up a 10 GB hard disk after collecting roughly 500 ABRs. If you had a busy clinic, you could fill up the hard drive quite quickly. You should digitize at a high enough rate to safely avoid aliasing, but not so fast as to have issues with data storage. Most commercial AEP units limit the number of data points that can be used to obtain a response. Let us say that your memory array is limited to 1024 (2^{10}) words of memory. For a 20-ms time window, your sampling period is 20 ms / 1,024 = 20 μ s, or a sampling frequency of 50,000 Hz. In this example, aliasing is not a problem, unless you suspect that there is energy in the response that exceeds 50,000/2 = 25,000 Hz. In some instances, you will not know exactly the Nyquist frequency of the response you are measuring. In these cases, using a filter that eliminates energy at and above a frequency where aliasing could be an issue is warranted. In our example, using a filter that eliminates energy at and above 25,000 Hz would solve the problem. This type of filter is called a low-pass filter. When the purpose of a low pass is to prevent aliasing, then this low-pass filter is called an antialiasing filter.

DIGITAL-TO-ANALOG CONVERSION

In most (perhaps all) current commercially available AEP systems, the acoustic stimuli used to elicit an evoked potential are digitally generated by the computer. These digital signals are converted to analog signals by a device called a digital-to-analog converter (DAC). Aliasing can also arise with digital-to-analog conversion. To avoid aliasing, the output voltage of the DAC can be low-pass filtered at the appropriate frequency (i.e., less than half the digitization frequency) by a device called an anti-imaging filter. It should be noted that the earphones used for clinical AEP measures generally have low-pass cutoffs less than 10,000 Hz and that these transducers may serve as anti-imaging filters if DAC rates above 20 kHz are used.

Noise Reduction

For human recordings, AEP amplitude is typically much smaller than that of the background noise. Any unwanted electrical activity will be called noise. For AEP purposes, this noise can be composed of both periodic and aperiodic activity and can be of both biologic and nonbiologic origin. Biologic sources of noise include muscle activity and the

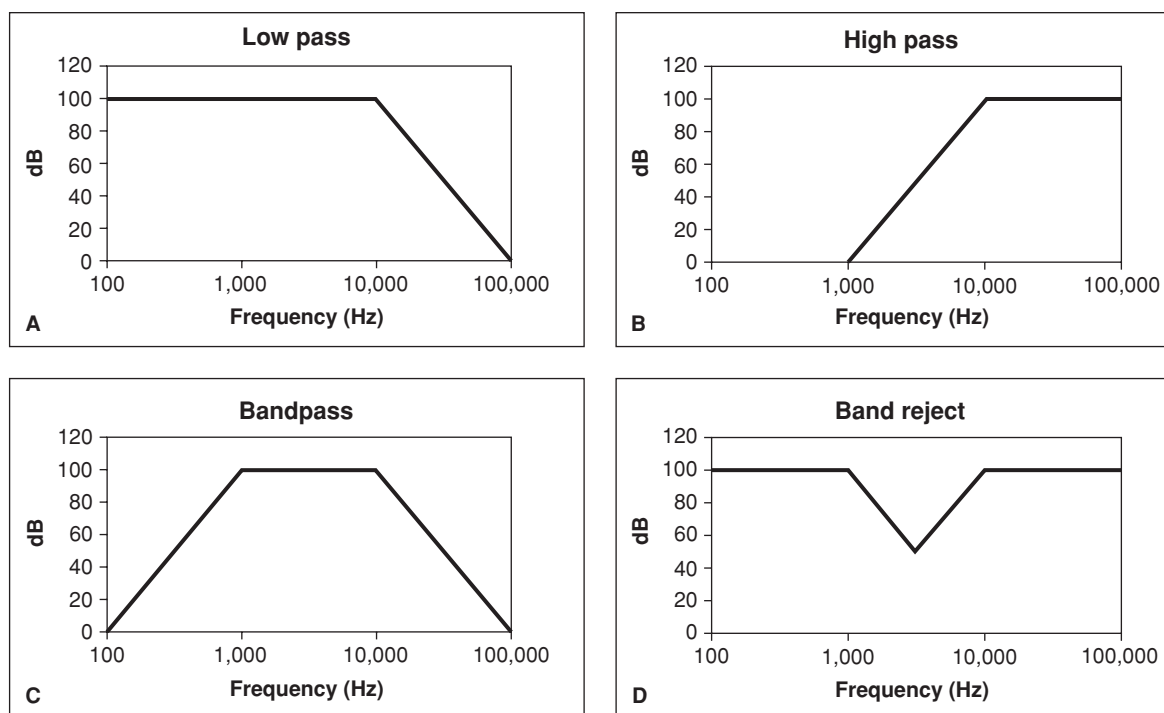

FIGURE 11.3 Filter response types are schematized: Low pass [A], high pass [B], bandpass [C], and band reject [D]. [Reprinted from Burkard R, Secor C. [2002] Overview of auditory evoked potentials. In: Katz J, ed. *Handbook of Clinical Audiology*. 5th ed. Baltimore, MD: Lippincott Williams & Wilkins; pp 233–248, with the permission of Lippincott Williams & Wilkins.]

EEG, both of which represent aperiodic noise. Nonbiologic sources of noise include aperiodic noise arising from the bioamplifier and periodic (60 Hz, or 50 Hz for our European and other readers) line-power noise. The 60-Hz (or 50-Hz) noise may arise from within the AEP system itself, but often this noise arises from the room where the AEP is being performed. This may be generated by overhead lights or be emitted by other electrical equipment in the room. Such 60-Hz (or 50-Hz) electrical noise is generated in the room, and the subject acts like an antenna. If this line noise is picked up by the electrodes on the subject's scalp, it is amplified (with the biologic activity). A few microvolts of line noise become a few volts, if a gain of 1,000,000 is used by the bioamplifiers.

How do you reduce unwanted electrical noise? First, low electrode impedances can reduce 60-Hz (or 50-Hz) line noise. Second, making the subject comfortable and encouraging them to sleep (if that does not negatively affect the response of interest) can substantially reduce noise arising from muscle activity. Third, differential amplification (i.e., using three electrode leads per recording channel) can reduce common-mode noise. Fourth, filtering the output of the bioamplifier can reduce noise. Finally, signal averaging reduces unwanted background noise. We have previously discussed electrode application and the use of differential amplification. In the following paragraphs we will provide more detail on the use of filtering and signal averaging to reduce unwanted noise.

Filtering involves eliminating noise that is outside the frequency range of the desired response. Most of the energy in, for example, the click-evoked ABR, is in the 30 to 3,000 Hz frequency range. Selectively eliminating electrical activity below 30 Hz and above 3,000 Hz will reduce the background noise with relatively minor changes to the ABR. Figure 11.3 shows the four basic types of filter functions. A low-pass filter (Figure 11.3A) reduces a signal above a given frequency, but allows lower frequency energy to pass through. A high-pass filter (Figure 11.3B) reduces a signal below a specified frequency, but passes signals above that frequency. A band-pass filter (Figure 11.3C) passes energy between two cutoff frequencies, but reduces energy above and below this frequency band. Finally, a band-reject or notch filter (Figure 11.3D) reduces energy between two cutoff frequencies, but passes energy above and below this band. The cutoff frequency (or half-power point) of a filter is the frequency at which the voltage at the filter output is reduced to 70.7% of the input (or is -3 dB). The rejection rate, or filter skirt, of a filter refers to how fast the voltage is reduced outside of the passband. This is often reported in decibels per octave. If the voltage of a signal is reduced by half (-6 dB) when the frequency is doubled (one octave is a doubling of frequency), then the filter rolls off at a rate of 6 dB/octave. Many filters roll off in integer multiples of 6 dB/octave, and each of these 6 dB/octave multiples is referred to as a pole. Thus, a 48 dB/octave filter is called an eight-pole filter.

It is important that you know the spectrum (frequency content) of the AEP you are recording, so that when you filter, you do not throw the baby out with the bathwater (i.e., you greatly reduce the AEP while reducing the amplitude of the noise). As most review chapters on the various AEPs will provide suggested filter settings for recording that response, determining optimal AEP filter settings should be a simple matter of following the suggestions in these chapters.

Despite our best efforts with getting the subject to relax, obtaining low and balanced electrode impedances, and using differential amplification with judicious filtering, the AEP of interest will still usually be smaller than the ongoing background electrical noise. In other words, the AEP is at a poor signal to noise ratio (SNR). In many instances, the response is much smaller than the amplitude of the background noise, making it difficult or impossible to identify the AEP. To improve the SNR (to make the AEP visible), we use time-domain signal averaging. The theory underlying signal averaging invokes several assumptions about the signal (i.e., the AEP) and the noise (see Hyde, 1994 for a more detailed treatment of this issue):

1. The AEP is always the same in response to a constant stimulus.
2. The noise is truly random (i.e., it is constantly changing).
3. The signal (the AEP) and the noise are independent.

For time-domain signal averaging, we present the same stimulus repeatedly while summing the response in memory. The average response is created by dividing the summed voltage at each time point in the memory array by the number of stimuli presented. Differences in the statistical properties of the signal (the AEP) and the noise lead to improvement in the SNR. For signal averaging to work correctly, we must initiate the summation into the memory array at a constant time relative to stimulus presentation. We typically start signal averaging at the onset of the stimulus. If we do this, then, according to the first assumption above, the AEP is constant to each stimulus presentation. For example, let us say we have a 1- μV AEP that we sum over 16 stimulus presentations:

$$1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 = 16 \mu\text{V}.$$

The average amplitude is thus $16 \mu\text{V}/16$ sweeps = $1 \mu\text{V}$. This is expected, as we said the stimulus is constant for each presentation. Let us say the background noise is $4 \mu\text{V}$. The $\text{SNR} = 1 \mu\text{V}/4 \mu\text{V} = 0.25$. The signal is small compared to the noise, and it will be difficult to see the AEP. Let us sum together the response to 16 “noise” time epochs. In this case, because the noise segments are random, we sum these noise estimates in a manner that differs from that used for the signal. We square each value, sum these squared values, and take the square root. The interested reader is referred to

Hyde (1994) for a more detailed explanation. According to this formula

$$(4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2 + 4^2)^{1/2} = 16 \mu\text{V}.$$

The average noise is now $16 \mu\text{V}/16$ sweeps = $1 \mu\text{V}$, and the SNR is now $1 \mu\text{V}$ signal/ $1 \mu\text{V}$ noise = 1. Thus, signal averaging over 16 sweeps changed the SNR from 0.25 to 1: A factor of 4 improvement. Under optimal conditions, the SNR increases in proportion to the square root of the number of sweeps.

Recommendations for the number of sweeps used clinically (in chapters that follow, and elsewhere) are based on the experimental and clinical experience of the investigators, or after review of the relevant literature. These recommendations can only be considered guidelines. The number of stimulus presentations required to obtain a given response depends on response amplitude (which varies with the AEP, stimulation and recording parameters, and the particular subject), background noise amplitude (which is dependent on subject and recording factors), and the target SNR (which is dependent on particular clinical objectives). For threshold estimation, the SNR should be on the order of 1 or more, as you are only interested in whether a response is present or not. For determination of peak latencies and amplitudes, an SNR of 2 or greater is desirable, as you are trying to accurately estimate response variables, which will be influenced by poor SNR.

You might read in the literature that you should obtain 2,000 sweeps for an ABR. Such statements, however, can only be considered suggestions, that will not be optimal under some circumstances. For one subject, to a lower level click stimulus, you might record a response amplitude of $0.1 \mu\text{V}$. Let us say there is a $10 \mu\text{V}$ background noise. The SNR is 0.01, and this only improves by a factor of 44.7 for 2,000 sweeps, and the SNR of the averaged response will still be less than 1 (0.447). In this example, the recommended number of sweeps is inadequate. In a different subject, when you present a high-level stimulus, your response might be $0.6 \mu\text{V}$. This patient is quite relaxed and has $3 \mu\text{V}$ of noise, resulting in an SNR of $0.6/3 = 0.2$. Presenting 2,000 sweeps, the SNR (under optimal conditions) is 8.94 (0.2×44.7), which is a better SNR than is required for most clinical purposes. You could have saved yourself some time by stopping data acquisition before the 2,000 stimuli had been presented. Although guidelines of sweep numbers are of course useful, a clear understanding of the principles underlying signal averaging can lead to online protocol changes that will allow more efficient data collection, as well as reduce the likelihood of stopping signal averaging before an interpretable AEP is obtained. There are techniques that allow online estimation of SNR, and stopping rules can be used that stop data acquisition when a criterion SNR (and/or probability level that a response is

present) is achieved or a maximum number of responses have been averaged. One such technique (called Fsp) is described later in this chapter.

NORMATIVE ASPECTS OF THE ABR

In this section we will review some normative aspects that form the basis for the clinical applications of the ABR that are reviewed in Chapters 13, 14, and 16. We will review the recommended recording parameters of the ABR, briefly mention several relevant subject variables, and in more detail review the effects of several stimulus variables on the ABR.

As shown in Figure 11.1, the ABR from a normal-hearing and neurologically intact young adult to a moderately high level click stimulus results in a series of five to seven positive peaks. The peak amplitudes are, in most instances, less than 1 μ V.

Subject Variables

The ABR is not substantially influenced by attention or sleep state (Kuk and Abbas, 1989; Picton and Hillyard, 1974), which makes it optimal for evaluating patients who are unable or unwilling to cooperate, such as infants or young children.

There are several subject variables that can affect the latency and the amplitude of the ABR, including core temperature, gender, and age. A decrease in core temperature results in an increase in ABR peak latencies, an increase in interwave intervals (IWI), and a decrease in peak amplitudes (Hall et al., 1988; Marshall and Donchin, 1981). It is important to monitor core temperature during intraoperative monitoring. This is because a patient's core temperature may be outside of the normal range during, for example, heart surgery (Stockard et al., 1978), and core temperature changes can have an influence on the interpretation of the results. Females generally show shorter response latencies and IWIs, as well as larger response amplitudes, than males (Kjaer, 1979; Schwartz et al., 1994). These sex differences cannot be explained by differences in head size alone, but rather appear to be attributable, at least in part, to differences in cochlear length. Human females have shorter cochleae than their male counterparts (Sato et al., 1991). Don et al. (1993), using the high-pass subtractive masking technique (see below), reported that shorter cochlear length results in greater traveling-wave velocity, which is believed to account for some of the gender-related differences noted above. Finally, in regard to subject age, ABR peak latencies, IWIs, and amplitudes have been shown to vary with the age of a subject. Infant peak latencies and IWIs are longer than those seen in adults (Cox, 1985). Older adult subjects have ABRs that are typically reported to be longer in latency and smaller in amplitude, as compared to younger adult subjects

(Schwartz et al., 1994). However, many of these older subjects have a hearing loss, which makes it difficult to separate the changes in the ABR that occur as a result of advancing age from the changes that can occur from a hearing loss.

Another issue that is not yet fully understood is how age affects the ABR IWIs. Rowe (1978) reported that the I–III IWI increased with increasing age, whereas the III–V IWI remained unchanged. In contrast, Costa et al. (1990) found that the I–II and I–III IWIs actually decreased with increasing age. These inconsistencies can make it challenging to interpret ABR results, especially when considering peak latencies, as well as IWIs, which are often used for site-of-lesion testing. Perhaps the evaluation of the I–V interval using derived-band responses (see Eggermont and Don, 1986) could be profitably combined to shed further light on the complicated and inconsistent effects of aging on the ABR IWIs.

Stimulus Variables

As mentioned above, the ABR is sensitive to manipulations in stimulus parameters, including stimulus polarity, whether the stimuli are presented monaurally or binaurally, stimulus spectrum, level, and rate. We will review the effects of these stimulus factors on the ABR in the paragraphs that follow.

A number of studies have investigated how click polarity affects the human ABR. Hair cells are only excited by a deflection of the stereocilia in the direction of the basal body (i.e., the hair cells perform a half-wave rectification of the input signal). Simple models of the auditory system suggest that the rarefaction phase of a stimulus should be the most effective (see Hall, 1995, pp 143–144). Empirically, some studies have shown shorter peak latencies and larger peak amplitudes to rarefaction than to condensation clicks (e.g., Stockard et al., 1979). However, other studies indicated that not all subjects show these trends and that polarity effects are, at best, small and variable (Borg and Lofqvist, 1981; Schwartz et al., 1994). Don et al. (1996) provide an in-depth discussion of the challenges in determining whether there are truly latency changes with changes in stimulus polarity. ABRs to monaural stimuli are smaller than to binaural stimuli (Owen and Burkard, 1991). If an ABR is collected in response to monaural stimulation from each ear and summed, this “summed monaural” response typically has a larger Wave V amplitude than is seen when one actually binaurally stimulates the subject (Owen and Burkard, 1991). This amplitude reduction for the true binaural response, as compared to that of the “summed monaural” response, is often interpreted as evidence of binaural interaction in the ABR. Most studies of binaural interaction using the difference between the sum of the monaural responses and the binaural response ignore the possibility that there are neural elements that (as shown in animal work) can be driven by either ear. These neural elements, therefore, contribute

twice in the monaural sum. However, its doubled contribution is not considered in response to binaural stimulation. Thus, even with no binaural interaction, there will always be a difference between the sum of the monaural responses and the binaural response suggesting binaural interaction. This potential confound makes it difficult to use the magnitude of the difference as a quantitative measure of the amount of binaural interaction.

Click stimuli are broad in frequency, which results in stimulation of much of the cochlea. To stimulate a limited region of the cochlea, you must either use a narrow-spectrum stimulus (such as a toneburst), use a masking procedure, or use a combination of a narrow-spectrum stimulus and maskers. Low-frequency tonebursts will typically produce longer ABR peak latencies, because of the increased traveling-wave delay to more apical cochlear regions. When presented at high stimulus levels, low-frequency tonebursts may actually generate an ABR that arises from the higher frequency (more basal) regions of the cochlea (Burkard and Hecox, 1983b). To reduce this basal spread of activity in response to low-frequency stimuli, several masking procedures have been developed and investigated. These masking procedures include (1) click stimuli with notched noise (Pratt and Bleich, 1982); (2) click stimuli and high-pass subtractive masking (Don and Eggermont, 1978; Teas et al., 1962); (3) toneburst stimuli in high-pass noise (Kileny, 1981); and (4) toneburst stimuli in notched noise (Picton et al., 1979). We will not review this literature further in this chapter. An excellent review of this topic can be found in Stapells et al. (1994).

To estimate ABR threshold, the level of the stimulus must be varied. ABR peak latencies increase whereas peak amplitudes decrease with decreasing click levels. Waves I, II, and IV are often difficult to identify at moderate click levels and below. Wave V is often the only wave that can be identified near threshold, although in some cases Wave III can also be seen at and near ABR threshold. The slope of the Wave V latency/intensity function (i.e., the change in Wave V latency for a given change in stimulus level) to click stimuli is typically near $-40 \mu\text{s}/\text{dB}$ in normal-hearing young adults (Burkard and Hecox, 1983a; Hecox and Galambos, 1974).

Click rate also influences the ABR. As the click rate increases, peak latencies and IWIs increase, whereas peak amplitudes decrease (Burkard and Hecox, 1987). It should be noted that Wave V amplitude does not always decrease linearly with increasing rate. In normal-hearing young adults, Burkard and Hecox (1983a) showed a small decrease in Wave V amplitude with increasing rate from 15 to 30 Hz, and little amplitude change from 30 to 90 Hz. Burkard et al. (1990) used 50 dB nHL clicks in a group of normal-hearing young adults. They reported a mean Wave V amplitude increase with increasing rate from 30 Hz ($0.388 \mu\text{V}$) to 90 Hz ($0.409 \mu\text{V}$). These results demonstrate that Wave V amplitude to moderate-level clicks is only modestly affected by increasing rate. As Wave V is the wave most often seen at near-threshold levels,

using a relatively fast stimulus repetition rate (30 to 50 Hz) is optimal for threshold estimation, as this will reduce the amount of time it takes to obtain an ABR.

NOVEL STIMULUS MANIPULATIONS FOR CLINICAL APPLICATIONS OF THE ABR

The cochlear delay line, that is, the increased response latency with decreasing stimulus frequency, leads to an ABR whose peak latencies and amplitudes are dominated by the activity of the higher frequency portions of the cochlea. In this section, we discuss how several creative stimulus manipulations are used in the attempt to account for this delay. We will also discuss their possible clinical utility. Consider this brief inclusion of several stimulus manipulations that have possible clinical applications as a thought-provoking prelude to subsequent chapters that describe the clinical utility of the ABR (i.e., Chapters 13, 14, and 16).

High-pass Subtractive Masking and the Stacked ABR

WHY STANDARD ABR MEASURES CANNOT DETECT SMALL TUMORS

Two requirements for any ABR measure used for tumor detection are that (a) the tumor exerts sufficient pressure to desynchronize, block, or alter the conduction properties of eighth nerve elements and (b) the tumor affects a sufficient number of those neural elements. Obviously, any ABR measure will fail if either of these two requirements is not met. However, for standard ABR latency measures such as the I–V IWI and the interaural Wave V (IT5) delays, there is an additional, third requirement: The tumor must affect the activity of those neural elements that determine the peak latency of the brainstem response to the stimulus. In other words, normal standard ABR latency measures are determined by only a subset of auditory nerve fibers. In particular, the latency of the standard ABR is determined by the high-frequency fibers. The high failure rate in detecting small intracanalicular (in the internal auditory meatus) tumors is not surprising because normal standard ABR latencies are possible if the synchronous activity of the high-frequency fibers that determine the latency is not sufficiently compromised by the tumor. Thus, even if a small tumor affected a substantial number of activated neural elements representing mid-to-low frequencies, the peak latency may not change much because the activity of these elements does not determine the peak latency of the standard ABR. If standard ABR latency measures detect the tumor, then a sufficient number of the neural elements that determine the peak latency have been affected. If, however, the ABR latency measures miss the tumor, then an adequate number of the appropriate

neural elements were not affected. It is this possible failure to affect a sufficient number of appropriate neural elements that makes latency measures insensitive to some, but not all, small tumors. We hypothesize that the variable success of the standard ABR measures in detecting small tumors is due, in part, to the variable underlying neuroanatomic organization of eighth nerve fibers and the variable location and encroachment of small tumors.

If latency is often insensitive to the effects of small tumors, what about Wave V amplitude? Amplitude measures should be very sensitive to loss or desynchronization of eighth nerve activity. Many studies examined standard ABR amplitude measures and concluded that they are often too variable compared with latency measures. Two major contributors to this amplitude variability discussed above are (a) the residual noise in the average and (b) phase cancellation of activity related to progressive activation and response time variations across the cochlea. Standard ABR wave amplitude measures do not reflect all the neural activity from click stimulation because of phase cancellation. In particular, studies have shown that activity from low-frequency regions of the cochlea contributes little to the standard ABR Wave V amplitude (Don et al., 1994, 1997, 2005). Therefore, like standard latency measures, standard amplitude measures will miss tumors that do not sufficiently affect high-frequency fibers.

THE STACKED ABR: A NEW MEASURE FOR DETECTING SMALL ACOUSTIC TUMORS

If a new ABR measure is to be successful at detecting small acoustic tumors, it must avoid the main shortcomings described above. We hypothesize that to do so, it must be a measure of neural activity from all of the cochlea, not just the high-frequency regions. We have previously cited ABR studies demonstrating that high-frequency activity dominates the latency and amplitude responses, and we hypothesized that small tumors do not always affect these fibers. Is there neuroanatomic evidence to support this hypothesis?

Anatomic Considerations

Acoustic tumors generally arise from Schwann cells in the vestibular division of the eighth nerve in the internal auditory canal and eventually extend into the cerebellopontine angle. The tumors can arise from either the superior or inferior divisions of the vestibular nerve and encroach upon the cochlear nerve. To understand the effect of a small tumor on the cochlear nerve, we need to understand the tonotopic neuroanatomic organization of the fibers in the cochlear nerve. Figure 11.4 is adapted from Spoendlin and Schrott (1989). In this transverse section of the human internal auditory canal we see the seventh (facial) nerve (VII; upper left) and three divisions of the eighth (VIII) (auditory and vestibular) nerve. Clockwise from upper right, the divisions of the eighth nerve are as follows: First, the superior ves-

FIGURE 11.4 Tonotopic organization of the human auditory nerve. Transverse section through the internal auditory canal of an 8-year-old child, showing the position of the facial nerve [VII], the superior division of the vestibular nerve [vest. sup.], the inferior division of the vestibular nerve [vest. inf.], and the auditory nerve with the nerve fibers for the most basal end [Hook], for the lower basal turn [Ia], the upper basal turn [Ib], and the second and apical turns [II]. [Reprinted from Spoendlin H, Schrott A. (1989) Analysis of human auditory nerve. *Hear Res.* 43, 25–38, with the permission of Elsevier Science.]

tibular nerve; second, the inferior vestibular nerve; third, the auditory (cochlear) nerve. In the auditory nerve, high-frequency fibers arising from the lower and upper basal turns of the cochlea lie inferiorly (Ia) and superiorly (Ib), respectively. Fibers from the second and apical turns of the cochlea lie in the medial portion of the cochlear nerve (II), adjacent to the inferior vestibular nerve.

This figure clearly shows that if a tumor arose from that adjacent portion of the inferior vestibular nerve, it would affect the lower frequency fibers in the second and apical turns first. There are tumor patients with only low-frequency or upward-sloping hearing losses (Johnson, 1977). In some of those cases, it is possible that a tumor here might be partly responsible for such hearing losses. As can be seen in this figure, depending on where the vestibular schwannoma arises, high- or low-frequency fibers can be affected first. At the House Clinic in Los Angeles, approximately half the eighth nerve tumors originate from the inferior vestibular nerve, with the other half arising from the superior vestibular nerve (Dr. Fred Linthicum, personal communication). In addition, tumors do not always simply push against the nerve trunk, exerting pressure from the periphery of the trunk inward. Instead, there is strong evidence that the tumor often invades or infiltrates the nerve trunk. Studies have demonstrated that invasion of the cochlear nerve by solitary vestibular

schwannomas is common. Neely (1985) found invasion of the nerve trunk in all 22 cases he studied; Marquet et al. (1990) and Forton et al. (1990), in over 50% of their cases; and Dr. Fred Linthicum, in half of the cases in a series of 28 tumors from the House Clinic (personal communication). In particular, neurofibromatosis type II tumors typically infiltrate the nerve trunk. Therefore, fibers other than those on the surface of the trunk may be affected. Clearly, a measure of neural activity from all parts of the cochlea would be better in detecting small tumors than ABR measures confined to the high frequencies alone.

DESCRIPTION OF THE STACKED ABR

We mentioned above that amplitude measures should be able to reflect neural activity that has been desynchronized or blocked by a tumor. However, we presented several major problems with standard measures, in particular, the detrimental effect of varying SNR and the dependence of these measures on high-frequency activity because of phase can-

cellation of activity from lower frequency regions. Don et al. (1997, 2005) have proposed an ABR measure to circumvent these problems. This measure, the stacked ABR amplitude, is sensitive to neural fiber activity from all frequency regions of the cochlea. Thus, the measure will reflect the loss of synchronized neural fiber activity, no matter which fibers are compromised by a tumor, as long as the stimulus level is high enough to activate most of the neural fibers in all the frequency regions. Determining the stacked ABR amplitude requires the derived-band and stacked ABR techniques. A click stimulus is used to activate the whole cochlea, and the resulting response is separated into five frequency bands by using a high-pass masking technique with response subtraction (Don and Eggermont, 1978; Parker and Thornton, 1978a, 1978b). The ABRs representing these five frequency bands are called derived-band ABRs and are used in constructing the stacked ABR.

The derived-band ABR technique requires six stimulus conditions. These six stimulus conditions are noted in the first column on the far left of Figure 11.5 and from top

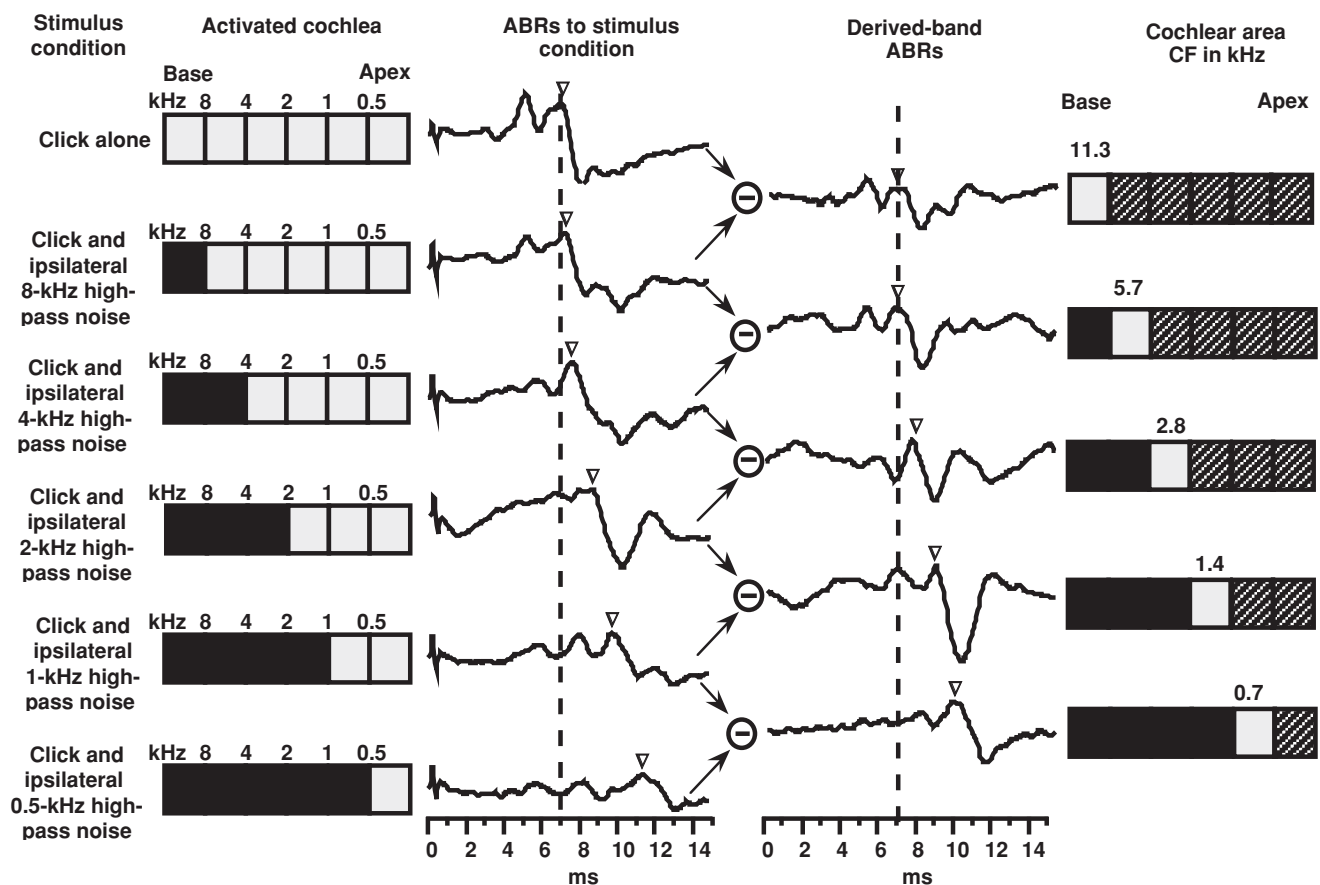

FIGURE 11.5 Schematic description of the high-pass masking and subtraction technique used to obtain derived-band ABRs. **First column:** The six stimulus conditions. **Second column:** Schematics of the areas of the cochlea stimulated for that condition. **Third column:** ABR waveforms to stimulus conditions. **Fourth column:** Derived-band ABR waveforms resulting from successive subtraction of conditions. **Fifth column:** Schematics of the octave-wide areas of the cochlea whose activity is represented in the derived-band ABRs. [See text for detailed explanation.]

to bottom are the presentation of clicks alone, followed by clicks presented with simultaneous ipsilateral high-pass masking pink noise with cutoff frequencies of 8, 4, 2, 1, and 0.5 kHz. A schematization of the cochlear regions activated (illustrated by the lightly shaded regions) by the unmasked and various high-pass masker cutoff conditions is shown in column 2. ABRs to the clicks without masking noise, and each of the five high-pass noise conditions, are shown in the third column from the left. Note the increase in ABR peak latency with decreasing high-pass masking noise cutoff frequency. If the ABR obtained from one high-pass masker cutoff condition is subtracted from the ABR obtained with the high-pass masker cutoff frequency that is one octave higher in frequency, you obtain the derived-band responses (shown in the fourth column from the left), which shows an increase in derived-band response latency with decreasing derived-band cutoff frequencies. For the high-pass responses, the ABR arises from all cochlear regions apical to the high-pass masker cutoff frequency. In contrast, the derived-band responses are thought to arise from the octave-wide cochlear region delimited by the two high-pass masker cutoff frequency conditions used to create the derived band (e.g., from the 4- to 8-kHz region when you subtract the 4-kHz high-pass condition from the 8-kHz high-pass condition; see Don et al. 2005). This octave-wide cochlear region for each derived band is illustrated by the lightly shaded regions in the rightmost column of Figure 11.5.

The theoretical center frequencies (CFs) of these derived bands are simply and arbitrarily defined as the geometric mean of the two cutoff frequencies of the stimulus conditions involved in the subtraction. Specifically, the theoretical CF for each derived band is computed as the square root of the product of the two successive high-pass filter cutoff frequencies used for the band. For example, the derived-band ABR resulting from subtracting the response to clicks + 4 kHz high-pass masking noise from the response to clicks + 8 kHz high-pass masking noise would have a theoretical CF of about 5.7 kHz ($\{4 \times 8\}^{1/2} \approx 5.7$). For the click-alone condition, 16 kHz is used for the calculations. Thus, the theoretical derived-band CFs for the five derived-band ABRs are 11.3, 5.7, 2.8, 1.4, and 0.7 kHz.

The delay in peak activation (ΔT) from different regions of the cochlea (Figure 11.5, fourth column from the left, labeled “Derived-band ABRs”) demonstrates that the activity of the cochlea underlying the generation of the standard ABR is not synchronous in time, but is progressively delayed as more apical cochlear regions are activated. This clearly illustrates how activity from lower frequency regions is phase-canceled by activity from higher frequency regions. For example, the peak of Wave V in the 0.7-kHz derived-band ABR is in phase and canceled by the trough following the peak of Wave V in the 1.4-kHz derived-band ABR. Similar phase cancellation can be seen between other successive derived-band waveforms. As a result, the amplitude of the standard ABR to clicks alone does not reflect

FIGURE 11.6 The stacked ABR is formed by shifting the derived bands to align the Wave V peaks, then adding the waveforms together. The Wave V amplitude of the stacked ABR is the new measure of interest.

the total amount of neural activation. Figure 11.6 illustrates the construction of the stacked ABR from the derived-band ABRs in Figure 11.5. The stacked ABR is constructed by (a) time shifting the derived-band waveforms so the peak latencies of Wave V in each derived band coincide and (b) adding together these shifted derived-band waveforms. The Wave V peaks of the derived-band ABRs are aligned to the Wave V peak latency for the arbitrarily selected 5.7-kHz derived band. The top waveform is the stacked ABR, the sum of the temporally aligned derived-band ABRs shown below it. By temporally aligning the peak activity initiated from each segment of the cochlea, we synchronize the total activity and minimize phase-canceling effects. Thus, compared with standard ABR amplitude measures, the amplitude of the stacked ABR Wave V reflects more directly the total amount of cochlear activity. We refer to this as the *stacked ABR amplitude*.

Before reviewing some results with this measure, we must discuss some important technical aspects associated with the stacked ABR. ABRs have poor SNRs because responses originate from deep brainstem structures located at a significant distance from the surface-recording electrodes. Even after extensive averaging, ABRs are often still dominated by unaveraged residual background physiological noise. In the stacked ABR approach, it is imperative that the ABR waveforms reflect mostly neural response, not noise. Therefore, techniques for recording and processing

ABRs to ensure consistently low residual noise in the averages (Don and Elberling, 1996; Elberling and Don, 1984) are combined with the derived-band ABR method. In particular, the Fsp measure (Elberling and Don, 1984) is used to help estimate the SNR of an ABR. In addition, we apply a Bayesian weighting approach developed by Elberling and Wahlgreen (1985) to form averages that give more weight to sweeps having less noise and to minimize the destructive effects of large episodic background noise on the ABR. Thus, the stacked ABR method combines the derived-band ABR method with techniques that ensure low levels of residual noise and create weighted averages to minimize the destructive effects of episodic noise. Suggestions for obtaining high-quality derived-band/stacked ABR responses can be found in Don and Kwong (2013).

In an initial study of 25 tumor cases, Don et al. (1997) found that five small (≤ 1 cm) intracanalicular tumors were missed by standard ABR latency measures (IT5 and I-V delay). However, they demonstrated that all five were detected by this new stacked ABR method. In a larger follow-up study of 54 small tumor cases, Don et al. (2005) demonstrated that the Stacked ABR achieved 95% sensitivity and about 88% specificity with respect to young nontumor, normal-hearing subjects. Figure 11.7 is a plot from Don et al. (2005) showing the cumulative percentile curves for the stacked ABR amplitudes for nontumor, normal-hearing subjects (NTNH) and for the small acoustic tumor subjects (SAT). The stacked ABR amplitudes were normalized to the mean value of adults of the same gender tested under similar testing conditions. Don et al. (2005) established target criteria for excellent sensitivity (95%) and acceptable specificity (50%) and evaluated separately the sensitivity and specificity of these target criteria. It can be seen in Figure 11.7 that a target sensitivity of 95% yields a specificity of 88% relative to the NTNH population. Furthermore, the criterion value for a target specificity of 50% resulted in detection of all the tumor cases in their study (100% sensitivity). Thus, it appears that the stacked ABR measure can significantly reduce the number of nontumor patients sent for imaging, without missing a tumor.*

The Chirp

Our understanding of how the cochlea works goes back to the seminal (and Nobel prize-winning) work of Georg von Bekesy. From this work, we know that high frequencies stimulate the base of the cochlea, whereas low frequencies excite the apex of the cochlea. One consequence of this type of “cochleotopic” representation is that the high-frequency (basal) cochlear regions are stimulated first, with the more

FIGURE 11.7 The cumulative distribution curves for the normalized stacked ABR amplitudes for both the NTNH and the SAT populations. A criterion to achieve 95% sensitivity yields 88% specificity and a criterion to achieve 50% specificity yields 100% sensitivity. [Reprinted from Don M, Kwong B, Tanaka C, Brackmann DE, Nelson RA. [2005] The Stacked ABR: A sensitive and specific screening tool for detecting small acoustic tumors. *Audiol Neurootol*. 10, 274–290, with permission of S. Karger AG, Basel.]

apical regions stimulated after a bit of a delay (take a peek at the derived-band response latencies shown in Figure 11.5, for a visual representation of this phenomenon). Dau et al. (2000) described an upward frequency sweeping chirp that was used to compensate for the temporal dispersion that occurs in the cochlea. This has come to be called the “Dau” chirp. It has now been reported that a single chirp is not adequate, as the optimal chirp (at least for normal-hearing young adults) gets shorter as the stimulus level increases (Elberling et al. 2010). Figure 11.8 (from Elberling et al., 2010) shows the electrical waveform of a family of chirps, as well as that of a click. Note that with increasing chirp number, its duration increases. Figure 11.9 (also from Elberling et al., 2010) shows grand mean ABR waveforms for the click and chirps, for three stimulus levels. It can be seen that at least for a few of the chirps the grand mean ABR Wave V amplitude appears to be larger than that for the click. Finally, in Figure 11.10 (again, from Elberling et al., 2010), the optimal chirp duration (i.e., that chirp duration which produces the largest Wave V amplitude) varies with stimulus level. Recall that the larger numbered chirps are longer in duration; it can be clearly seen here that the optimal chirp duration increases with decreasing chirp level. Increasing Wave V amplitude by using chirps is one good way of reducing test time for, for example, newborn hearing screening. However, most of the work using chirps has, to date, focused on normal-hearing young adults, and more work is needed to determine the optimal chirp duration across level for newborns and to identify the effects of hearing loss on chirp-evoked ABRs. Some preliminary data

*The stacked ABR was licensed to Bio-logic Corp (now owned by Natus Corp) and was implemented on their ABR system. However, Bio-logic/Natus no longer own the license nor sell or support the systems with the stacked ABR.

suggest that chirps elicit larger amplitude ABRs than clicks (at similar sensation levels) in human adults with sensory hearing loss (Maloff and Hood, 2014).

SUMMARY

In this chapter, we have briefly described the anatomy of the auditory nervous system, provided an overview of the various flavors of AEPs, presented a terse overview of the technical aspects of eliciting and recording an AEP, and summarized the effects of various stimulus manipulations on the ABR. We ended by describing some recent work involving high-pass subtractive masking (called the stacked ABR) and upward-frequency-sweeping FM tones (chirps). We hope that you will go out and do something important with your newfound knowledge.

FOOD FOR THOUGHT

1. Do you agree or disagree with the following statement: Students should not be forced to learn the technical details about AEP recording and stimulus generation, as audiologists are not supposed to be technicians.
2. Do you think an audiologist who is trained to do AEPs could expand their clinical practice to include somatosensory-evoked potentials, visual-evoked potentials, vestibular-evoked myogenic potentials, and facial nerve monitoring? In responding to this question, make sure you comment on the adequacy of your professional training for expanding their recording of EPs beyond AEP and describe what additional education and/or training would be required for you to feel comfortable recording (and interpreting) non-AEPs.
3. Do you think it is worth purchasing the equipment and learning about stacked ABRs, or should audiologists not record stacked ABR, as MRIs are quite good at identifying even intracanalicular tumors?

Electrocochleography

Rosamaria Santarelli and Edoardo Arslan*

INTRODUCTION

Electrocochleography (ECoChG) is the technique of recording the electrical responses that occur in the cochlear hair cells and auditory nerve in response to acoustic stimulation. ECoChG potentials were first obtained by Wever and Bray (1930) who recorded the electrical responses evoked by different acoustic stimuli by using a wire hook electrode placed on the auditory nerve in cats. These potentials closely reproduced the sound waveform and also transmitted speech with great fidelity when electric signals were sent to a loudspeaker, so that the experimenters were able to communicate from one room to another by whispering in the cat's ear. Wever and Bray interpreted these responses as arising from the auditory nerve; however, further research demonstrated that they were generated in the cochlea and they came to be known as cochlear microphonic (CM). Since then, several types of evoked cochlear responses have been recorded from experimental animals as well as from patients showing perforation of the tympanic membrane or who have had ear surgery, via an electrode on the promontory wall or in the window niche. Subsequently, ECoChG potentials were recorded from the promontory wall in humans by using a needle electrode which was passed through the tympanic membrane with the aid of an operating microscope (transtympanic approach).

The assessment of the origin of the different types of cochlear potentials in different experimental settings as well as the introduction of several techniques for ECoChG recording in humans prompted the proposal that ECoChG be used in clinical practice. In the 1970s, academic centers began using the transtympanic approach to assess hearing threshold in uncooperative children (Aran et al., 1971; Arslan et al., 1983). However, soon after its introduction for hearing evaluation, ECoChG was set aside because auditory brainstem responses (ABRs) were recognized as a reliable noninvasive tool for hearing threshold estimation in uncooperative children. Nevertheless, over the years the identification of distinctive features of ECoChG potentials in some ear disorders such as Ménière disease (Eggermont,

1974) together with the development of noninvasive recording techniques spurred the inclusion of ECoChG in the standard protocol for the diagnosis of Ménière disease in many medical centers.

In recent decades, the identification of new disorders such as auditory neuropathy (AN), believed to involve the auditory nerve, inner hair cells (IHCs), and/or the connecting synapses (Starr et al., 1996), prompted the use of a sensitive recording technique for defining the details of potentials arising in both the cochlea and auditory nerve. In addition, it was recognized that the reliability of ABRs in hearing threshold estimation testing was reduced in some categories of children such as those affected by neurologic disorders involving the brainstem (Kraus et al., 1984), thus leading to revision of the role of ECoChG in clinical practice and its proposal as a valuable tool for the functional assessment of auditory periphery.

In this chapter, we shall review first the main features of the different components of ECoChG potentials and their underlying generators, and then focus on crucial information related to the recording technique. In subsequent sections we will analyze the features of the ECoChG potentials recorded from the promontory of normally hearing individuals in response to different types of acoustic stimuli and address the changes induced in these responses by cochlear hearing loss. The main features of ECoChG potentials along with their clinical use will then be addressed for specific disorders such as Ménière disease and AN as well as for hearing dysfunction associated with neonatal illnesses.

GENERAL FEATURES OF ECoChG POTENTIALS

The ECoChG potentials evoked in response to acoustic stimuli result from the superimposition of three components, two originating from receptor elements, the CM and summing potential (SP), and the other, the compound action potential (CAP), arising from auditory nerve fibers (Eggermont, 1976). These components are intermingled in the recordings obtained in response to stimuli of a given polarity and, depending on the type and intensity of acoustic stimulation, cannot easily be distinguished from one another. The most popular method for separating CM from SP and CAP components is

*Deceased

FIGURE 12.1 Procedure utilized to separate the cochlear microphonic [CM] from the compound action potential [CAP] and summating potential [SP]. The **top panel** displays the responses to condensation [C, *gray line*] and rarefaction [R, *black line*] clicks recorded from the promontory wall in one normally hearing subject in response to high-level click stimuli (110 dB peSPL). In the **middle panel** the condensation and rarefaction waveforms have been averaged to attenuate CM thus revealing SP and CAP [C + R average]. The CM shown in the **lower panel** results from subtracting the [C + R] average from the ECoChG response to condensation clicks. [Reprinted with permission from Santarelli R, Starr A, Michalewski H, Arslan E. [2008] Neural and receptor cochlear potentials obtained by transtympanic electrocochleography in auditory neuropathy. *Clin Neurophysiol.* 119, 1028–1041.]

illustrated in Figure 12.1. The top panel displays the ECoChG waveforms recorded from the promontory wall in one subject with normal hearing in response to high-level click stimuli (110 dB peak equivalent SPL). Superimposed responses to condensation and rarefaction clicks show the phase-reversed CMs intermixed with negative in-phase SP and CAP. Since CM activity is related to the basilar membrane motion, the procedure of averaging the responses evoked separately by condensation and rarefaction stimuli is applied to extract the CAP together with the superimposed SP. This is shown in the middle panel where the condensation and rarefaction waveforms have been averaged to cancel the CM and reveal the SP and CAP components. The averaged curve is then subtracted from the response evoked by condensation (or rarefaction) stimuli to obtain the CM (lower panel).

CM is believed to originate mainly from the sum of the extracellular components of receptor potentials arising in IHCs and outer hair cells (OHCs), with the latter

contributing more to CM generation because of their greater number (Dallos and Cheatham, 1976). Taking into account the estimated length constant (the distance at which the voltage declines to 37% of its value as measured at the place of origin) of the extracellular potential decay along the cochlear partition, the CM recorded at the promontory is thought to arise chiefly in hair cells located in the basal portion of the cochlea. This has been confirmed by experimental data showing that the low-frequency microphonic measured at the round window in guinea pigs is dominated by contributions arising from the basal turn of the cochlea (Patuzzi et al., 1989). Recently, compared the CM and CAP tuning curves obtained for round window recordings in mice through a forward masking paradigm and found that whereas CAP responses are sharply tuned along the whole cochlear partition, CM potentials are tuned only at high frequencies. At these frequencies the rapidly changing phase prevents appreciable summation of extracellular potentials generated by transduction currents in hair cells. Therefore, the CM responses recorded at the round window are thought to result from the passive activation of cochlear receptors with little or no contribution from the active component related to the activity of the cochlear amplifier. These findings suggest that otoacoustic emissions (OAEs) and CM recordings cannot be considered equivalent in assessing the functional integrity of OHCs as they reflect different features of OHC activation, that is, an electric event correlated with the passive motion of the basilar membrane in the case of CM potentials and a mechanical event resulting from active contraction of OHCs for OAE responses.

Compared to CM, the origin of SP is much more controversial. In general, the SP is considered to be a gross reflection of the DC component of receptor potentials, which results from asymmetries in the hair cell transducer function. Because the SP recorded at the round window in chinchillas has been found to decrease in amplitude by over 50% after selective destruction of IHCs (Durrant et al., 1998), the main contribution to SP generation is believed to arise from activation of IHCs located in the basal cochlear turn.

One typical feature of the SP component is that its polarity is dependent upon several factors such as the frequency and intensity of acoustic stimulation, location of the recording electrode, and presence of a cochlear lesion. These polarity changes are believed to depend on the location from which the electrode “sees” the distortion component arising from IHC activation, but they could also reflect the differential contribution of OHCs and IHCs to SP generation. Durrant et al. (1998) have suggested that the residual SP recorded at the round window in chinchillas after selective destruction of IHCs results from the activation of apical OHCs. This is because the receptor potentials arising in OHCs located in the basal turn are symmetrical and cannot contribute to SP generation. In addition, it is generally

acknowledged that electrical activity arising from neural sources such as auditory nerve and cochlear nuclei also contributes to SP generation. Specifically, the abrupt negative potential preceding the CAP evoked by clicks or tone-burst stimuli is believed to arise only from hair cells; however, the baseline shift recorded during sustained tone-burst stimulation is thought to reflect the activation of both receptor and neural elements.

CAP results from the weighted sum of the extracellular components of the action potentials generated by individual auditory nerve fibers in response to acoustic stimulation. In the late 1950s Goldstein and Kiang (1958) hypothesized that CAP could be modeled mathematically as the convolution of the voltage contribution of individual nerve fibers (unit response) with the corresponding probability density function for unit discharges. Subsequently, Kiang et al. (1976) estimated the unit responses by triggering the averaged neural potentials recorded at the round window in cats in response to click stimulation with the spikes arising from individual fibers with different characteristic frequencies (CFs). Then, the contribution of single fibers to the CAP waveform was estimated by convoluting the averaged unit response with the corresponding poststimulus time histogram. The resulting waveforms were summed with appropriate weightings according to the number and distribution of CFs in the auditory nerve. The prediction curve closely resembled the CAP response recorded at the round window in response to click stimulation.

On the basis of these findings, Elberling (1976) modeled the response of the whole auditory nerve evoked by high-level click stimuli. Although click stimulation sets in motion the whole cochlear partition, the model predicts that only fibers with high CF contribute to the CAP. This is because the action potentials arising from fibers with low CF tend to disperse in time as the traveling wave progresses toward the apex of the cochlea thus resulting in a limited probability of summation (Figure 12.2). On the other hand, the number and type of neural fibers contributing to CAP in the basal portion of the cochlea depend on the intensity of click stimulation. Indeed, lowering stimulus level results in a reduced recruitment of high-threshold fibers showing high CF and short latency of activation. As a consequence, the main contribution to CAP generation at low intensity comes from fibers showing lower CF and longer activation latency.

Responses arising from far more restricted areas of the basilar membrane can be obtained by using tone-burst stimuli presented at low intensity (Eggermont, 1974). CAP tuning curves obtained for round window recordings in mice in response to tone-burst stimulation (Cheatham et al., 2011) proved to be very similar to the profiles of tuning curves of single nerve fibers tuned to the frequency of tone-burst stimulation. This means that the CAP recorded in response to tone-bursts appears to be sharply tuned at low intensity and tends to lack frequency selectivity at

FIGURE 12.2 Schematic diagram of the prediction of the compound action potential [CAP] evoked by click stimulation according to Elberling's model. Unit responses are shown in the **upper panel** spaced with increased latency corresponding to their position along the cochlear partition. The **lower panel** reports the calculated sum-response showing that only fibers with high characteristic frequency contribute to CAP generation. [Reprinted from Elberling C. [1976] Simulation of cochlear action potentials recorded from the ear canal in man. In: Ruben RJ, Elberling C, Salomon G, eds. *Electrocochleography*. Baltimore, MD: University Park Press; pp 151-168.]

high stimulus levels. This point is crucial when using CAP evoked by tone-burst stimuli for hearing threshold estimation since frequency selectivity of the CAP response is expected to be preserved only at low-to-moderate stimulus intensities.

RECORDING TECHNIQUES

Recording Site

There are several technical approaches for recording ECoChG potentials. In the transtympanic approach, a sterile stainless steel needle electrode, insulated except for the tip, is passed through the tympanic membrane and placed on the promontory wall with the aid of an operating microscope. This procedure requires general anesthesia in children and local anesthesia of the tympanic membrane in adults. It should be performed with the assistance of a physician. Nevertheless, the medical risk of piercing the eardrum is minimal. Another intratympanic technique used at some medical centers consists of placing a "golf-club" electrode in the round window niche after performing posterior myringotomy (Aso and Gibson, 1994). Both intratympanic procedures yield high amplitude potentials because the active electrode is close to the bioelectric generators of cochlear responses. Specifically, the "window-niche" approach is the most sensitive procedure and has the advantage of providing better estimation of residual hearing at low frequencies, thus providing useful information before cochlear implantation in children;

however, it is far more invasive compared to the transtympanic approach.

Several extratympanic techniques have been proposed for ECoChG recording. Usually, the active electrode is a ball-tipped electrode placed on the skin of the outer ear canal or on the eardrum. The potentials recorded from the eardrum are larger than those obtained with the electrode resting on the wall of the ear canal, but overall, amplitudes of the ECoChG responses recorded from extratympanic sites are far smaller compared to the intratympanic approach because of the greater distance of the active electrode from the cochlea and auditory nerve.

Differences between ECoChG recordings obtained from intratympanic and extratympanic sites are illustrated in the example given in Figure 12.3. ECoChG waveforms were collected from one child with cochlear hearing loss by simultaneously recording intratympanic and extratympanic potentials. The first were obtained through a transtympanic approach whereas the latter were recorded by

FIGURE 12.3 Simultaneous intratympanic and extratympanic recordings of ECoChG responses. ECoChG waveforms were collected from one child with cochlear hearing loss at decreasing stimulus levels by simultaneously recording from intratympanic [black line] and extratympanic [gray line] sites. CAP amplitudes proved to be far smaller in the extratympanic derivation with consequent overestimation of the amount of hearing loss. [Reprinted with permission from Santarelli R, Arslan E. [2013] Electrocochleography. In: Clesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

means of a ring electrode resting on the skin of the outer ear canal close to the annulus. It can be noticed that CAP amplitude is remarkably greater in the transtympanic derivation. As a consequence, in this particular case, relying on the extratympanic approach for hearing threshold assessment would have led to an overestimation of hearing loss of no less than 10 dB.

In general, the choice of the recording site depends on the purpose of ECoChG recordings. A highly sensitive approach is required when recording low-amplitude potentials, requested in hearing threshold assessment, or for evaluation of cochlear activities in patients with AN. In contrast, recording from extratympanic sites appears to be highly reliable for suprathreshold clinical application such as ECoChG recordings used for the diagnosis of Ménière disease. The extratympanic approach is probably the procedure of choice in this condition because of the obvious advantage of being noninvasive and independent of the medical setting. Nevertheless, the choice of both electrode site and position in this clinical application also depends on the experience of individual examiners in using a specific technique.

Stimuli

Clicks or tone-bursts are the most commonly used stimuli for evoking ECoChG potentials. When using the transtympanic approach, stimulation is usually performed in the free field. In our laboratory we use two high-frequency loudspeakers mounted on a single polyurethane horn (Santarelli et al., 2008). In such conditions the calibration of the stimulus should be very accurate and it is performed by means of a professional sound level meter with the microphone placed at the distance of the patient's ear from the horn. The procedure of comparing the peak-to-peak amplitude of the click to the peak-to-peak amplitude of a 2-kHz tone can be used to calibrate the click level (peak equivalent sound pressure level, peSPL). The maximum stimulus intensity for clicks used in our laboratory is 120 dB peSPL (corresponding to 90 dB nHL, as referred to the psychoacoustical threshold of normally hearing subjects) whereas tone-bursts are presented at the maximum intensity of 100 dB SPL.

In the extratympanic approach and in intratympanic ECoChG recordings with the electrode placed in the round window niche, acoustic stimulation is performed by using headphones or insert phones.

As mentioned above, stimulation with clicks is not frequency selective and mainly reflects the activation of the basal portion of cochlear partition, with the contribution of more basal regions varying with the intensity of stimulation. Tone-bursts are considered to be frequency selective, but the degree of frequency selectivity critically depends on the intensity of stimulation.

Another point to be considered when using tone-burst stimulation concerns the rise–fall time of stimuli. Short rise

time, while enhancing synchronization of neural activity by increasing the number of activated fibers, has a detrimental effect on frequency selectivity because of the progressive recruitment of units with high CF. This is a crucial point when using low-frequency tone-burst stimuli for hearing threshold estimation. In practice, preservation of both synchronization and frequency selectivity requires a trade-off between center frequency and rise time of tone-bursts. A rise time equaling two periods of the sine wave is accepted as a good compromise (Eggermont, 1976).

It is important to note that the choice of type and intensity of stimuli depends on the purpose of ECoChG recording. Although click presentation remains the most widely used stimulation, we shall see later in this chapter that tone-bursts or more complex stimuli resulting from the combination of different acoustic waveforms have been proposed for specific clinical applications or for evaluation of the electrical activity arising from apical portions of the cochlea.

Recording

Both amplification factor and number of averaged sweeps depend upon the amplitude of the potentials that are recorded. When using the transtympanic approach, an amplification factor of 50,000 is appropriate, whereas higher amplification factors could be required when recording from an extratympanic site.

The number of acquired samples for a single average, when using an intratympanic approach at high stimulation level, can be as low as 100 to 200. However, more samples are usually required at low intensity to reduce the amount of noise and to improve the clarity of the waveform. In our laboratory we use 500 samples for each stimulus polarity (condensation and rarefaction). More trials may be required (at least 1,000) when using an extratympanic approach, the number of averaged samples depending upon the specific electrode placement.

The bandwidth of filter settings should be kept as wide as possible (5 to 8,000 Hz). A high cutoff frequency is desirable to avoid distortion of rapid components as high-frequency noise can effectively be eliminated off-line by using digital filters. A low cutoff frequency is highly recommended for recording “slow” ECoChG potentials such as those obtained from patients with AN and for measuring SP amplitude during sustained tone-burst stimulation.

Signal Processing and CAP Extraction

As mentioned above, the procedure most used to cancel the CM and extract both SP and CAP components consists of averaging the responses evoked separately by condensation and rarefaction stimuli (Figure 12.1). This procedure assumes that the CMs evoked by stimuli of opposite

polarity are in exact counterphase. This may not always be the case for several reasons. First of all, asymmetry of CM potentials may occur in cochlear lesions. Moreover, acoustic stimulation, particularly when performed at high intensity in the free field, may lead to generation of reflection waves in the outer ear canal which impinge differently on the tympanic membrane when inverting the stimulus polarity. Most importantly, differences in CAP latency have been observed in response to condensation and rarefaction stimuli also in normally hearing ears. These differences have been found to be significantly greater in patients with endolymphatic hydrops. Therefore, a new algorithm has been developed based on the theory of optimal filtering, which estimates CAP and CM components in response to clicks of the same polarity without making any assumption regarding the shape of cochlear potentials (Sparacino et al., 2000). An example is reported in Figure 12.4 for ECoChG waveforms obtained from one normally hearing ear in response to 110 dB peSPL clicks. It can be seen that the use of the optimal filtering procedure

FIGURE 12.4 Analytical procedure based on the theory of optimal filtering to separate the cochlear microphonic [CM] from the compound action potential [CAP] and summing potential [SP]. The **top panel** displays the responses to condensation [C, *black line*] and rarefaction [R, *gray line*] clicks recorded from the promontory wall in one normally hearing subject in response to high-level click stimuli [110 dB peSPL]. The ECoChG waveform obtained by the procedure of averaging the traces to stimuli of opposite polarity is displayed in the **middle panel**. In the **lower panel** CAP and SP have been independently estimated in response to condensation or rarefaction stimuli by using the optimal filtering procedure. The use of this procedure reveals differences in CAP latency and SP amplitudes between stimuli of opposite polarity which would have been overlooked using the classical CM cancellation method.

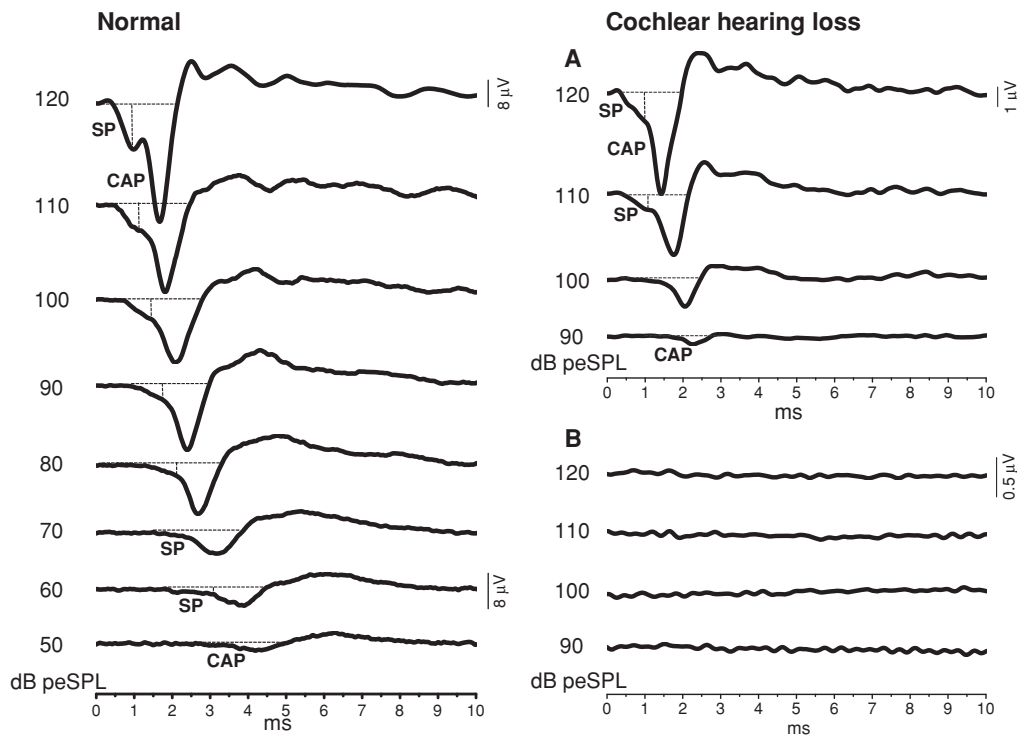

FIGURE 12.5 ECoChG potentials in response to clicks at decreasing stimulus intensities recorded from one normally hearing child (left panel) and two hearing-impaired children (right panel), one with moderate hearing loss (A) and the other showing profound deafness (B). In the subject with normal hearing, decreasing stimulus level results in gradual latency increase and amplitude reduction of both SP and CAP peaks. SP and CAP were recorded in moderate deafness with increased threshold and reduced amplitude compared to the normal control. In contrast, no ECoChG potentials were obtained from the child with profound deafness. SP and CAP labels are reported for the maximum level and for threshold intensity. Time 0 marks CM onset, the horizontal lines refer to baseline whereas dashed vertical lines mark the SP and CAP peaks in this and in the figures following.

reveals differences in CAP latency in response to clicks of opposite polarity. These differences would have been overlooked using the classical CM cancellation method. In addition, when using the optimal filtering algorithm in this particular example, different SP amplitudes are obtained in responses evoked by condensation and rarefaction clicks. In contrast, SP could not be identified in the waveform obtained through the classical method probably because the amplitude differences between the SP components in response to clicks of opposite polarity result in a smeared SP response in the averaged curve.

THE NORMAL ECoChG RESPONSE

After canceling the CM, ECoChG potentials consist of SP and CAP components. The shape, amplitude, and peak latency of these responses are dependent on both stimulus type and intensity. An example of ECoChG recordings obtained from a normally hearing child in response to 0.1 ms clicks at decreasing stimulation intensities is shown in Figure 12.5

(left panel). At 120 dB peSPL the ECoChG waveform begins with the receptor SP, which appears shortly after the onset of CM as an abrupt negative deflection preceding the CAP. Both SP peak amplitude and slope diminish as stimulus level is reduced. In this particular example, SP is still identifiable at an intensity as low as 60 dB peSPL (corresponding to 30 dB nHL).

CAP arises from SP as a negative peak whose latency is progressively delayed as signal intensity decreases. Decreasing stimulus level also results in CAP amplitude reduction whereas the duration is relatively constant at suprathreshold intensities and broadens at low stimulus level. In this particular example, CAP is identified as low as 50 dB peSPL, which corresponds to 20 dB nHL referred to the psychoacoustical threshold of normally hearing subjects.

Mean latency, amplitude, and duration of ECoChG potentials are plotted against stimulation intensity in Figure 12.6 for a large sample of normally hearing ears (36 ears from 23 children). Latency was calculated with respect to CM onset, whereas amplitude was measured with respect

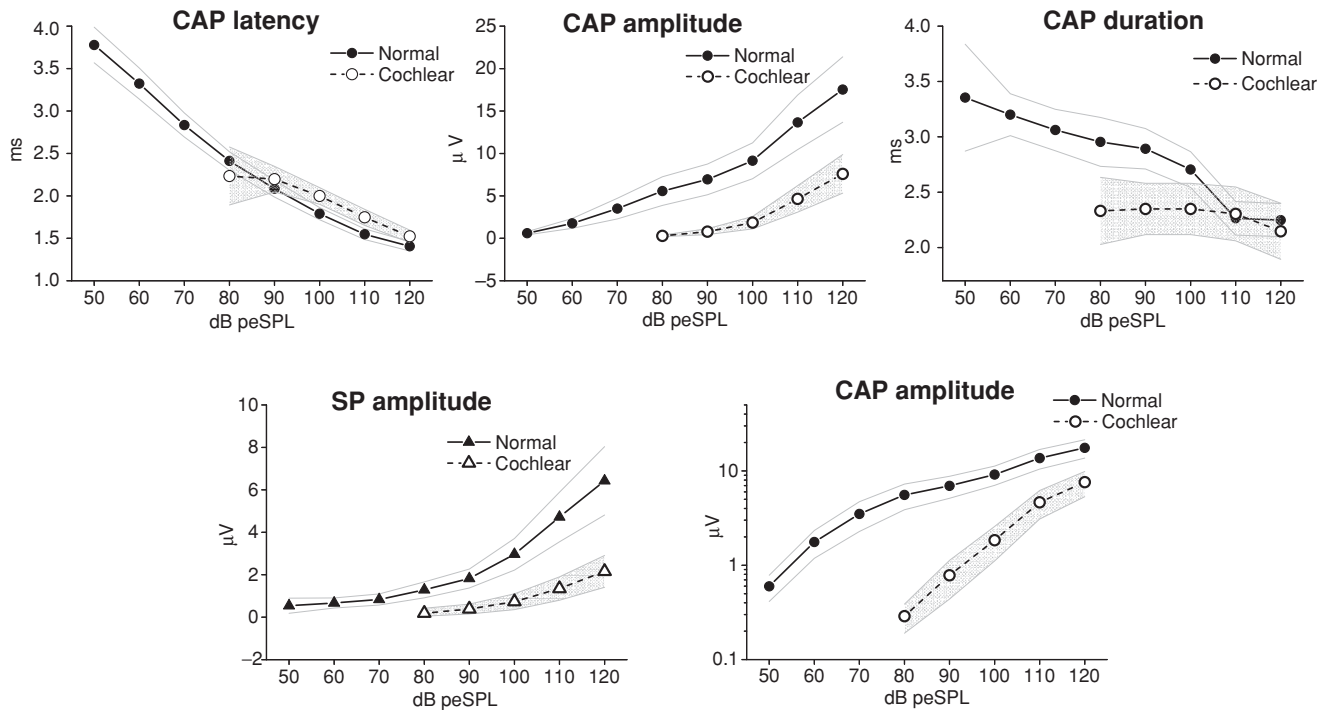

FIGURE 12.6 Intensity functions of CAP and SP potentials in normal hearing and cochlear hearing loss. Mean CAP latency, amplitude, and duration with 95% confidence limits [shaded area] are reported as a function of stimulus intensity for a group of normally hearing ears [36 ears from 23 children] and ears with cochlear hearing loss [19 ears from 23 children, CAP threshold from 80 to 100 dB peSPL]. Intensity curves calculated for SP amplitudes are reported in the **lower panel**. Both SP and CAP showed a reduced amplitude in cochlear hearing loss compared to normal hearing without differences in CAP latency. In the **lower panel**, CAP amplitudes have also been plotted on a logarithmic Y-scale to show the knee-point marking the activation of the cochlear amplifier at low intensity. In contrast, the amplitude-intensity function calculated for cochlear hearing loss shows an entirely linear behavior and an increased steepness reflecting the lack of cochlear amplifier. [Modified with permission from Santarelli R, Arslan E. [2013]. *Electrocochleography*. In: Celesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83-113.]

to prestimulus baseline. As in the example reported in Figure 12.5, decreasing stimulus level results in lengthening of CAP latency and decrease of CAP amplitude. Interestingly, the slope of the amplitude-intensity function is steep at high levels and becomes shallower at low intensities. The duration, which was measured from SP onset to CAP return to baseline, tends to increase at low intensities, but it is not longer than 3 to 4 ms at threshold (50 dB peSPL). The behavior of CAP intensity functions can be explained by taking into account the degree of synchronization of auditory nerve firing during the progression of the traveling wave along the cochlear partition. As mentioned above, at high intensities the most striking contribution to CAP recording during click stimulation arises from auditory fibers innervating the most basal portion of the cochlea. As a consequence, CAP shows a short latency, large amplitude, and short duration because of the synchronous firing of large numbers of high-CF units with high thresholds and short latencies of activation. Decreasing signal intensity induces firing of low-threshold fibers with lower CF and

delayed latency of activation because of the progression of the traveling wave along the cochlear partition. The discharge of these units appears to be more dispersed in time and has lower probability of summation compared to high-threshold fibers. As a result, when decreasing the stimulus level, CAP broadens and decreases in amplitude whereas peak latency increases. Nevertheless, the electrical activity arising from auditory fibers innervating the cochlear apex has little or no probability of summation (see Figure 12.2). In practice, the CAP elicited by clicks through a wide range of stimulus intensities mostly results from the activation of auditory fibers with CFs higher than 1 kHz.

CAP recordings obtained in response to tone-burst stimuli at low-to-moderate intensities are sharply tuned on the stimulus frequency. Figure 12.7 illustrates an example of the CAP intensity series obtained from a normally hearing ear (same ear as in Figure 12.5) in response to tone-burst stimuli at different frequencies. Mean CAP peak latency, amplitude, and duration calculated across 10 ears with normal hearing are also reported. Because at low stimulus

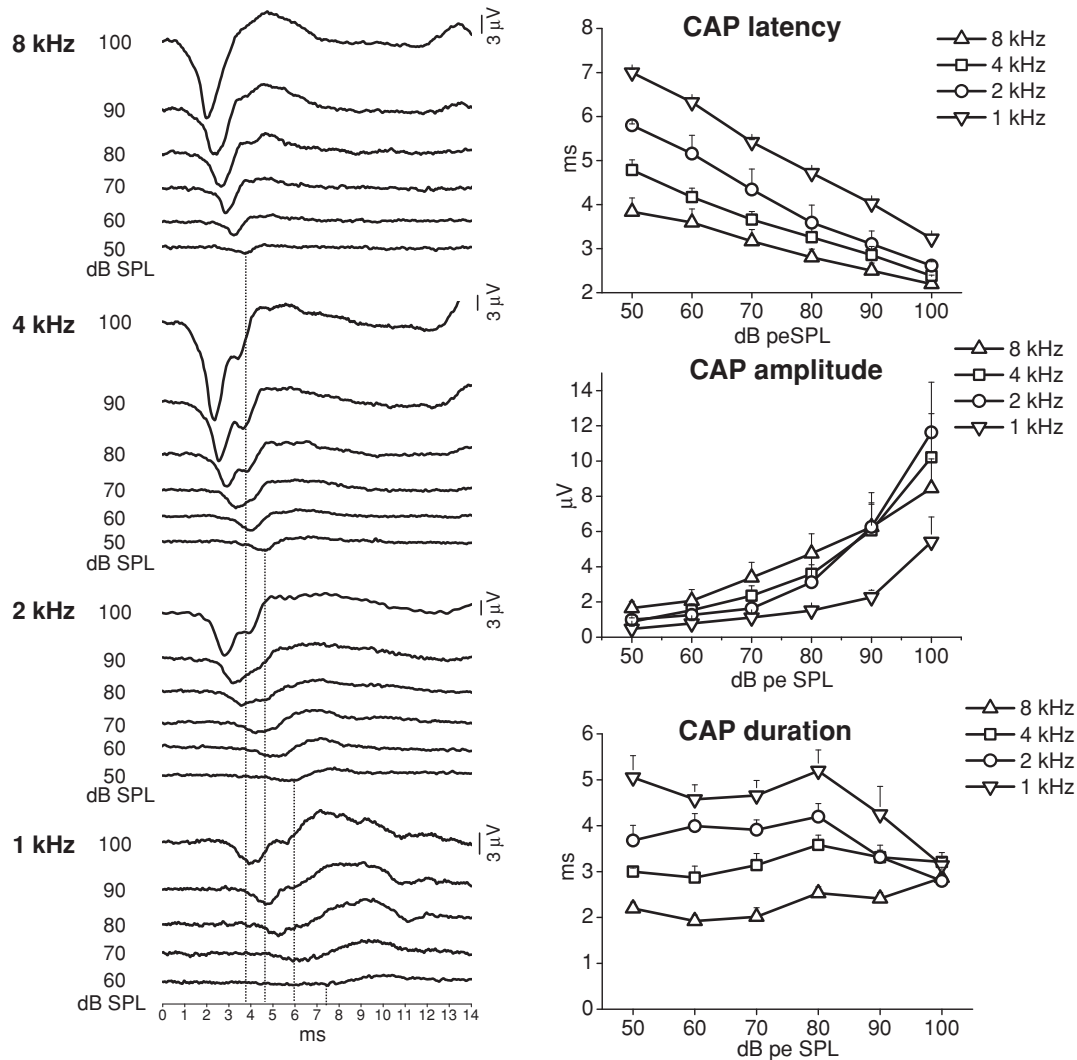

FIGURE 12.7 CAP recordings in response to tone-burst stimuli in ears with normal hearing. The **right panel** shows an example of CAP intensity series obtained from one normally hearing ear [same ear as in Figure 12.5] in response to tone-burst at frequencies of 8, 4, 2, and 1 kHz at decreasing stimulation intensity. Mean CAP peak latency, amplitude, and duration calculated across 10 ears with normal hearing are reported in the **right panel**. At low stimulus intensity, CAP latency and duration increase and amplitude decreases when lowering stimulation frequency reflecting the activation of more apical regions of the cochlear partition. These differences tend to disappear at high stimulus level because of the progressive recruitment of high-CF fibers. One bar indicates one standard error. [Reprinted with permission from Santarelli R, Arslan E. [2013] Electrocochleography. In: Ceesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

levels tone-burst stimulation results in selective activation of restricted regions of the cochlea, both CAP latency and duration tend to increase with decreasing stimulus frequencies. This reflects the activation of increasingly apical regions of the cochlear partition. These latency and duration changes at different frequencies tend to become smaller at high stimulus levels because of the activation of progressively larger cochlear regions biased toward the cochlear base. This behavior is cause for concern when using tone-

burst stimuli for the assessment of hearing threshold at specific tone frequencies.

ECoG POTENTIALS IN COCHLEAR HEARING LOSS

Cochlear lesions result in variable degrees of hearing impairment because of hair cell loss. Extensive damage is associated with severe-to-profound hearing loss with absent CAP at high

stimulation intensity, whereas lower degrees of hair cell loss result in variable amounts of CAP threshold elevation.

ECochG recordings obtained in response to click stimulation at decreasing stimulus levels from two children showing respectively moderate and profound hearing loss are reported on the right side in Figure 12.5. No CAP response can be identified at the maximum intensity (120 dB peSPL) in the child with profound deafness (Figure 12.5B). The subject with moderate hearing impairment (Figure 12.5A) shows both SP and CAP components with peak latencies within the normal range; however, CAP threshold appears to be increased and amplitude is markedly reduced compared to the normally hearing control.

Figure 12.6 reports the mean intensity functions obtained from 19 children with bilateral cochlear hearing loss showing CAP response in ECochG recordings (23 ears). These are superimposed on the corresponding functions calculated for ears with normal hearing. To limit heterogeneity, this sample included only children with isolated sensory/neural hearing loss and flat configuration of the audiometric profile as evaluated by behavioral audiometry in the years following ECochG recording. Moreover, etiology of the hearing disorder was genetic in almost all cases. Further criterion for selection was that CAP threshold fell between 80 and 100 dB peSPL to limit the variability of the CAP parameters related to the extension of cochlear damage. Looking at the mean intensity functions calculated for this sample of children, both SP and CAP amplitudes proved to be significantly smaller compared to normally hearing ears. These differences are likely to reflect the decrease in hair cell number, which results in a global reduction of auditory nerve fiber activation. CAP latencies appear to be within normal limits, whereas CAP duration is close to normal values at high levels and deviates from the normal behavior at low intensities as no response prolongation was found when lowering the stimulus level. The absence of remarkable differences in both CAP latency and durations between normal and hearing-impaired ears at high stimulus intensity reflects the preservation of fibers with high threshold and short latency of activation. Shortening of CAP duration at low stimulus levels is likely to result from the loss of low-threshold neural fibers with longer latency of activation. Nevertheless, both CAP latency and duration in response to clicks depend on the audiometric profile as differences in hearing threshold at different frequencies are the major determinant of nerve fiber recruitment along the cochlear partition.

In Figure 12.6 CAP amplitude–intensity curves are also plotted on a logarithmic Y-scale. The knee-point in the intensity function calculated for normal ears marks the transition from the steep to the shallow portion of the curve, which refers to the activation of the cochlear amplifier at low stimulus intensities. In contrast, the amplitude–intensity function calculated for cochlear hearing loss shows an entirely linear behavior associated with an increased steep-

ness of the curve compared to normal hearing. Conceivably, the linearity of amplitude–intensity function in cochlear hearing loss results from the lack of cochlear amplifier with consequent reduction of the compressive behavior found in normal hearing.

The use of ECochG recordings in estimating hearing threshold in uncooperative children relies on the correlation between audiometric and CAP thresholds. Although the stimuli used in behavioral and electrophysiological evaluation differ in both duration and frequency, a close correlation between CAP and audiometric thresholds has been found in several studies performed in both adults and children (Aran et al., 1971; Eggermont, 1976). The most reliable measures were obtained in adults and in children who were able to perform conventional audiometry (Parving et al., 1981). Specifically, when using click stimuli, the best correlation between CAP and behavioral thresholds was found at audiometric frequencies of 1, 2, and 4 kHz with correlation coefficients in the order of 0.8 and slopes of the regression line close to 1. The correlation improves when using tone-burst stimuli in the middle frequency range, whereas at 0.5 kHz the slope of the regression lines deviates considerably from 1 (Eggermont, 1976). Recently, to obtain a functional evaluation of the most apical regions of the cochlea, a promising technique has been proposed based on the use of chirps (Chertoff et al., 2010). These are transient stimuli in which the high frequencies have been delayed to compensate for the time-shift between high- and low-frequency regions of the cochlea, thus enhancing the discharge synchronization of the neural fibers innervating the apical regions. Compared to the CAP elicited by classical clicks, the neural responses evoked by chirps show higher amplitudes and reduced slope of the latency–intensity function possibly as a result of a greater contribution to neural activation from the low-frequency portions of the cochlea.

Besides providing a certain degree of frequency selectivity in threshold estimation, the use of tone-bursts in cochlear hearing loss may complement the stimulation with clicks also to provide additional information that proves to be extremely useful when planning the rehabilitative strategy. Figure 12.8 illustrates the ECochG waveforms recorded in response to clicks and tone-burst stimuli from a child with cochlear hearing loss because of biallelic mutation in the *GJB2* gene. CAP was absent in the left ear in response to click stimulation whereas it was recorded from the right ear with 105-dB peSPL threshold. The behavior of intensity functions was suggestive of a cochlear lesion. In the ECochG waveforms in response to tone-burst stimuli presented at the maximum intensity of 100 dB SPL, CAP was identified only at frequencies of 1 and 2 kHz, whereas no response was recorded at higher frequencies. Sound-field audiometry performed 2 years later indicated 70- to 75-dB hearing threshold from 1 to 4 kHz, thus failing to reveal any difference between middle and high frequencies. Interestingly,

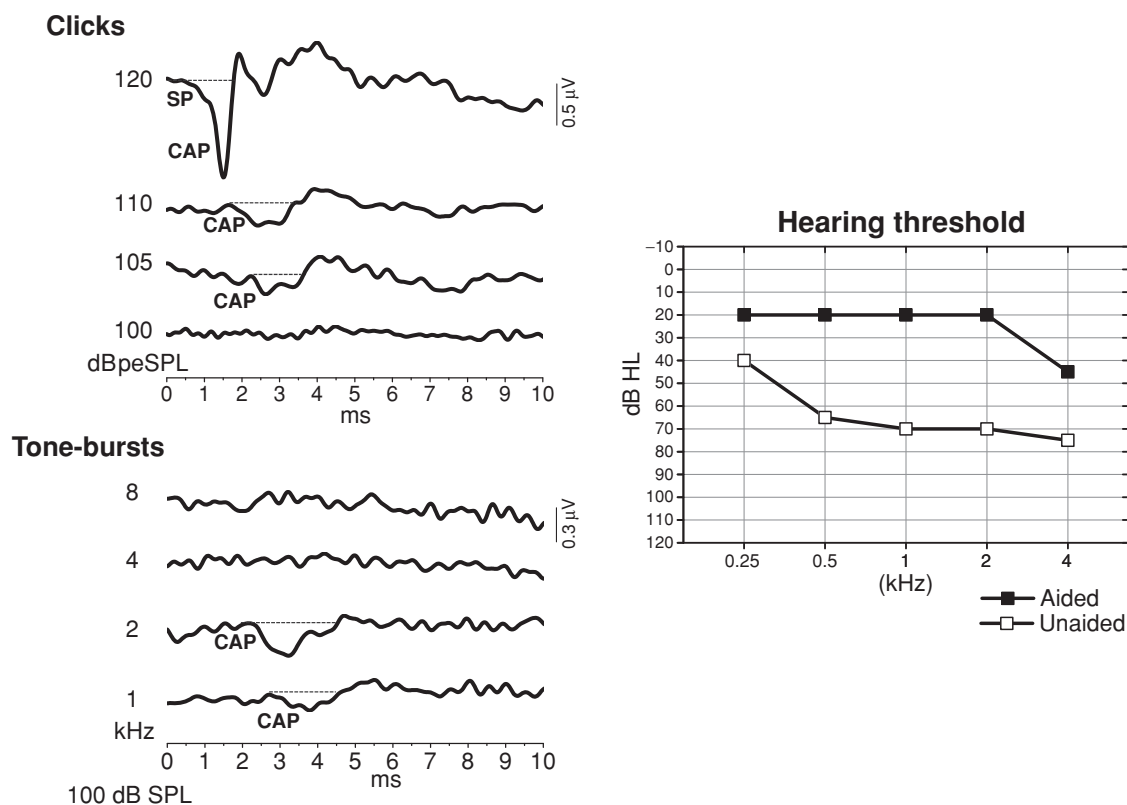

FIGURE 12.8 ECoChG responses and audiometric thresholds from one child with cochlear hearing loss because of biallelic mutation in the *GJB2* gene. ECoChG potentials to clicks and tone-burst stimuli at decreasing stimulus intensity are displayed in the **left panel**. CAP threshold in response to clicks was 105 dB peSPL [corresponding to 75 dB nHL] whereas CAP responses were elicited only at 0.1 and 2 kHz during tone-burst stimulation with 100-dB SPL threshold. Sound-field audiometry including both unaided and aided thresholds for warble-tones at different frequencies is reported on the **right panel**. The low functional gain found at 4 kHz was in accordance with ECoChG responses to tone-burst stimulation thus indicating a predominant involvement of high frequencies by the cochlear damage.

looking at the aided thresholds obtained after achieving the best hearing aid fitting, the functional gain measured at 4 kHz proved to be smaller compared to lower frequencies. This result taken together with the electrophysiological findings suggests cochlear damage primarily involving the high-frequency regions of the cochlea. This information could be valuable for refining hearing aid fitting and could assist in setting the parameters of the frequency transposition algorithm.

Increasing hair cell loss results in extensive cochlear damage with absence of CAP in profound deafness. In contrast, CM potentials are always recorded in ECoChG waveforms obtained from hearing-impaired subjects whatever the degree of hearing loss and are believed to result from the activation of residual hair cells (Schoonhoven et al., 1999). Figure 12.9 shows an example of CM recordings obtained in response to click stimuli at decreasing stimulus intensities from two hearing-impaired ears showing elevated CAP threshold (90 dB peSPL) and absence of CAP, respectively. CM waveforms recorded from one ear with normal

hearing are also shown. It can be seen that CM is clearly identifiable in both hearing-impaired subjects, although with smaller amplitudes compared to the normal control. Specifically, when comparing CM amplitudes in ears with normal hearing with those obtained from ears with cochlear hearing loss, they proved significantly smaller in hearing-impaired children compared to normal subjects; however, no differences were found between ears with elevated CAP thresholds (same samples as in Figure 12.6) and ears with absence of CAP (32 children, 64 ears). On the basis of these findings it is conceivable that the absence of CMs in surface recordings such as ABRs may be related to the low sensitivity of this technique in detecting low-amplitude CM potentials occurring in ears with extensive cochlear damage. By the same token, the detection of CM in surface recordings does not invariably indicate normal CM and preservation of OHC function. This point is relevant in the diagnosis of AN.

Children showing no CAP in ECoChG recordings in response to clicks, who have been followed up at our hospital,

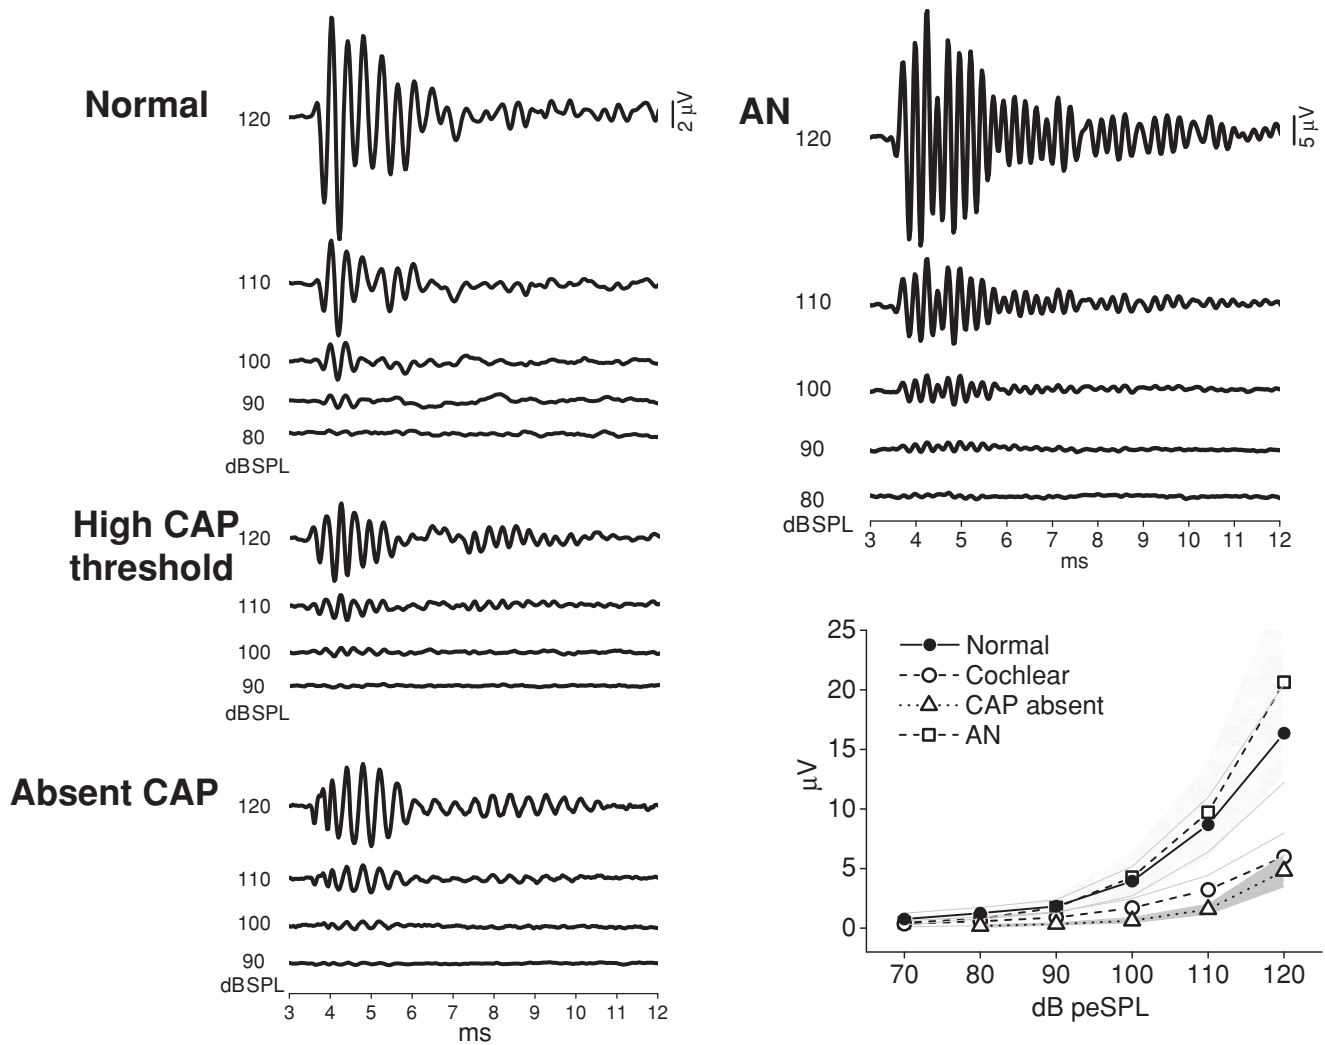

FIGURE 12.9 Cochlear microphonics [CMs] recorded in response to click stimuli at decreasing stimulus intensities from normally hearing individuals, children with cochlear hearing loss, and patients showing the clinical picture of auditory neuropathy [AN]. Examples of recordings from one normally hearing and two hearing-impaired ears, one with elevated CAP threshold [90 dB peSPL] and the other with absent CAP, are shown on the **left side** whereas CMs waveforms recorded from one patient with AN are displayed in the **upper right corner**. Mean amplitudes plotted against stimulus intensity for corresponding groups of subjects are reported on the **right side**. CM potentials are clearly identifiable in both hearing-impaired ears with smaller amplitudes compared to the normal control. In contrast, CM amplitudes obtained in the AN subjects were within control values. [Modified with permission from Santarelli R, Arslan E. [2013] *Electrocochleography*. In: Celesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

turned out to have profound hearing loss with preservation of some residual hearing at low frequencies as evaluated by behavioral audiometry. This is shown in Figure 12.10 for a group of 68 children. Although indicating a remarkable improvement of puretone sensitivity with hearing aid use, aided thresholds appeared to be beyond the range of conversational speech. On the basis of these findings and taking into account the development of speech perception and language skills, 62 children out of 68 underwent cochlear implantation. The remaining six patients, although included in the candidacy protocol for cochlear

implantation, continued to use hearing aids because their parents refused surgery. These findings are relevant in that they suggest that absence of CAP in ECoChG potentials in response to high-intensity clicks invariably indicates profound deafness associated with inadequate hearing aid benefit. This information is valuable particularly for rehabilitation planning in uncooperative children for whom the benefits of hearing aid use is difficult to assess because of the reduced ability to perform at behavioral audiometry and speech perception tests. Thus, including ECoChG recordings in the assessment protocol for cochlear

FIGURE 12.10 Means of unaided (*open squares*) and aided (*filled squares*) hearing thresholds with 95% confidence limits (*shadowed area*) from 68 children showing no CAP to click stimulation at high stimulus intensity (120 dB peSPL). All children were fitted with power hearing aids. The *shadowed rectangle* indicates the intensity range calculated for conversational speech. Mean aided thresholds appear to fall beyond the range of conversational speech. [Reprinted with permission from Santarelli R, Arslan E. [2013] *Electrocochleography*. implantation would help in the timely choice of the best rehabilitative strategy.

ECoG RECORDINGS IN MÉNIÈRE DISEASE

The diagnosis of Ménière disease mainly relies on clinical symptoms and thus may be difficult to make, particularly at an early stage. In the 1970s, the finding of increased SP amplitude in ECoG waveforms recorded from patients with Ménière disease was considered as a possible objective hallmark of the disorder (Eggermont, 1976). Since then, several studies have reported that SP amplitude is significantly increased in Ménière disease compared to individuals with normal hearing and hearing-impaired subjects with comparable amount of hearing loss (Mori et al., 1987).

Studies performed on the temporal bones of deceased patients have shown that endolymphatic hydrops is the primary histologic hallmark of the disorder. The increase in endolymph volume is likely to result in an increased pressure in the scala media leading in turn to changes in the electrical properties of hair cells. As a consequence, the receptor potential becomes distorted because of an increase of the DC component, which results in a large SP response. This hypothesis is corroborated by several experimental studies performed in guinea pigs, documenting that changes

in SP amplitude could be induced by modifying the resting position of the basilar membrane by means of different techniques such as the association of a continuous low-frequency tone during tone-burst stimulation or the perfusion of perilymphatic spaces with hypotonic solutions.

Unfortunately, in spite of the significant differences in SP amplitude between patients with Ménière disease and subjects with normal hearing or affected by cochlear hearing loss, there is considerable overlap between groups so that the sensitivity of SP amplitude in diagnosing the disorder appears to be no greater than 30% (Mori et al., 1987). Possible underlying reasons are the high variability of SP amplitude in both normal and hearing-impaired subjects and the variable amount of SP attenuation in cochlear hearing impairment resulting from different degrees of hair cell loss. Therefore, the SP enhancement induced by the endolymphatic hydrops may be masked by the amplitude reduction resulting from hair cell loss particularly in the presence of a high degree of hearing impairment. For these reasons, SP amplitude has been replaced by the measure of SP/CAP ratio with improved sensitivity of up to 60% (Coats, 1981; Mori et al., 1987; Orchik et al., 1993; Pou et al., 1996; Sass, 1998). Currently, SP/CAP ratio is the most popular measure performed on ECoG recordings in Ménière disease because it is reliable and easy to obtain. In the majority of studies, ECoG recordings have been obtained in response to high-intensity clicks (90 dB nHL) by using an extratympanic approach. According to the results of these studies, an SP/CAP ratio higher than 0.3 to 0.4 is considered as highly suggestive of endolymphatic hydrops in humans.

Besides changes in SP amplitude, a prolonged duration of ECoG responses has been observed in the ECoG waveforms recorded from patients with Ménière disease (Eggermont, 1976). The increase in duration of ECoG potentials has been attributed to alterations in timing of hair cell activation leading in turn to prolongation of SP potentials. Alternatively, degeneration of terminal dendrites of auditory nerve fibers may lead to abnormal postsynaptic potentials which superimpose on the synchronized neural response (CAP). Examples of ECoG potentials recorded from patients with Ménière disease in response to 120 dB SPL (90 dB nHL) clicks are displayed in Figure 12.11 for two patients showing normal hearing threshold in one ear and moderate hearing loss in the other ear with a puretone average (PTA) (0.5, 1, 2, and 4 kHz) threshold of 30 and 45 dB HL, respectively. These recordings are compared to ECoG waveforms recorded from one normally hearing subject and from one patient with cochlear hearing loss with a PTA of 45 dB HL. In these subjects, SP/CAP ratio was 0.15 to 0.2 whereas the response duration was around 2 ms. In contrast, patients with Ménière disease showed SP/CAP ratios higher than 0.4 whereas the response duration was considerably prolonged with respect to both normal and hearing-impaired subjects.

FIGURE 12.11 ECoChG recordings in response to 120-dB peSPL clicks from one normally hearing individual, one patient with sensory/neural hearing loss, and two subjects with Ménière disease. Compared to the subjects with normal hearing or with sensory/neural hearing loss, patients with Ménière disease showed increased SP/CAP ratio, delayed CAP peak latencies, and prolonged waveform durations. [Modified with permission from Santarelli R, Arslan E. [2013] *Electrocochleography*. In: Celesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

To improve the sensitivity of ECoChG recordings in detecting endolymphatic hydrops, further measures have been suggested in addition to the SP/CAP ratio. Ferraro and Tibbils (1999) proposed that when using tone-burst stimulation, response duration could be taken into account by calculating an index resulting from the ratio of the area subtended by the total ECoChG waveform to the area subtended by the CAP component below the SP. However, it is unclear whether the inclusion of this measure in the clinical protocol of the diagnosis of Ménière disease provides a substantial advantage compared to the evaluation of the SP/CAP index alone.

Another interesting measure suggested in addition to SP/CAP ratio is the latency difference between the CAP responses evoked by stimuli of opposite polarity (Orchik et al., 1998; Sass et al., 1998). This difference is significantly increased in patients with endolymphatic hydrops possibly as a result of the asymmetry in dynamics of the basilar membrane motion because of increased endolymph volume. It has been estimated that measuring this index in combination with the SP/CAP ratio results in an increase of sensitivity of up to 87%. In this regard, the above-mentioned procedure of optimal filtering could prove very useful for performing the cancellation of CM while preserving the shape of both SP and CAP components for a given stimulus polarity.

A further promising technique relies on reduced modulation of SP amplitude induced by the presentation of a

continuous tone in combination with tone-burst stimuli at a frequency of 1 kHz (Iseli and Gibson, 2010). In this stimulation paradigm the increased tension of the basilar membrane because of the endolymphatic hydrops decreases the bias induced by tone presentation which is usually found in ears with normal hearing. This measure has proved to be more sensitive in detecting endolymphatic hydrops compared to the classical SP/CAP index. Sensitivity improves by up to 95% when using this index in combination with the absolute SP amplitude measured on ECoChG responses evoked by tone-burst stimulation.

One of the main drawbacks of the measures proposed as alternative to, or in combination with, SP/CAP ratio is that these procedures are not easily performed. Therefore, the measure of SP/CAP index in response to high-intensity clicks remains the most popular index used to support the diagnosis of Ménière disease because of the high level of specificity, simplicity in stimulus generation, and reliability in identification of both SP and CAP.

ECoChG POTENTIALS IN AUDITORY NEUROPATHY

AN is a hearing disorder characterized by disruption of temporal coding of acoustic signals in auditory nerve fibers resulting in impairment of auditory perceptions relying on temporal cues (Starr et al., 2008). In the healthy cochlea,

dynamics of activation of both postsynaptic membrane and auditory nerve fibers are well suited for fast and precise signal transmission. At the presynaptic level, temporal precision of acoustic signaling is guaranteed by the fast kinetics of synaptic release, which is triggered by calcium influx through one or two calcium channels, tight coupling of these channels to the vesicle release sites, and parallel release of multiple vesicles through the ribbon synapses. High rates of glutamate release lead in turn to the generation of excitatory postsynaptic potentials (EPSPs) which trigger spike initiation in the auditory nerve fibers through the activation of AMPA receptors. The latter have low affinity for glutamate, which results in quick times of activation and deactivation of postsynaptic membrane thus ensuring preservation of nerve fiber sensitivity in spite of the high amounts of neurotransmitter released in the synaptic cleft. At the level of auditory nerve, both the velocity and precision of spike initiation and propagation are guaranteed by the abundance of Nav1.6 channels and their strategic disposition along the nerve fibers.

The disruption of any one of these mechanisms impairs the precision of temporal coding of acoustic signals. For example, at the presynaptic level, impairment of multivesicular release results in reduction of neurotransmitter availability at the synaptic cleft with generation of small EPSPs with abnormal morphology and dispersed in time. At the postsynaptic level, decrease in the number of auditory nerve fibers and demyelination of spared axons result in a reduction of auditory input directed to the central nervous system and slowed conduction velocity in residual fibers. In both presynaptic and postsynaptic disorders abnormal synchrony of auditory nerve activity underlies the profound alterations of ABRs and impairment of speech perception, both occurring in the presence of normal physiological measures of OHC activities (OAEs and CM). With regard to CM amplitudes, they proved to be within normal limits in patients with AN (Santarelli et al., 2006a). Indeed, mean CM amplitudes calculated for a sample of 11 AN patients with several etiologies (Figure 12.9), albeit showing a high degree of variability, proved to be not significantly different from the corresponding values obtained for normal controls.

Alterations of auditory nerve synchrony may result from genetic disorders or from a wide range of other etiologies (infectious, toxic-metabolic, immunologic) (Santarelli et al., 2006b). However, definite etiologic factors can be identified in about half of patients with AN (Starr et al., 2008). Because of the high variability of etiologic factors and related pathophysiological mechanisms, the term “auditory neuropathies” would be more appropriate (Santarelli et al., 2013). The most well-known forms of AN are the result of genetic diseases and may present as isolated hearing disorders or associated with multisystem involvement (Santarelli, 2010). In general, the majority of isolated AN forms are associated with presynaptic mechanisms, whereas AN disorders with mul-

tisystem involvement are invariably subtended by postsynaptic mechanisms and are most commonly associated with peripheral and optic neuropathies.

Among the AN forms unrelated to genetic etiology, the most frequently observed are those possibly affecting children discharged from the neonatal intensive care unit (NICU). It has been estimated that about 5.6% of children failing newborn hearing screening show abnormal ABRs and presence of OAEs consistent with the electrophysiological profile of AN, the majority being discharged from the NICU. Moreover, postmortem examination carried out on temporal bones of deceased neonates has revealed selective IHC loss with high frequency in premature infants compared to full-term babies. On the basis of this finding IHC loss was suggested as a hallmark of AN (Amatuzzi et al., 2011).

In the last decade, the use of ECoChG recording has been gaining importance in the diagnosis of AN for it makes it possible to define the details of both receptor and neural responses in the various forms of the disorder (McMahon et al., 2008; Santarelli and Arslan, 2002; Santarelli et al., 2008). Such information may prove extremely valuable in defining objectively the site of auditory neural dysfunction and to shed light on the underlying pathophysiological mechanisms to plan appropriate rehabilitative strategy.

Several ECoChG patterns have been identified in response to click stimuli (Santarelli et al., 2008, 2013). In general, IHCs lesions are expected to result primarily in SP abnormalities whereas disorders affecting ribbon synapsis and auditory nerve fibers would induce changes of CAP parameters and morphology with preservation of SP amplitude and latency. Nevertheless, it should be noted that different ECoChG patterns can be intermixed because of the possible coexistence of pre- and postsynaptic lesions in some forms of AN particularly at an advanced stage.

In one of the most frequently observed ECoChG patterns the response consists of a prolonged negative deflection showing no separation between SP and CAP components. Figure 12.12 (left side) shows an example of ECoChG responses recorded in AN at decreasing stimulus levels superimposed on the corresponding traces obtained from one normally hearing control. These recordings were obtained from one adult patient with isolated AN of unknown etiology which had started in adolescence. It can be seen that the SP–CAP complex recorded in the normal control was replaced in the AN patient by a negative potential which appeared to be markedly attenuated in amplitude, increased in duration, and delayed in peak latency.

A second pattern frequently observed in AN consists of the receptor SP potential with normal amplitude and peak latency followed by the sustained negative response. In some subjects a small CAP with delayed peak latency is superimposed on the prolonged potential at high stimulus levels. An example is shown on the right side of Figure 12.12 for an 11-year-old boy presenting with a familiar form of isolated

FIGURE 12.12 ECoChG responses from two patients with auditory neuropathy [AN]. ECoChG waveforms recorded from two representative subjects with AN [gray line] are reported for decreasing stimulus levels superimposed on the corresponding traces obtained from one normally hearing ear [black line]. In the example illustrated in the **left panel** ECoChG potentials found in the normal control are replaced by an attenuated prolonged negative response showing no separation between SP and CAP components. ECoChG recordings from the second patient [**right panel**] showed that the receptor SP is followed by a sustained negative potential with a superimposing small CAP at high stimulus intensity.

AN of unknown etiology. This ECoChG pattern showing preservation of SP followed by the prolonged potential is highly suggestive of a peripheral disorder associated with preservation of IHC activation.

A less frequently observed ECoChG pattern consists of only the SP component not followed by the prolonged activity. This may indicate preservation of IHC function not followed by nerve fiber activation.

To compare the ECoChG responses recorded from AN patients with normal healthy controls, the whole ECoChG response was considered as a single event (SP–CAP) because SP and CAP cannot be identified separately in about half of AN patients (Santarelli and Arslan, 2013; Santarelli et al., 2008). Mean measures of SP–CAP peak latency, amplitude, and duration calculated for a sample of 11 AN patients with several etiologies are reported as a function of stimulus intensity in Figure 12.13 and superimposed on the corresponding values calculated for normally hearing subjects. Compared to subjects with normal hearing, SP–CAP potentials recorded from patients with AN appear significantly decreased in amplitude, delayed in peak latency, and increased in duration.

One problem arising with the prolonged potentials recorded in AN patients is whether they originate from neural or receptor activation. With this in mind, we used an adaptation procedure that preferentially attenuates the neural responses with minor changes in SP amplitude (Santarelli and Arslan, 2013; Santarelli et al., 2008, 2013).

What happens in ears with normal hearing is that decreasing the time interval between successive stimuli results in attenuation of CAP amplitude. These changes are likely to result from the complex interaction of several phenomena such as velocity of neurotransmitter release and reuptake, sensitivity of postsynaptic receptors, and refractory properties of auditory nerve fibers, with all of these factors interacting in a complex way and contributing differently to adaptation when changing stimulus level and repetition rate. When using trains of clicks presented at an intensity higher than 60 dB nHL, CAP amplitude progressively decreases for interstimulus intervals lower than 500 ms, the amount of CAP attenuation being independent of signal intensity. One example of ECoChG potentials recorded at an intensity of 110 dB peSPL from one normally hearing ear is reported in Figure 12.14. The stimulus sequence

FIGURE 12.13 Intensity functions of CAP and SP potentials in patients with auditory neuropathy [AN]. Mean SP-CAP latency, amplitude, and duration with 95% confidence limits (*shadowed area*) are reported as a function of stimulus intensity for a group of patients with AN [11 subjects] superimposed on the corresponding values calculated for normally hearing controls [same sample as in Figure 12.6]. Since in the majority of AN patients SP and CAP could not be identified separately, the whole ECoChG response was considered as a single event [SP-CAP]. Compared to subjects with normal hearing, ECoChG potentials recorded from patients with AN were significantly decreased in amplitude, delayed in peak latency, and increased in duration. [Modified with permission from Santarelli R, Arslan E. (2013) *Electrocochleography*. In: Clesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

FIGURE 12.14 Adaptation of cochlear potentials. ECoChG recordings obtained at 110 dB peSPL in response to the stimulus sequence reported at the *bottom* are displayed in the **left panel** for one normally hearing child and three AN subjects, one boy affected by a familiar form of AN of unknown etiology, and two children with one carrying biallelic mutation in the *OTOF* gene and the other showing hearing impairment related to a rocky neonatal course. In the **right panel** the means and standard errors of normalized SP-CAP amplitudes at 110 dB peSPL are reported as a function of click position in the stimulus sequence for controls and three groups of patients, one group of young adults with AN related to different etiologies [11 patients], children carrying biallelic mutation in the *OTOF* gene [8 patients], and hearing-impaired children discharged from the NICU [10 patients]. In the normally hearing controls, CAP amplitude was markedly attenuated after adaptation whereas SP attenuation was much lower. In patients with AN, SP-CAP amplitudes were markedly reduced after adaptation and the amount of response attenuation was comparable with that calculated for CAP in normally hearing controls. [Modified from Santarelli R, Del Castillo I, Starr A. (2013) *Auditory neuropathies and electrocochleography*. *Hear, Balance Commun.* 11, 130–137.]

consists of an initial click which is followed 15 ms later by a train of 10 clicks separated by an interstimulus interval of 2.9 ms. This sequence was repeated every 191 ms. The duration of the intertrain interval is likely to affect minimally the amplitude of ECochG potentials evoked by the first click of the stimulus sequence. It can be seen that CAP amplitude shows a marked attenuation from the first (1 in Figure 12.14) to the second (2 in Figure 12.14) click of the stimulus sequence, which corresponds to the first click of the high-rate train (ISI 15 ms). Then, further decrease in CAP amplitude is observed during the following 3 to 4 clicks of the train sequence because of further increase of stimulus repetition rate (ISI 2.9 ms). In contrast, SP amplitudes show little or no attenuation from the first to the eleventh click of the stimulus sequence. In this particular example, the amount of attenuation was 50% and 22% for CAP and SP components, respectively. Looking at the means of CAP and SP amplitudes in Figure 12.14, calculated for a group of normally hearing children (same sample as in Figure 12.4), it appears that CAP amplitude drops by about 30% from the first to the second click and shows an additional attenuation within the following 2 to 3 clicks thus attaining a reduction of 60% by the end of the stimulus sequence. The amount of mean SP attenuation is much smaller compared to CAP as the decrease in amplitude from the first to the last click of the sequence reaches 30%.

Examples of ECochG recordings obtained from AN patients in response to high stimulation rate are compared in Figure 12.14 to the responses collected from normal controls. The upper ECochG waveform refers to one boy affected by a familiar form of AN of unknown etiology. ECochG potentials showed no separation between SP and CAP components and were considerably prolonged in duration compared to the normal response. Stimulation at high rate induced a remarkable attenuation of the whole SP–CAP potential with an overall amplitude reduction of 52%. Mean attenuation amplitudes calculated across 11 AN patients (same sample as in Figure 12.13) proved to be comparable to the corresponding values calculated for normal controls. Therefore, the prolonged responses recorded from patients with AN are likely to reflect the activation of auditory nerve fibers. Broadening and attenuation of ECochG potentials reflect impairment of neural fiber synchrony with reduced probability of summation of unitary activities. Thus, the disruption in synchrony may be related to abnormal IHC activation in those AN forms associated with abnormal SP or result from a reduced number of auditory neurons and alteration of conduction velocity in spared auditory fibers when the prolonged potentials follow a normal SP. A lesion selectively involving the terminal unmyelinated portion of auditory nerve fibers has been hypothesized for AN patients affected by optic atrophy because of a mutation in the *OPA1* gene (Huang et al., 2009).

In conclusion, information provided by ECochG recordings are relevant in that they help to identify the

lesion site by distinguishing the AN disorders involving IHCs from neural disorders associated with normal SP responses. This information may be of value in predicting the outcome of cochlear implantation since a good outcome is expected in cochlear implant recipients affected by AN disorders involving IHCs, whereas the benefits of cochlear implantation in patients showing neural forms of AN are critically dependent on number and function of spared auditory neurons.

One of the most well-known forms of congenital AN is due to mutations in the *OTOF* gene (DFNB9) with a recessive pattern of inheritance. The *OTOF* gene encodes otoferlin, a transmembrane protein belonging to the ferlin protein family, which plays a crucial role in fast vesicle release at the synapse between IHCs and auditory nerve fibers. It has also been implicated in vesicle replenishment at the synaptic pole of IHCs. To date, more than 50 pathogenic mutations of the *OTOF* gene have been identified, the majority of which are inactivating mutations, which result in a very homogeneous phenotype of profound hearing loss. Over 50% of children carrying biallelic mutations in the *OTOF* gene show preservation of OHC function as indicated by OAE recording, together with absent or high-threshold ABRs.

Examples of ECochG waveforms recorded from five children carrying biallelic mutations in the *OTOF* gene are displayed in Figure 12.15 for 120 dB peSPL intensity superimposed on the grand average of recordings obtained from 26 normally hearing children. The ECochG waveform begins with the SP showing normal amplitude and peak latency. This is followed by a prolonged negative response similar to the broad negative potential recorded in other forms of AN (Santarelli and Arslan, 2013; Santarelli et al., 2009). In some patients, a small CAP is superimposed on this prolonged activity at high stimulus intensity. Interestingly, the sustained potentials are recorded as low as 60 dB peSPL in spite of the profound hearing loss, which was estimated on the basis of visual-reinforced audiometry. The use of the neural adaptation procedure yielded attenuation values similar to those calculated for normal hearing and for other forms of AN (Figure 12.14, means of eight patients), thus indicating that this prolonged activity is generated by auditory nerve fibers (Santarelli and Arslan, 2013; Santarelli et al., 2009).

The normal amplitude and latency of SP potentials recorded in patients carrying mutations in the *OTOF* gene point to preserved activation of IHCs. The sustained response following the SP may result from the dendritic potentials arising in the distal portion of the afferent fibers. It has been hypothesized that a reduction of otoferlin activity leads to abnormal function of the synaptic ribbons with abolition of the fast phase of exocytosis and impairment of multivesicular release. This results in generation of small EPSPs with abnormal morphology and dispersed in time with consequent decrease in synaptic reliability. Indeed,

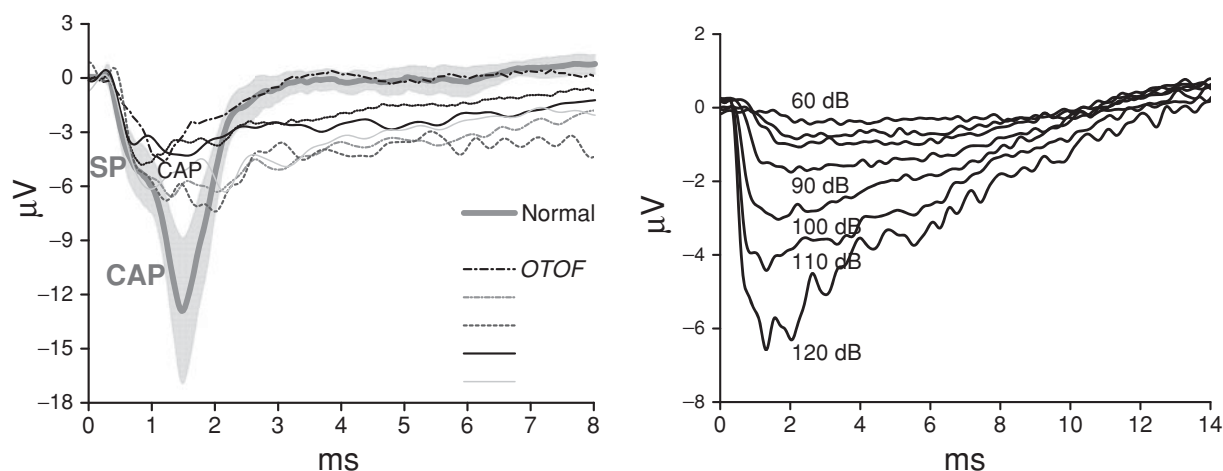

FIGURE 12.15 ECoChG potentials recorded from children carrying biallelic mutation in the *OTOF* gene. Cochlear potentials recorded at 120 dB peSPL are reported on the **right side** superimposed on the grand average of the corresponding waveforms obtained from 26 normally hearing ears with 95% confidence limits [shaded area]. In children with mutations in the *OTOF* gene ECoChG responses begin with a normal SP followed by a prolonged low-amplitude negative potential. This response is identifiable as low as 60 dB peSPL, which is about 50 dB lower than behavioral threshold (**right panel**). [Reprinted from Santarelli R, Del Castillo I, Starr A. (2013) Auditory neuropathies and electrocochleography. *Hear, Balance Commun*; 11, 130–137.]

small EPSPs elicited at low stimulus intensity are not followed by spike generation whereas at high intensity, EPSPs may occasionally reach the threshold to trigger action potentials with consequent generation of small CAPs.

These mechanisms are relevant from the point of view of rehabilitation programs for deaf children carrying mutations in the *OTOF* gene. In these patients an excellent outcome of cochlear implantation is expected with restoration of auditory function because auditory nerve fibers are believed not to be primarily involved by the damage related to otoferlin dysfunction.

ECoChG POTENTIALS IN PATIENTS AFFECTED BY CNS DISORDERS

The predictive ability of ABRs in estimating hearing thresholds in some categories of children has since 1984 been questioned by Kraus et al. (1984). They showed that hearing thresholds obtained by conventional audiometry in infancy were better than those estimated on the basis of neonatal ABRs in 15% of their sample of children showing ABR abnormalities. Since the clinical history of these patients was suggestive of prematurity, respiratory distress, and hyperbilirubinemia, they hypothesized that these factors depressed brainstem electrical activity with consequent interference in ABR generation. In recent years, several authors have pointed out that the depression of brainstem electrophysiology affects both amplitude and latency of ABR waves, with changes in amplitude being more pronounced than prolongation in latency. Specifically, decreased wave V amplitude, missing waves, and prolonged

I–V interval have been reported in children with cerebral palsy (Jiang et al., 2011). Moreover, full-term neonates suffering from hypoxia-ischemia have shown a decrease in amplitude of ABR waves as evaluated by the maximum-length sequence (MLS) technique (Jiang et al., 2013). The reduction was more pronounced for wave V compared to earlier components possibly as a result of predominant involvement of the rostral part of the brainstem. In contrast, neonates with perinatal conditions other than hypoxia-ischemia display a reduction in ABR amplitude which mainly affects earlier components.

In addition to these findings, several studies have found discrepancies between CAP and ABR thresholds in children showing CNS pathology possibly associated with depression of brainstem electrical activity (Arslan et al., 1997; Ryerson and Beagley, 1981). Figure 12.16 displays ABR and ECoChG waveforms recorded from three children showing such threshold discrepancies. The first case refers to a 4-year-old child who was born with signs of an as yet unidentified clinical syndrome who had suffered from severe neonatal asphyxia. At the time of our first observation the child presented with tetraparesis, absence of language, and severe mental retardation. He had been diagnosed with profound hearing loss on the basis of ABR recording and was fitted with power hearing aids. Parents requested evaluation at our hospital because the child began crying every time they attempted to force him to wear hearing aids. ABRs evoked by click stimuli showed no components except for wave I which was recorded as low as 70 dB nHL bilaterally. CAP was identified in ECoChG recordings with normal amplitude and latency as low as 50 dB peSPL (corresponding to

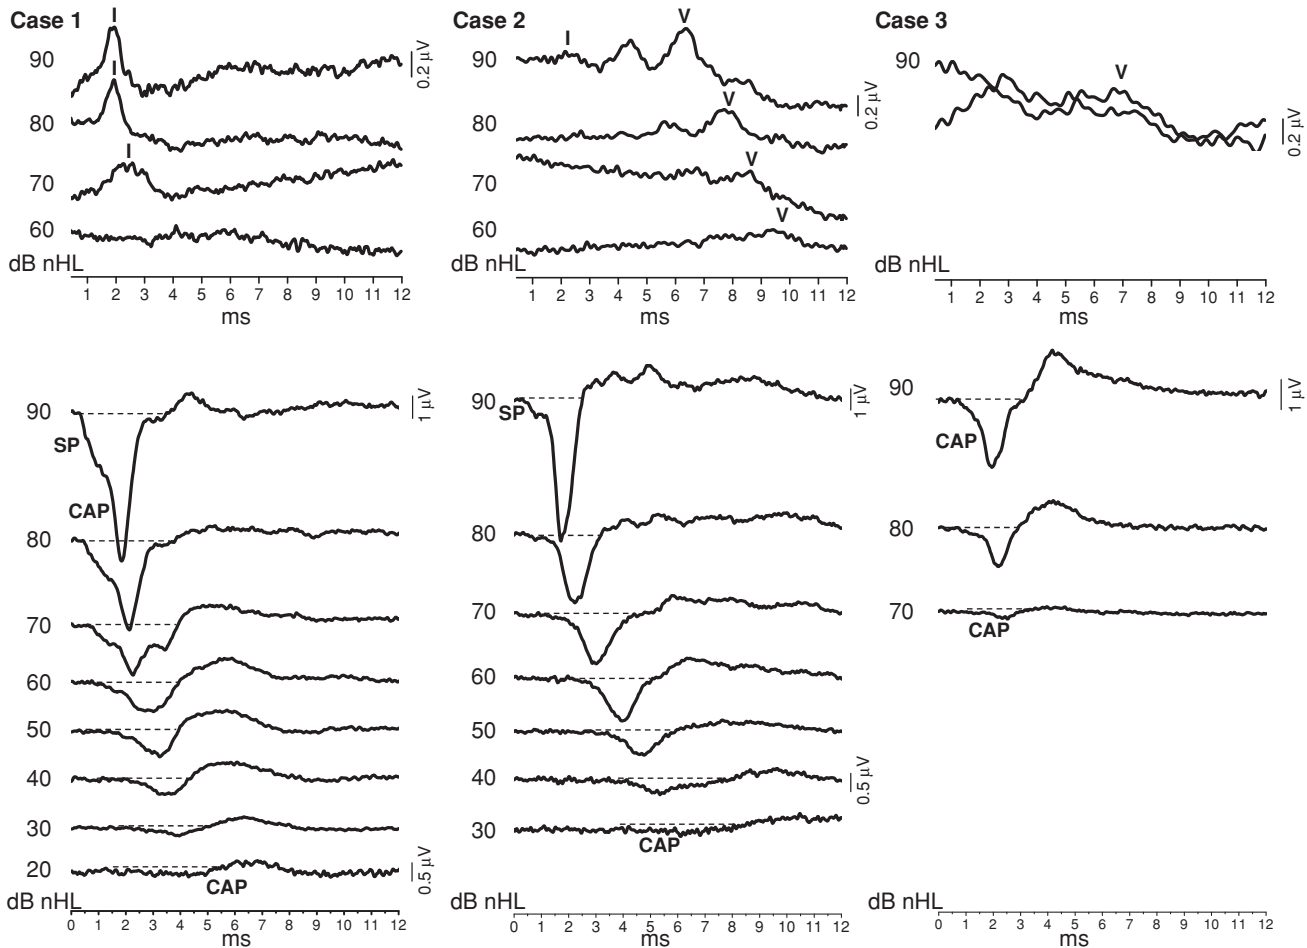

FIGURE 12.16 ABR and ECoChG potentials from children with CNS disorders. ABR and ECoChG potentials evoked by clicks are shown at decreasing stimulation intensities for three children with CNS disorders. Intensity has been expressed in dB nHL to facilitate the comparison between ABR and ECoChG thresholds. Case 1 (**left panel**) refers to a 4-year-old boy with tetraparesis, severe mental retardation, and absence of language. Only wave I was identified in ABR recordings whereas CAP was recorded with normal threshold, latency, and amplitude. ABR and ECoChG recordings displayed in the **middle panel** were collected from a 10-year-old girl affected by Wolf-Hirshhorn syndrome who presented with tetraparesis, severe mental retardation, and absence of language. Wave V threshold was 60 dB nHL in the better ear whereas CAP was identified in the ECoChG waveforms as low as 30 dB nHL with increased latency because of the coexistence of conductive hearing loss. In the example reported in the **right panel**, ABRs were recorded with 90 dB nHL threshold from an 8-month-old child who was born premature and suffered from sepsis and bowel occlusion. ECoChG recordings showed a small CAP with 70 dB nHL threshold.

20 dB nHL) in both ears thus indicating a normal hearing capacity. This example demonstrates that in subjects with signs of CNS pathology the reliability of ABR in hearing threshold assessment may be markedly reduced.

In the second example, ABR and ECoChG recordings were collected from a 10-year-old girl affected by Wolf-Hirshhorn syndrome who presented with tetraparesis, severe mental retardation, and absence of language. Wave V threshold in the better ear was 60 dB nHL and thus she was fitted with hearing aids bilaterally. The girl underwent ECoChG recording because she refused to use amplification. CAP was identified in the ECoChG waveforms recorded

from the better ear as low as 30 dB nHL, which indicates that CAP threshold was 30 dB better than that estimated on the basis of ABR recordings. Moreover, CAP latency-intensity function suggested conductive hearing loss, which was in accordance with otoscopic and tympanometric signs of tympanosclerosis. Even in this case, CNS pathology hampered ABR generation with consequent reduction of wave V reliability in hearing threshold estimation. Moreover, the coexistence of conductive hearing loss could have contributed to further decreasing the synchronous firing of ABR generators at low intensity through attenuation of the auditory input to the brainstem.

FIGURE 12.17 Comparison between wave V and CAP thresholds. The graph reports the distribution of differences between ECoChG and ABR thresholds as evaluated for 597 ears in 302 children submitted to ECoChG and ABR recording in the same testing session at the Treviso Regional Hospital from 2000 to 2012. Patients have been grouped according to etiology or risk factors for hearing loss. Negative values indicate that ECoChG thresholds are better than ABR thresholds. Differences between ABR and ECoChG thresholds higher than 10 dB were found in 34% of all ears. [Modified with permission from Santarelli R, Arslan E. (2013) Electrocochleography. In: Celesia GG, ed. *Disorders of Peripheral and Central Auditory Processing. Handbook of Clinical Neurophysiology*. Vol 10. Amsterdam: Elsevier; pp 83–113.]

Case 3 refers to an 8-month-old child who was born premature and suffered from sepsis and bowel occlusion. OAEs were absent and ABRs in response to clicks were recorded with 90-dB nHL threshold bilaterally. ECoChG recordings showed a small CAP, which was recorded at an intensity as low as 70 dB nHL in the right ear and 60 dB nHL in the left ear revealing a 20- to 30-dB difference between ABR and ECoChG thresholds. These findings have also been considered as reflecting sustained depression of brainstem auditory function.

Figure 12.17 illustrates the distribution of differences between wave V and CAP thresholds calculated for 302 children (597 ears) who underwent ABR and ECoChG testing at our department from 2000 to 2012 (Santarelli and Arslan, 2013). Ears have been grouped into several classes on the basis of etiology or risk factors for hearing loss. The larger group consists of children discharged from NICU. Other etiologies were genetic (isolated or syndromic hearing loss), prenatal (mostly CMV infections), acquired (mostly meningitis), and unknown. Negative values indicate that ECoChG thresholds are better than ABR thresholds. Differences in threshold estimation between ABR and ECoChG recordings higher than 10 dB were found in 34% of all ears. Interest-

ingly, 21% were from infants discharged from the NICUs. Therefore, relying on the identification of ABR wave V for the assessment of hearing sensitivity in this group of children would have led to an overestimation of hearing loss with inappropriate choice of rehabilitative strategy. Nevertheless, it should be pointed out that this sample also includes children for whom threshold discrepancies could also be related to abnormal firing of auditory nerve fibers (see the paragraph following).

In conclusion, ECoChG recordings are mandatory for hearing threshold assessment in uncooperative children presenting with neurologic disorders and abnormal ABRs.

ECoChG POTENTIALS IN CHILDREN DISCHARGED FROM THE NEONATAL INTENSIVE CARE UNIT

Infants discharged from the NICU are at increased risk for sensory/neural hearing loss because of the exposure to many risk factors such as prematurity, low birth weight, respiratory distress, anemia, noise, and ototoxic drugs. The combined

effects of all risk factors result in variable amounts of damage involving OHCs, IHCs, or both. As a consequence, hearing-impaired infants discharged from the NICU present with variable degrees of sensory/neural hearing loss possibly related to specific audiologic pictures such as AN. Indeed, about 5.6% of children failing newborn hearing screening show abnormal ABRs and presence of OAEs consistent with the electrophysiological profile of AN.

As mentioned above, a reduced correlation between ABR and hearing thresholds has been well documented in premature babies and in those suffering perinatal asphyxia as a consequence of abnormal firing of brainstem generators of ABRs which retain little or no connection with the dynamics of auditory periphery activation. For this reason, ECoChG recordings in children discharged from the NICU showing abnormal ABRs are mandatory if hearing thresholds cannot be ascertained reliably through noninvasive procedures. On the other hand, abnormal ABRs may also result from alterations of auditory nerve firing because of disruption of temporal coding of acoustic signals in auditory nerve fibers. Indeed, postmortem examination carried out on temporal bones of deceased neonates has shown extensive hair cell damage with a higher frequency of selective IHC loss in premature infants compared to full-term babies (Amatuzzi et al., 2011). Since the electrophysiological profile of AN has been found with high frequency in premature infants, the dysfunction of IHCs has been proposed as the primary mechanism underlying AN in children discharged from the NICU. Recently, the use of intratympanic ECoChG recording has been proposed for this category of patients to define the details of cochlear potentials and, in general, to evaluate hearing threshold for rehabilitative purposes (Santarelli and Arslan, 2013).

ECoChG potentials recorded at decreasing stimulus levels from one representative infant discharged from the NICU who showed the electrophysiological profile of AN are displayed in Figure 12.18 superimposed on the corresponding recordings obtained from one normally hearing child. The clinical history was suggestive of prematurity, hypoxia, and hyperbilirubinemia. At high stimulus intensity ECoChG waveforms display the SP potential with reduced amplitude compared to the normally hearing child. This is followed by a negative response showing reduced amplitude, delayed peak latency, and markedly increased duration compared to the normally hearing subject. Stimulation at high rate (Figure 12.14, mean of 10 children) was consistent with the prolonged potentials being generated by neural rather than receptor elements since the size of attenuation after adaptation was similar to that calculated for subjects with normal hearing and other forms of AN. Thus, the ECoChG profile obtained from AN children discharged from the NICU is indistinguishable from the most common pattern observed in patients with other forms of AN. Specifically, since SP amplitude calculated for these infants (12 children, mean SP amplitude $4 \pm 3.3 \mu\text{V}$) is about half that obtained from

FIGURE 12.18 ECoChG responses recorded from one child discharged from the NICU showing the electrophysiological picture of auditory neuropathy [AN]. ECoChG waveforms [black line] are superimposed on the corresponding traces recorded from one normally hearing ear [gray line] in response to clicks at decreasing stimulus levels. ECoChG responses recorded in the AN child showed the SP with reduced amplitude compared to the normally hearing control, which was followed by a prolonged negative response similar to that obtained in other forms of AN. [Reprinted from Santarelli R, Del Castillo I, Starr A. [2013] Auditory neuropathies and electrocochleography. *Hear, Balance Commun.* 11, 130–137.]

normally hearing controls, alteration of auditory nerve fiber discharge seems to be primarily related to a receptor rather than a neural disorder. This result appears to be in accordance with the finding of a reduced number of IHCs in the cochlea of premature infants.

Low-amplitude prolonged negative potentials were also recorded from infants discharged from the NICU who showed abnormal ABRs and no OAEs. Specifically, of the 59 children from NICU showing abnormal ABRs and absent OAEs who have been submitted to ECoChG recordings at our

FIGURE 12.19 Distribution of CAP thresholds in two groups of children discharged from the NICU, one showing OAEs and absent ABRs [AN] and the other showing no OAEs [N-AN]. Children with the profile of AN had normal or moderately elevated ECoChG thresholds, whereas higher CAP thresholds were found in the N-AN group. [Reprinted from Santarelli R, Del Castillo I, Starr A. [2013] Auditory neuropathies and electrocochleography. *Hear, Balance Commun.* 11, 130–137.]

department between 2001 and 2011, 61% showed prolonged responses with no separation between SP and CAP, 13% had distinct SP and CAP associated with an increase of response duration, whereas 25% showed no response at the maximum stimulation intensity (120 dB peSPL). Therefore, the ECoChG pattern observed in the majority of these children seems indistinguishable from that obtained from the group of infants with the electrophysiological profile of AN.

Figure 12.19 reports the distribution of ECoChG thresholds in the two samples of children discharged from the NICU, one with OAEs (AN, 25 children) and the other without OAEs (N-AN, 59 children). It can be seen that patients with the AN profile show normal or moderately elevated CAP thresholds, whereas higher CAP thresholds were found in children showing no OAEs. These differences may reflect different mechanisms and extension of damage underlying hearing impairment, which is consistent with the high variability of risk factors acting in the NICU. In this view, the distribution of CAP thresholds may reflect a “spectrum” of lesions resulting from different amounts of IHC and OHC loss, synaptic damage, and depression of auditory nerve fiber activity. Independent of OHC function as indicated by OAE detection, abnormal SPs followed by the prolonged potentials are likely to be associated with IHC disorders, whereas an ECoChG pattern showing normal SPs followed by the sustained responses may result from synaptic dysfunction or is underlain by damage to the terminal dendrites as suggested for some forms of AN in humans or for noise-induced trauma in guinea pigs.

CONCLUSION

From the point of view of diagnostic evaluation, ECoChG recordings proved to be useful for specific applications such as the diagnosis of Ménière disease. More importantly, the use of ECoChG potentials could help bring together knowl-

edge from basic research and clinical evaluation as the combination of ECoChG recordings with other techniques may contribute to defining the dysfunction in the auditory periphery and to localizing the underlying lesion. This could provide crucial information in the identification of abnormal cochlear responses and may assist in the choice of rehabilitative strategy, particularly in specific categories of children such as those affected by CNS disorders or discharged from the NICU. Moreover, the identification of specific ECoChG patterns possibly associated with defined gene mutations may elucidate both site and mechanisms underlying the various forms of AN. Finally, the inclusion of ECoChG recordings in the protocol for candidacy for cochlear implantation in children could assist in the assessment of the amount of useful residual hearing for acoustic amplification.

FOOD FOR THOUGHT

1. Do you think that CM detection in surface recording can be considered as a reliable hallmark of AN in subjects with abnormal ABRs?
2. Could intratympanic ECoChG recordings be proposed as the procedure of choice for assessing hearing thresholds in uncooperative children showing associated disabilities and abnormal ABRs?
3. Would you include intratympanic ECoChG recordings in the standard protocol for diagnosing AN?

DEDICATION

This chapter is dedicated to the memory of Prof. Edoardo Arslan who recently passed away.

He made a substantial contribution to improve knowledge in clinical electrophysiology and had long-standing influence in the field of transtympanic electrocochleography.

He set up most of the electrophysiological apparatus used to record electrocochleography in our laboratory and inspired the interpretation of the findings reported in this chapter with continuous critical discussion.

Auditory Brainstem Response: Differential Diagnosis

Frank E. Musiek, Jennifer E. Gonzalez, and Jane A. Baran

INTRODUCTION

Brief History

Four years after the original article on the auditory brainstem response (ABR) appeared in the literature, Starr and Achor (1975) published their now classic paper on the possible diagnostic use of ABR with neurologic lesions of the auditory brainstem. In their groundbreaking article, they showed abnormal ABR waveforms were relatively common in patients with brainstem involvement of various types. These findings were indeed impressive because the ABR was seldom abnormal in normal control subjects, was noninvasive, and cost relatively little to conduct as a test procedure. This early clinical research relied heavily on the generator sites of the ABR as an anatomical guide to the site of lesion. At about the same time as the Starr and Achor article, Robinson and Rudge (1975) published their clinical research on 30 patients with multiple sclerosis (MS). They reported that 22 of their 30 patients revealed abnormal ABR findings. These results, like those of Starr and Achor, impressed both the audiologic and neurologic communities. Another early study on the use of ABR in patients with neurologic involvement of the brainstem was conducted by Stockard et al. (1977). This was an extensive study on a large cross section of patients (over 100) with a variety of neurologic disorders, which highlighted the potential clinical use of the ABR. These groundbreaking studies, though performed on slightly different populations and using slightly different approaches, all demonstrated the diagnostic value of ABR for brainstem involvement.

In 1977, another classic paper was published by Selters and Brackmann (1977). This report outlined the use of the ABR in the detection of acoustic tumors. Since surgical success with the removal of these tumors was and is often dependent on early detection, interest in this article was extremely high among otologists, audiologists, neurologists, and neurosurgeons. Selters and Brackmann's findings provided a glimpse of studies to come that confirmed their early findings, that is, that the ABR was highly sensitive to acoustic tumors. These researchers also reported a low false-positive rate for the ABR, but cautioned against strict interpretations of the ABR in individuals with severe hearing loss, especially

when the high frequencies were affected. Selters and Brackmann championed the practice of interpreting the ABR in light of findings on the audiogram.

These early studies on ABR abnormalities associated with auditory nerve and brainstem pathologies laid the groundwork for continued and expanded clinical applications of the ABR. The clinical research in the 1970s showed the reliability and dependability of the ABR—which remains a key to its continued use. It also demonstrated one of the most important aspects of ABR use, that is, it can be applied across a wide variety of disciplines. At times, this resulted in disagreement and controversy, but it contributed to the remarkable advances and acceptance of the ABR as a diagnostic procedure that followed.

OVERVIEW OF GENERATOR SITES

As alluded to above, the anatomy of the generator sites of the ABR were, and continue to be, critical to diagnostic interpretations. As would be expected, the early research on generator sites of the ABR was done on animals (Buchwald and Huang, 1975). However, as pointed out by Møller and Jannetta (1985), the neural auditory pathways of the auditory nerve and brainstem are different in animals than in man. These differences are probably most obvious for the auditory nerve, which in humans is much longer than it is in small animals. A similar relationship exists for the auditory brainstem pathway, which is also longer in humans when compared to small animals.

Lesion studies from small animals, though helpful, were not as relevant as lesion studies in humans. By the early to mid-1980s anatomical correlates to brainstem lesions in humans were accumulating. These studies were giving rise to the possibilities that the animal data may not be providing the best perspective on the ABR generator sites in humans (Starr and Hamilton, 1976). Although these studies were indeed helpful in attempts to define the ABR generators in humans, the extensive and secondary effects of the lesions often made interpretation difficult. In addition, the ABR is to some degree time locked, meaning that at certain points in time, certain neurons will respond. This is true for the most part, but not totally. For example, some more caudally situated neurons may respond more slowly and

therefore may contribute to an ABR response that is generated largely at a more rostral generator site. This complexity is likely increased by the difference in timing of axonal versus synaptic potentials in the brainstem, both of which can contribute to aspects of the ABR waveform (see Møller and Jannetta, 1985).

Early estimates of the generators for the ABR in humans were somewhat different than what we know now. Perhaps the main differences were differences in Wave II and Wave V. Early interpretations based on animal data suggested that Wave I was generated by the auditory nerve, Wave II by the cochlear nucleus (CN), and Wave V by the inferior colliculus (see Møller and Jannetta, 1985). In the early and mid-1980s, Møller collaborated with Jannetta, a neurosurgeon, to record directly from the auditory nerve and brainstem of humans during neurosurgery. This team effort yielded critical information in regard to the generator sites of the ABR in humans. Accounts of a number of experiments to define generator sites are described by Møller (2000) and the following information is based on this review.

Møller's first major finding in intracranial recordings from humans was that Waves I and II were both generated by the auditory nerve. Wave I appeared to be generated by the more distal aspect and Wave II by the more proximal aspect of the auditory nerve. These waves, which were recorded intracranially, matched well in latency to the latencies of Waves I and II recorded clinically. If Wave II is triggered by the proximal auditory nerve and not the CN in the brainstem then what is generated by the CN? Møller's recordings from near the CN indicated that it matched in latency of Wave III of extra-cranial ABR recordings. More recordings led to the conclusion that Wave III in humans is a CN-generated response. It appears that Wave IV is likely generated primarily by the superior olivary complex based on Møller's observation, whereas Wave V of the ABR is likely generated for the most part by fibers of the lateral lemniscus as they enter into the area of the inferior colliculus. The inferior colliculus, which was originally believed to be the generator site for Wave V, is now believed to be related to a slower, broader wave, likely the negative part of Wave V.

The intracranial recordings of the ABR in humans by Møller and Jannetta showed that the generator sites of the ABR were in fact different from those of earlier interpretations, which were based on animal data. The identification of the generator sites in humans was a major step toward settling the issue of the generators of the ABR and providing a framework for clinical interpretation of this electrophysiological response.

THE IMAGING ISSUE

There has been and continues to be controversy regarding referral patterns for individuals who are suspected to be at risk for vestibular schwannomas (acoustic tumors). There are two competing views. One view is that the patient

should be referred directly for imaging, usually magnetic resonance imaging (MRI), to determine if a tumor of the eighth nerve is present. This decision is typically made by the otologist based on the observation of a unilateral sensory/neural hearing loss and/or related auditory symptoms significant enough to support the need for an MRI. This approach has been bolstered by arguments that ABR testing may miss small acoustic tumors (Gordon and Cohen, 1995). The opposing view is that, if the patient is a good candidate for electrophysiological testing, an ABR be conducted before a MRI referral is made. The key argument for this approach is that it will reduce the number of over-referrals for MRI. With healthcare costs being scrutinized more than ever, this approach seems logical and also has garnered support (Musiek et al., 2007; Zappia et al., 1997).

The authors realize that the arguments made for both views have merits, but believe there is, and should be, a role for ABR as a screener for acoustic tumors in present-day medicine. Acoustic tumors are a relatively rare occurrence, reportedly about 1/100,000 in the general population (Kotlarz et al., 1992). However, unilateral sensory/neural hearing loss in adults, a key factor for MRI referral, has a high prevalence with estimates of 21% of all adults undergoing audiologic assessment (Urben et al., 1999). The occurrence of acoustic tumors in individuals with unilateral sensory/neural hearing loss, though higher than in the general population, is still rare with estimates in the 2% to 3% range (Urben et al., 1999; Watson, 1999). Given these statistics, it is easy to recognize how over-referrals primarily based on unilateral sensory/neural hearing loss can occur. Urben et al. (1999) offer a logical decision-making procedure that incorporates the use of ABR test results in the clinical decision as to which patients should be screened and which procedures should be performed for individuals presenting with unilateral sensory/neural hearing loss.

Current concerns over healthcare costs make ABR screening for acoustic tumors a strong consideration. Fair estimates of ABR testing in the United States are in the \$300 to \$400 range, whereas MRIs with gadolinium contrast can range from \$2,400 to \$3,000 (Murphy and Selesnick, 2002). Other factors besides the expenses associated with MRI should be considered. Patient access to MRI can be a problem in rural areas, and patients with metal implants or other metal devices cannot be assessed with MRI. Also, some patients cannot tolerate MRI testing because of severe anxiety and/or claustrophobia (Katz et al., 1994).

It is well known that MRI is considered the gold standard for the detection of acoustic tumors; however, it is not well known that MRI is not perfect and false positives do occur. MRI has been regarded as more useful than ABR in the detection of small intracranial tumors. In one study, however, the false-positive rate for intracranial tumors was 8 in 25 (32%) using gadolinium enhancement (Arriaga et al., 1995). In their review of the literature, House et al. (2008) reported an MRI false-positive rate ranging from 2%

to 32%. This group also reported a case of a false-positive result of an apparent tumor at the fundus of the internal auditory meatus (IAM) measuring $8 \times 3 \times 4$ mm. At surgery, all four cranial nerves of the IAM were normal. House et al. (2008) offered a note of caution stating that anything resulting in vascular engorgement such as inflammations or infections may look like a neoplasm on contrasted enhancement of an MRI.

It is fair to say that the medical management of small acoustic tumors has changed over the years. There recently has been a greater tolerance for “watching and monitoring” small mass lesions (Bakkouri et al., 2009). This is especially the case for the older patient who has minimal neurologic symptoms. The issue of wait and watch is not without controversy as some surgeons believe that outcomes will be better if smaller tumors are detected early (House et al., 2008). However, it does seem that a greater tolerance for watching and waiting has evolved with evidence for doing so (Bakkouri et al., 2009). Although it is true that many tumors may not grow or may grow only slowly without any serious consequences, it is impossible to predict which tumors will grow slowly and which will grow more rapidly. Therefore, it would seem that once the presence of a small tumor has been confirmed, monitoring with both ABR (and possibly a stacked ABR procedure) and MRI may be advantageous as the combination of these two measures could provide both anatomic and physiological evidence of change or lack of thereof.

Another potential shortcoming of reliance on MRI without including ABR testing is that the ABR provides an index of physiology, which at times certainly differs from anatomical indices (e.g., MRI). There can be abnormal function of the auditory nerve without the problem being a space-occupying lesion such as a vestibular schwannoma or acoustic tumor. Various auditory neuropathies, minor vascular problems, inflammations, and infections may not show up on imaging studies, but may still affect hearing. Moreover, auditory nerve problems in many cases are handled differently than cochlear problems and this differentiation needs to be made. That is, many auditory nerve problems can be of a more serious nature and a possible threat to the patient’s overall health, whereas many cochlear problems, though handicapping, are not as much of a health risk.

THE AUDITORY BRAINSTEM RESPONSE: DIAGNOSTIC ASPECTS

In discussing the ABR in its capacity to aid in the diagnosis of specific pathologies, it must first be understood that the procedures used are measures of the function or physiology of the auditory nerve and brainstem and not measures of the structure or anatomy of these areas. By using the pattern of findings obtained for each individual patient through this physiological procedure, it is possible to make inferences

about which pathologies may be causing the disruptions in the typical ABR pattern. Although some pathologies of the auditory nerve result in similar patterns on the ABR, due to the relatively small area of the auditory pathway affected, pathologies in more rostral areas of the brainstem tend to result in a wider array of findings, which are dependent on both the size and location of the lesion. Our focus on pathologic ABR patterns will begin with a description of the findings in patients with auditory nerve involvement and will then progress to ABR findings associated with brainstem dysfunction.

ABR AND AUDITORY NERVE INVOLVEMENT

In examining the ABR in the context of auditory nerve involvement, it is useful to break this category into three parts representing the most frequently described pathologies of the eighth nerve: vestibular schwannoma, auditory neuropathy spectrum disorder (ANS), and other pathologies (including Charcot–Marie–Tooth (CMT) syndrome, vascular loop syndrome, and auditory nerve aplasia and hypoplasia). The “other pathologies” is a somewhat limited list that is far from complete, but it does relate information on some of the more common pathologies affecting the auditory nerve.

Vestibular Schwannoma

Vestibular schwannomas (also commonly termed acoustic neuromas, acoustic tumors, or eighth nerve tumors) are structural anomalies that are so named because of their location and the specific cells that are comprised. These tumors most commonly arise from the proliferation of myelin-producing Schwann cells encasing the vestibular portion of the eighth nerve. Although myelin in the brainstem proper is produced by oligodendrocytes, the myelin surrounding the auditory nerve is produced by Schwann cells, hence the tumors arising from these cells are appropriately referred to as vestibular schwannomas. Making up an estimated 90% of all tumors of the temporal bone, vestibular schwannomas generally are benign and slow growing (Bebin, 1979). These tumors are estimated to grow between 0.1 and 0.2 cm in diameter per year in many cases; however, there are some documented cases in which the tumor does not change in size (Bederson et al., 1991). Unilateral tumors occur in the vast majority of cases (95%), with the most common symptoms being unilateral tinnitus and unilateral progressive hearing loss on the side of the tumor (Jerger and Jerger, 1981). Since the auditory and vestibular portions of the auditory nerve are in such close proximity to one another, their growth in the majority of cases results in high-frequency hearing loss because of the compression of the outer boundary of the auditory portion of cranial nerve VIII. Vestibular symptoms are rarely present because of the

slow rate of growth for these tumors and the tendency of the central nervous system (CNS) to compensate for these gradual changes. If these tumors grow to be larger than about 2 cm in diameter, they may begin to spread into the cerebellopontine angle (CPA), at which point the brainstem may also show signs of compromise.

PATTERNS OF ABR FINDINGS IN VESTIBULAR SCHWANNOMA

Absolute Latency Delay

An absolute latency delay for Wave V is likely in cases of vestibular schwannoma and can be used as a diagnostic index. The difficulty is that delayed absolute latency of Wave V can also be a result of cochlear or even conductive hearing loss. The measurement of absolute latency of Wave V is used when the earlier waves are absent, which can create a diagnostic problem in differentiating retrocochlear from cochlear loss (this topic is discussed later in this chapter) (Figure 13.1). In these situations, other measures of the ABR as well as patient history can become important and helpful. Of course, the intensity of the stimulus, recording techniques, and measurement of the waveform can also influence the absolute latency and therefore should be considered (Musiek, 1991; Musiek et al., 1996). When Wave V latency measurements are greater than 6.1 ms in response to a click stimulus presented at a moderately high intensity level, the possibility of an eighth nerve tumor should be considered. It should be remembered that the absolute latency of Wave V becomes more important when other ABR indices cannot be used. Because of the high-frequency weighting (around 3 kHz) that a click stimulus takes on when presented through a normally structured peripheral auditory system, extended Wave V absolute latencies are a cause for concern

FIGURE 13.1 An auditory brainstem response obtained from a middle-aged patient with a severe high-frequency cochlear hearing loss. The ABR tracings show a delay in the absolute latency of Wave V and the absence of the earlier ABR waves [subtract 0.9 ms per ER-3A inserts*]. Note: For the case studies reported here and in the following figures the ABRs were conducted at 80 to 90 dB nHL using a 100 μ s click stimuli at repetition rates of 11 to 17 clicks per second. Filtering was 100 to 3,000 or 1,500 Hz with a 12-dB/octave roll off unless otherwise noted.

*Insert phone delay = 0.90 ms.

particularly when audiometric findings indicate relatively good high-frequency hearing. When high-frequency hearing is poor, the interpretation of Wave V latency can become ambiguous. This clinical situation is most difficult and other means to delineate eighth nerve involvement would be required. The absolute latencies of the earlier ABR waves (I and III) are not high in the interpretive scheme because if they are present in a potential case of an eighth nerve tumor other indices can and would be used.

Interwave Latency Delay

Interwave latency delays are measurements sensitive to the physiological changes that take place with vestibular schwannomas. Because of the fact that most eighth nerve tumors grow between the generator sites of Waves I and III, the I–III interwave interval (IWI) is likely to be extended in these cases (Musiek et al., 1986b). In many clinics and laboratories a I–III IWI extending beyond 2.4 ms is considered abnormal (see Hall, 1992). One of the problems often encountered in applying the I–III IWI is when these two waves (I and III) cannot be obtained, which is a situation that is often encountered when a significant cochlear hearing loss is present (Musiek et al., 1986b). When both Waves I and III are present in patients with eighth nerve tumors, the IWI measurement is extended 85% to 100% of the time. As such, it is a highly sensitive measure (Antonelli et al., 1987; Musiek et al., 1986b; and for review see Musiek et al., 2007). Since the I–III IWI is of significant value in the interpretation of the ABR for diagnostic purposes, clinicians may use a variety of means to obtain these waves. In cases where Wave I is absent or difficult to visualize, electrocochleographic approaches and/or an increased stimulus intensity may be used to enhance Wave I so the I–III IWI index can be derived.

The I–V IWI may also be used in the detection of vestibular schwannoma, though the extension of this interval is often a reflection of an increased I–III IWI measurement (Musiek et al., 1986b). However, in some cases, depending on the precise location and size of the tumor, the III–V IWI may be extended in addition to the I–III IWI making the I–V IWI most helpful to the interpretation as is discussed later in this chapter. Of course, in cases where Wave III is absent, the I–V interval becomes the IWI of choice. Although there is much information on norms for the I–V IWI index, much of the data are quite similar. Therefore, measurements of the I–V interval that exceed 4.4 ms are commonly considered abnormal across many clinics (Hall, 1992). This interval, though, involves a larger area of the auditory brainstem than does the I–III interval and thus cannot be used on its own to precisely determine a site of lesion as the I–V interval can be extended for eighth nerve tumors as well as for brainstem lesions. The I–II IWI could also be used diagnostically; however, since Wave II is not present in all nontumor individuals, its absence in patients with this potential diagnosis is not clinically dependable (see Hall, 1992). However, in

situations where there is suspicion of an eighth nerve tumor and Wave II is present and normal, it is likely that the auditory nerve is not involved (based on the Wave II generator site). The III–V IWI is likely to be normal in cases of vestibular schwannomas, as the generator sites for these waves are more rostral than the auditory nerve. However, in some cases of vestibular schwannomas, the III–V IWI is extended (Møller and Møller, 1983; Musiek et al., 2007). This has been attributed to large tumors in the CPA that have twisted and/or compressed the brainstem.

Interear Latency Comparisons

An interear latency comparison, or interaural latency difference (ILD), using Wave V measurements obtained from the left and right ears can be diagnostically relevant, especially when used alongside interwave latency measurements. First described by Selters and Brackmann (1977) and Brackmann and Selters (1979), ILD measurements are particularly attractive in the process of diagnosing vestibular schwannomas because in some cases, Wave V is the only wave of the ABR that is present in each ear; hence it has greater utility than interwave measures. Also, this is a “within patient” comparison, which has some nice clinical and research advantages. When using this index, one must be keenly aware of the effect that asymmetrical hearing losses have on the ABR. If an asymmetrical hearing loss of cochlear origin is present, it is possible to misinterpret the ABR as abnormal—especially in cases when the hearing sensitivity in the poorer ear is severe enough to result in an ABR with an extended Wave V absolute latency and an absence of the earlier waves. To ensure that the observed effect on the ABR is not because of asymmetrical sensory/neural hearing loss, Selters and Brackmann proposed the use of a correction factor of 0.1 ms for every 10 dB of hearing loss at 4 kHz greater than 50 dB HL; however, the use of correction factors in determining abnormality of ILD measurements can be cumbersome and at times may not be clinically insightful. In some cases, application of the various correction factors to adjust for the potential effects of high-frequency hearing loss can actually hinder correct interpretation (Cashman et al., 1993; Musiek et al., 2007). It must also be noted that asymmetrical hearing loss and vestibular schwannoma do not always occur in isolation, and it is possible to have effects on the ABR resulting from both a cochlear hearing loss and a retrocochlear pathology. Most would agree that when using this measurement, ILDs greater than 0.3 to 0.4 ms should be considered abnormal and would support a diagnosis of retrocochlear involvement as long as the contribution of a cochlear hearing loss can be ruled out (Musiek et al., 1989).

Amplitude Comparison of Waves

The Waves V/I amplitude ratio is another ABR index that has been used to aid in identifying vestibular schwannomas (Chiappa, 1983; Musiek et al., 2007). Before employing this index in the interpretation of the ABR, however, the reliabil-

ity of amplitude measurements must be examined because of their inherent variability. The ABR should be replicated at least once, and each waveform’s Wave I and V amplitude measurements should not vary by more than 20%. When Wave V exists as a portion of a IV–V complex, the greatest amplitude of the complex should be used when calculating the V/I amplitude (peak to trough) ratio. When the Wave V amplitude is less than 0.75 of the amplitude of Wave I, it is considered abnormal and is suggestive of retrocochlear pathology (see Musiek et al., 1996). It should be mentioned that a significantly smaller Wave V than Wave I does not occur very often even in pathology; however, when it does, it should be interpreted with concern (Musiek et al., 1996).

Waveform Morphology and Absence of Waves

Although a waveform’s overall appearance or morphology may be difficult to describe and therefore difficult to use in identifying vestibular schwannomas, the absence of waves on an ABR recording is a significant finding. The presence of an eighth nerve tumor should be considered if all waves of the ABR are missing. However, as mentioned in the discussion on asymmetrical hearing losses and their effect on the ABR, the absence of waves must be interpreted along with the audiometric results that were obtained for the patient. The most striking indication of a retrocochlear lesion is the absence of all ABR waves while audiometric results from that ear indicate relatively normal hearing sensitivity. Individual waves may also be absent in cases of vestibular schwannoma, with Wave III most commonly missing (Musiek et al., 1986a). An important interpretation is when Wave I is present and the remaining waves are absent. This is a strong indicator of retrocochlear involvement (see Figure 13.2). Generally, this particular interpretation can be made without an audiogram. However, the absence of early waves must be interpreted alongside the audiogram as individuals with cochlear hearing loss are likely to be missing Wave I, Wave III, or both. There are also some instances of normal hearing individuals (without tumors) missing Waves I and III, but this is relatively rare if appropriate stimuli and recording techniques are used (see Hall, 2007; Musiek et al., 2007). Therefore, the absence of earlier waves is not a reliable indicator of the presence of vestibular schwannoma.

Repetition Rate Shifts

The utilization of high repetition (high rep) rates to help in defining eighth nerve tumors has been controversial. This measure involves the comparison of the latency of Wave V at low and high rates of presentation such as 11 clicks per second to 81 clicks per second. If there is a greater than expected latency increase or a disappearance of Wave V during the high rep rate recording, then the interpretation is for possible eighth nerve pathology. Early reports have shown some value in this procedure (Daly et al., 1977). In many instances, high rep rate measures show abnormalities that have also been revealed by other ABR indices. In these cases,

FIGURE 13.2 A middle-aged patient with a left-sided vestibular schwannoma (acoustic tumor) with the waveform showing a poor morphology Wave I and no replicable later waves [subtract 0.9 ms per ER-3A inserts*]. *Insert phone delay = 0.90 ms. [Reprinted with permission from Musiek FE, Shinn JB, Jirsa RE. (2007) The auditory brainstem response in auditory nerve and brainstem dysfunction. In: Burkard RF, Don M, Eggermont JJ, eds. *Auditory Evoked Potentials: Basic Principles and Clinical Application*. Baltimore, CA: Lippincott Williams & Wilkins; pp 291–312.]

they may not be essential for the diagnosis (Musiek et al., 1996). However, high rep rate ABRs can be useful in helping to detect eighth nerve tumors and in some cases an abnormal high rep rate measure is the key index (Tanaka et al., 1996). It seems that even after many years of research this measure still remains controversial (see discussion regarding brainstem lesions).

Laterality

Since the site of lesion for vestibular schwannoma tumors is caudal to the location of the first binaural representation in the auditory system (the superior olivary complex), abnormal ABR findings are generally ipsilateral to the ear of stimulus presentation. However, if the tumor grows to a substantial size the contralateral ABR can be affected because of compression and possible twisting and displacement of the brainstem from midline. When this happens, Wave V or the IV–V complex will be missing, delayed, or reduced in amplitude resulting in a III–V IWI extension or a III–V IWI that cannot be measured (Musiek and Kibbe, 1986) (Figure 13.3). Clinically, this presentation of a contralateral ear abnormality could be helpful in a situation where there is considerable hearing loss and no readable ABR on the side of the lesion. If the contralateral ear has reasonable hearing and the ABR shows an effect on the later waves, suspicion of a large lesion

may be appropriate and further delineation should be sought (see section on brainstem involvement).

Threshold Measures

Another index which can help with the differentiation of vestibular schwannomas is comparing the behavioral threshold with the ABR threshold. It is well known that the ABR threshold can closely approximate the behavioral threshold of hearing. However, some preliminary data, as well as various case reports, have indicated that in patients with eighth nerve tumors, the difference between the measured ABR threshold and the behavioral threshold is more than would be expected—often, 30 dB or greater (Bush et al., 2008).

In patients with eighth nerve tumors, the most reliable diagnostic measurements to use are the I–III and I–V IWI measurements and the ILD, either alone or in combination. Using these indices in the interpretation of the ABR results in hit rates of 90% or better and false-positive rates of 20% or less (Musiek et al., 2007).

Stacked ABR

Although the ABR has high hit rates and low false-positive rates for medium- and large-sized vestibular schwannomas, smaller sized tumors are often missed because of the small number of nerve fibers affected by the growth. In addition

FIGURE 13.3 A scatterplot of I–III and III–V ABR interwave intervals for 11 subjects with large acoustic neuromas. The data displayed are for the contralateral ear (i.e., nontumor ear), all of which had normal or near-normal hearing. Note how the I–III interval is essentially normal for all 11 subjects, whereas the III–V interval is abnormal for 4 ears and Wave V was missing in 7 cases (indicated by vertical arrow). [Constructed from data presented in Musiek FE, Kibbe K. (1986) Auditory brainstem response wave IV–V abnormalities from the ear opposite large cerebellopontine lesions. *Am J Otol.* 7[4], 253–257.]

to the standard ABR missing smaller-sized tumors, which by nature of their size affect a smaller number of neurons, tumor location may also lead to false-negative results on the ABR. Given the high-frequency weighting of the click stimulus, a standard click ABR relies on the integrity of the outer boundary of the auditory nerve. Should the location of the tumor not be on this outer boundary but rather in the middle or inner portions of the nerve, the standard ABR is likely to miss these tumors.

Don et al. (1997) developed a method of detecting tumors that are missed by standard ABR testing because of either tumor location or size (i.e., the Stacked ABR). The Stacked ABR aims to measure neural activity not just from a narrow portion of the cochlea (as is the case when the standard ABR is employed), but from the length of the cochlea as a whole. The ABR results would then be a reflection of the neural synchrony lost because of the presence of a tumor regardless of which fibers are affected by that tumor (Don et al., 2005).

A click stimulus is used to evoke this ABR, and the response to the click is separated into five frequency bands via high-pass masking and response subtraction (Don and Eggermont, 1978; Parker and Thornton, 1978a, 1978b). Six stimulus conditions are used to obtain these ABRs and consist of clicks alone without masking and clicks presented along with five variations of simultaneous ipsilateral high-pass pink noise (cutoff frequencies of 0.5, 1, 2, 4, and 8 kHz).

Derived-band ABRs are then obtained by subtracting one high-pass masker condition's ABR from the ABR obtained with high-pass masking one octave above it. For example, the ABR obtained with 0.5-kHz high-pass noise is subtracted from the ABR obtained with 1-kHz high-pass noise. Once derived-band ABRs are obtained for all noise conditions, they are then shifted in time so that each Wave V is in alignment, thus the term "stacked." After the waveforms are aligned, they are added together to form the resulting Stacked ABR. The amplitude of the Stacked ABR is then compared to the ABR obtained using the click stimulus alone (without high-pass pink noise). In normal ears, Wave V from the Stacked ABR should have the same amplitude as the standard click-evoked ABR; however, when a small tumor is present or when the tumor affects more low-frequency-tuned nerve fibers, Wave V from the Stacked ABR will be smaller in amplitude than the amplitude noted in the standard ABR (Don et al., 1997). When tumors are 1 cm in diameter or smaller, the Stacked ABR is highly sensitive (95%) and specific (83%) (Don et al., 1997) (see Chapter 11 for more information on the Stacked ABR procedure).

Auditory Neuropathy Spectrum Disorder

Unlike eighth nerve tumors, which are structural abnormalities that affect the physiology measured with the ABR, ANSD is a purely functional or physiological abnormality that can include effects on the function of the auditory nerve. There

is no obvious structural abnormality causing the ABR to be affected; therefore, imaging (i.e., MRI) results in cases of pure ANSD are not remarkable. The strict definition of ANSD is the presence of otoacoustic emissions (a measurement of outer hair cell function) in the complete absence of the ABR. Therefore, the site of origin for ANSD is between the cochlea proper and the brainstem, with possible causes as injury to the synaptic junctions of the inner hair cells and/or the dendrites of the auditory nerve that receive neurotransmitters released by the inner hair cells, injury to the spiral ganglion, and/or damage to axons of cranial nerve VIII. When damage to the auditory nerve axons is present, effects tend to spread to portions of the brainstem. Sites of neuronal injury can occur to the myelin sheath, the axon, or both, as well as to the cell body. Therefore, the list of conditions that can cause ANSD and absent ABRs is widespread and includes low birth weight, prematurity, viral disease, seizure, anoxia, hypoxia, and CMT, Ehlers–Danlos, and Stevens–Johnson syndromes. ANSD may also occur spontaneously with no known pathologic cause. Hyperbilirubinemia (HB), or jaundice, is often linked to ANSD; however, it should be realized that this disorder is primarily a central auditory system disorder as the damage resulting from this pathologic process is first focused on brainstem nuclei (namely, the CN) and not the auditory nerve (Dublin, 1985). This damage may begin to encroach on the auditory nerve's root entry zone into the CN and then to the auditory nerve itself, but the typical understanding of ANSD with primarily auditory nerve damage is not the case with HB. Damage in HB begins in the brainstem and then descends to the auditory nerve.

The underlying physiology of ANSD is seen on the ABR as waveforms that have no measurable aspects (i.e., amplitude and latency of Waves I, III, and V) and are not replicable. Because there are no measurable aspects, none of the usual procedures can be carried out. However, a cochlear microphonic should be present on the ABRs obtained because aspects of cochlear function can be normal or near-normal in ANSD. The cochlear microphonic is a response predominantly generated by the outer hair cells in the cochlea, which occurs before Wave I of the ABR and follows the phase of the presented stimulus. When obtaining ABRs in suspected cases of ANSD, it is important to obtain separate replicated waveforms using single-polarity condensation and rarefaction click stimuli to identify the cochlear microphonic. The cochlear microphonic begins within 1 ms of stimulus presentation and will appear as an initial downward shift from baseline with a rarefaction click stimulus and as an initial upward shift from baseline with a condensation click stimulus. ABR tracings which lack the cochlear microphonic are likely the result of instrumental or clinician error (stimulus not delivered to patient or using alternating polarity clicks). Therefore, equipment and stimulus protocols should be checked to make sure the stimulus is properly delivered to the patient if all waveform aspects of the ABR are absent (see Chapter 14 for more on ANSD).

Charcot–Marie–Tooth Syndrome

As mentioned, CMT disease could be viewed as a specific type of auditory neuropathy. However, it stands as a well-recognized disorder on its own. It was and still is considered an inherited peripheral motor neuron disease, but reports of auditory involvement began to surface in the 1970s and 1980s. Weaknesses of hands and feet are often noticed with some cases clearly having auditory complaints (see Musiek et al., 1982). Patzkó and Shy (2010) relate that CMT is characterized by disruptions in myelin along the nerve axon or damage to the axon itself, which affects the velocity and size of the impulses conducted down the axon and communication among nerves. There are a variety of types of CMT mostly classified by myelin or axon involvement and the types of genes that are involved.

Of interest from an audiologic perspective is that CMT may affect the peripheral nerve (CMT1A) or the CNS (CMTX). Nicholson and Corbett (1996) showed delayed central time on ABR for a CMTX group and only a delayed Wave I for the CMT1A group. However, in another study on CMT1A, the ABRs were essentially normal. This raises the issue of the possibility that some forms of CMT may involve the auditory system and some may not. Clearly, abnormal ABRs have been reported in various groups of CMT patients with delays in the later ABR waves, as well as compromised amplitudes for Wave V (Rance et al., 2012). In apparent long-standing disease, auditory degeneration results in absent ABRs. Some of the variance in ABR findings may be related to the particular type of CMT, but to delineate this is beyond the scope of this chapter. It is worthy to note, however, that the ABR is a key procedure to utilize in the evaluation of CMT, especially when the patient has auditory symptoms.

Auditory Nerve Aplasia/Agenesis and Hypoplasia

In addition to the aforementioned auditory nerve disorders affecting the ABR, it is also possible for the auditory nerve to be missing (aplasia or agenesis) or underdeveloped (hypoplasia). In both cases, the malformation is congenital with the possibility of stenosis of the IAM or cochlear malformations. In a study of 13 ears from nine children with cochlear nerve deficiency, 4 ears exhibited small IAMs on MRI (Buchman et al., 2013). Of the nine children diagnosed with cochlear nerve deficiency, five were affected unilaterally and four were affected bilaterally. In all nine cases, a cochlear microphonic was present with absent ABRs in at least one ear. With a variety of temporal bone malformations that may accompany auditory nerve aplasia or hypoplasia, the audiologic profiles of these cases are wide ranging.

In the case of auditory nerve aplasia, the lack of the nerve prevents the transmission of auditory information to areas of the auditory system beyond the cochlea. It is expected that in an otherwise intact peripheral auditory system, individuals with auditory nerve aplasia will display

normal tympanograms, whereas acoustic reflexes will be absent when the aplastic auditory nerve is on the stimulated side. Otoacoustic emissions may or may not be present on the affected side depending on whether or not the cochlea is involved. As the ABR requires neural conduction along the auditory nerve in order for it to be evoked, an absence of the nerve results in the absence of the ABR waves.

In auditory nerve hypoplasia, cochlear function as measured by distortion product otoacoustic emissions (DPOAEs) may be related to the width of an accompanying IAM stenosis. A study of 10 subjects diagnosed with auditory nerve hypoplasia and nonsyndromic IAM anomalies (without other external malformations) found 3 subjects with a very narrow IAM (<30% of average), 3 subjects with intermediate IAM (30% to 70% of average), and 4 subjects with a slightly narrow IAM (>70% of average) (Ito et al., 2007). Of those 10 subjects, 1 from the intermediate group had reduced DPOAEs from 1,000 to 3,000 Hz and 2 from the slightly narrow group had normal DPOAEs in the same mid-frequency range. The remaining seven subjects, including the three in the very narrow group, two in the intermediate group, and two in the slightly narrow group had absent function or severe dysfunction as measured by DPOAEs, demonstrating that although cochlear function may be spared in some patients with slight narrowing of the IAM, findings of absent or severely impaired cochlear function are common among patients with auditory nerve hypoplasia. The ABR was absent in all 10 subjects of this study; however, Taiji et al. (2012) studied six ears with cochlear nerve hypoplasia, all associated with IAM stenosis, and found that whereas DPOAEs were present and normal in one of the six ears, threshold ABRs were present in three of the six ears, excluding the ear with normal DPOAEs. In the cases with demonstrated ABRs, thresholds (dB nHL where Wave V just began to appear) were elevated at 60, 80, and 90 dB nHL, whereas DPOAEs were absent in all three cases. This is not particularly surprising as DPOAEs are a measure of outer hair cell function, whereas a high-intensity ABR relies on inner hair cell integrity. None of the subjects studied had known syndromes or risk factors as a cause of their hearing losses, including HB, hypoxia, or premature birth. Therefore, the presence of an ABR in auditory nerve hypoplasia is difficult to predict from the audiometric profile.

Vascular Loop Syndrome

Vascular loop syndrome is a condition in which the cranial nerves (including the eighth cranial nerve) in the vicinity of the CPA are compressed by a blood vessel, with the anterior inferior cerebellar artery (AICA) being the most commonly affected vessel (Jannetta, 1967). This compression may result in a variety of auditory, vestibular, or facial symptoms among individuals depending on the location and amount of compression.

When compression is present on the auditory portion of the eighth cranial nerve, ABR results are often abnormal.

Extensions of the I–II and/or I–III interwave latencies on the affected side are typical, with these findings likely to improve with surgical intervention. ABR findings from vascular loop syndrome may not differ from those described for vestibular schwannoma; however, the ABR in either case will display abnormalities consistent with eighth nerve involvement. Differentiation between the two disorders after obtaining ABR may be made with imaging techniques such as MRI or computed tomography (CT) (see Møller, 2000; Musiek et al., 2012 for review).

ABR AND BRAINSTEM INVOLVEMENT

General Background

ABR findings in lesions of the auditory brainstem pathway continue to be an important clinical application for audiologists and neurologists. The early studies demonstrated the diagnostic value of the ABR when the auditory brainstem pathway was involved (Starr and Achor, 1975; Stockard et al., 1977). However, as data accumulated over the years clinicians and researchers began to realize that though still valuable, the ABR was not quite as sensitive to a wide variety of brainstem disorders (with the exception of intra-axial lesions) as it was for vestibular schwannomas (Musiek, 1991) for a number of reasons. First, there are a wide variety of known neurologic disorders that may affect the brain, whereas there are relatively few that compromise the auditory nerve (Chiappa, 1983, 1989; Musiek, 1991). However, those lesions that affect the auditory nerve, like vestibular schwannomas, almost always compromise the nerve directly. Second, some neurologic disorders may or may not target the auditory brainstem pathway. For example, MS may arise in the brainstem, but not necessarily in the auditory tracts. In this case the ABR would be normal, but without highly definitive imaging the examiner may not know this and assume that the ABR failed to identify this disease. Also, surveys have shown that the ABR hit rate for MS is in the neighborhood of 60% or slightly better. This is without defining the site of lesion as being in the auditory tracts (Musiek, 1991). However, in cases where the MS lesion is decidedly in the auditory pathway, the ABRs are almost always abnormal (Levine et al., 1993).

ABR testing has become highly useful for those lesions affecting the brainstem for which imaging is of little help. Imaging results are often normal in cases of HB and external toxic exposures and in some cases of head injury. Yet, in many of these cases, auditory and other symptoms abound. Careful ABR analysis in such cases may provide insights as to the nature of the auditory symptoms and the integrity of the auditory brainstem (see Musiek et al., 2007). Effective ABR analysis requires the understanding of the various ABR diagnostic indices and an understanding of various diagnostic patterns, some of which are specific to brainstem involvement.

PATTERNS OF ABR WAVES RELATED TO BRAINSTEM INVOLVEMENT

Absolute Latency Delay

The diagnostic index of absolute latency delay of Waves I, III, or the IV–V complex can reflect conductive, cochlear, or retrocochlear involvement. In regard to brainstem involvement, a delayed Wave I would not be highly useful. A delayed Wave III or IV–V without Wave I as alluded to earlier could be indicative of a number of different sites of lesions. A delayed Wave III with a normal III–V interval or a delayed V with absence of Waves I or III often occurs, but the clinician would have to utilize additional measures to determine if there is brainstem involvement (see Musiek and Lee, 1995; Musiek et al., 2007).

Interwave Latency Delay

The extension of the I–III, III–V, or I–V IWIs is perhaps the most revealing measurement of brainstem involvement. This is because these indices involve the brainstem generators of Waves III, IV, and V. Since Waves I and II are generated by the auditory nerve, the interpretation would be that the auditory nerve is intact and functioning if these waves are present at normal latencies (Møller, 2000). An extension of the I–III IWI could indicate that the auditory nerve is involved, that is, a lesion between the distal segment of the auditory nerve and brainstem or that the caudal brainstem is compromised at or in the area of the CN (Musiek et al., 1986b). Both of these interpretations are plausible and should be entertained. If the I–III IWI is extended but Wave II is present, one might argue for brainstem involvement only; however, there is little, if any, published research on this type of ABR pattern.

Based on generator sites, a III–V interval increase is firmly interpreted as brainstem involvement (Musiek and Lee, 1995; Musiek et al., 2007; Starr and Achor, 1975). It is possible that the III–V interval extension can result from an eighth nerve tumor, but generally these tumors would have to be quite large, affecting the brainstem considerably for this ABR abnormality to be seen (Musiek et al., 1996). This interpretation is dependable for indicating brainstem involvement, but one must be confident in the selection of the peaks of Waves III and V. These waves can be rather distorted and difficult to visualize in patients with brainstem lesions.

The I–V IWI is often extended in brainstem lesions, but it is to a great extent dependent on its subcomponents, the I–III and III–V intervals; that is, often an extended I–III or III–V IWI will drive the extended I–V interval. However, at times one of these subcomponents may be abnormal whereas the other is normal resulting in a normal I–V IWI. This highlights the importance of looking at all IWIs if they are present. For example, if normal IWIs are 2.4 ms or less for the I–III, 2.3 ms or less for the III–V, and 4.4 ms or less for the I–V IWIs, a patient could present with a 2.5 ms III–V and a 1.9 ms I–III and have a normal I–V interval (4.4 ms). Another situation is when the I–III and III–V

IWIs are normal, but when combined, they contribute to an extended I–V IWI (I–III = 2.3 ms, III–V = 2.3 ms), which results in an abnormal I–V interval of 4.6 ms. The main weakness of relying on IWI measures is that often they are not all available; therefore, some of these interpretations cannot be made (see Musiek et al., 1986b). A key advantage in utilizing IWIs is that hearing loss has little, if any, effect.

Interear Latency Comparisons

As discussed earlier, the ILD is a valuable index for the detection of eighth nerve tumors; however, this may not be the case with brainstem lesions (Musiek et al., 1989) because the majority of eighth nerve tumors are unilateral, resulting in unilateral latency delays. This means the ILD will be significant (as Wave V will be delayed more on one side than the other side). Brainstem lesions more often affect both brainstem tracts (ipsilateral and contralateral) either directly or indirectly because of the profuse number of cross-over tracts and commissures in the brainstem. These anatomical factors could lead to Wave V latency delays for both ears, and hence a nonsignificant ILD. As shown in Figure 13.4, the mean ILD for a group of patients with brainstem involvement was significantly smaller than a comparable group of patients with eighth nerve tumors (Musiek et al., 1989).

Amplitude Comparison of Waves

One of the more controversial diagnostic ABR indices is the Wave V to Wave I amplitude ratio. It is well known that Wave V or the IV–V complex is normally larger than Wave I in adults (Musiek et al., 1986a) possibly because more neurons are available as one progresses up the auditory pathway. The

FIGURE 13.4 Plot of the mean and one standard deviation for the interaural latency difference [ILD] for subjects with normal hearing, cochlear involvement, eighth nerve tumors, and brainstem lesions. [Constructed from data presented in Musiek FE, Johnson GD, Gollegly KM, Josey AF, Glasscock ME. [1989] The auditory brainstem response interaural latency difference [ILD] in patients with brainstem lesions. *Ear Hear.* 10[2], 131–134.]

FIGURE 13.5 The ABR from a young adult with an extra-axial brainstem lesion. All latencies were normal; however, Wave I was quite large [$\sim 0.7 \mu\text{V}$] yielding an abnormal amplitude ratio.

more nerve fibers that respond the larger the evoked potential response will be. In patients with pathologic conditions, potential damage to the more rostral brainstem fibers may result in the usually larger response (i.e., Wave V or the IV–V complex) being compromised. Neurologists have generally supported the use of the V–I amplitude ratio as a diagnostic criteria for brainstem involvement (Stockard et al., 1978). On the other hand, audiologists have been less enthusiastic about the diagnostic value of the V–I amplitude ratio. To best use this amplitude ratio certain criteria need to be satisfied. One is that the amplitudes of Wave I and V must be highly replicable on two successive trials (Musiek and Lee, 1995; Stockard et al., 1978). Also, in making the comparison of Wave V to Wave I the largest of the later peaks, either Wave IV or V, should be used (Musiek et al., 2007). When these conditions are met then the V–I amplitude ratio, though not highly sensitive, is highly specific if a ratio of less than 0.75 is used (Musiek and Lee, 1995) (see Figure 13.5).

Waveform Morphology and Absence of Waves

Brainstem involvement often results in a highly dependable index for brainstem abnormality when Waves I and III are present and the IV–V complex or Wave V is absent. Brainstem and auditory nerve compromise is also probable when Wave I is present and Waves III and V are absent. When Wave III is absent and Wave V is present, one should look at the I–V IWI. If this interval is normal, then it is likely that the response is normal. An abnormal outcome is when the I–V IWI does not fall within the normal range. Because Wave III absence alone has been reported in normal subjects, this finding must be interpreted with much caution (see Hall, 1992; pp 231–232). At times, Wave IV will be present and Wave V will be absent, which of course is an indication of brainstem involvement. However, in some instances with a high-intensity rarefaction polarity click Wave V can be a very low shoulder on Wave IV and may be mistakenly considered as absent (Gerling, 1989). This can often be clarified by using a contralateral recording, changing polarity, or dropping the intensity level of the click stimulus (Gerling, 1989). The absence of all waves can also occur in individuals with brainstem involvement, but this finding usually occurs

when there is concomitant peripheral hearing loss that prohibits the early waves from evolving.

Contralateral Effects

Large mass lesions on one side, such as an acoustic neuroma, can compress and torque the brainstem sufficiently to cause an ABR brainstem finding on the opposite side when stimulating that ear. This result is not a contralateral recording, but rather a recording from the acoustically stimulated ear (Musiek and Kibbe, 1986). The ear opposite the large lesion, if the hearing is reasonably good, will show normal Waves I and III and an abnormal III–V interval or compromised V or IV–V complex (Musiek et al., 1986a, 1986b). This kind of information can be clinically useful when there may be no ABR response or no hearing on the involved side. Testing the better side, if it yields a “contralateral effect” could be clinically insightful.

Repetition Rate Shifts

It has been thought for many years that increasing the rep rate during ABR testing would place greater physiological strain on the auditory nervous system, and in turn may uncover subtle brainstem abnormalities (see Hall, 1992, pp 138–141). There have been a number of reports that have shown ABR abnormalities at high rep rates, which were not as obvious at lower rates of stimulation (see Hall, 1992 for review). However, there have been questions raised regarding the value of rep rate functions in the diagnosis of auditory system compromise. Some reports indicate that when rep rate functions are abnormal other ABR indices are also abnormal, and therefore the finding of rep rate abnormalities does not distinctly contribute to a reliable diagnosis (Musiek and Lee, 1995; Musiek et al., 1996; see also Hall, 1992). A physiological consideration regarding rep rate functions is that many auditory neurons are capable of responding at much higher rates than most ABR equipment can deliver (usually <100 clicks per second), hence, the auditory system is not challenged as much as was originally thought. One of the most under-researched areas of ABR is the presentation of stimuli at very high rates. Procedures that include maximum length sequences (MLS) and continuous loop averaging deconvolution (CLAD) allow extremely high rates of presentation (up to or even greater than 700 to 800 clicks per second) that would physiologically challenge the brainstem pathways. Some valuable work has been done in this area, but more applied research should be done to recognize the full value of these procedures (see Burkard et al., 1990; Delgado and Özdamar, 2004; Musiek et al., 2007).

SENSITIVITY AND SPECIFICITY OF ABR TO BRAINSTEM LESIONS

Overall, it appears that ABR is not as sensitive to brainstem lesions as it is to eighth nerve tumors. A study that investigated the sensitivity for a variety of brainstem lesions found the hit rate was approximately 80%, which was about 10% lower

than that of acoustic tumors (Musiek et al., 1996). However, it appears that the ABR hit rate for brainstem involvement is dependent on the type of disorder (Musiek, 1991). For example, ABR abnormalities for intrinsic brainstem lesions are high (>95%), whereas for various degenerative disorders the hit rates are only moderate. Much of the variance is related to the precise location of the lesion (as mentioned earlier, sometimes the auditory pathways are not involved when a brainstem lesion exists), the nature and severity of the disorder, and the particular approach(es) for using ABR in the presence of these disorders. At the risk of oversimplification and brevity, the following is offered as a brief synopsis of ABR findings in some selected brainstem disorders.

Survey of ABR and Specific Brainstem Disorders

MULTIPLE SCLEROSIS

MS is classified as a demyelinating disease that is often progressive. The onset of the disease is generally in early adulthood and the disease occurs more often in cold climates. The symptoms of the disease often wax and wane, with periods of remission offset by exacerbations of symptoms. Central to the pathophysiology is the damage to the myelin sheaths of the axons of nerve fibers, which can occur in both the peripheral and central nervous systems. The symptoms of the disease depend on the site of involvement. That is, if the auditory nerve fibers are involved, auditory symptoms will often be noted. Even though most of the auditory brainstem pathways are myelinated, only a portion of the auditory nerve tract is myelinated (see Musiek et al., 2012, pp 297–299).

ABR is a useful tool for the evaluation of MS (see Figure 13.6). It can help in the diagnosis and in monitoring

FIGURE 13.6 An ABR from a young adult with multiple sclerosis and a slight high-frequency hearing loss [Key: RE, right ear; LE, left ear; RE-HR, right ear, high rep rate @ 77.9 clicks per second]. [Adapted from Musiek FE, Shinn JB, Jirsa RE. [2007] The auditory brainstem response in auditory nerve and brainstem dysfunction. In: Burkard RF, Don M, Eggermont JJ, eds. *Auditory Evoked Potentials: Basic Principles and Clinical Application*. Baltimore, CA: Lippincott Williams & Wilkins; pp 291–312 with permission.]

the disease's effects on the auditory system. Also, it can be of value in determining if new auditory symptoms in a patient with known MS are a result of MS affecting the auditory system or some other cause. The sensitivity of ABR for MS can be somewhat misleading. Reports indicate the hit rate is quite high, whereas others find it is only mediocre (Levine et al., 1993; Musiek et al., 1994). Much of this variance is related to the fact that in MS the auditory brainstem tract is not always involved (Levine et al., 1993; Musiek et al., 2007). Extended central conduction times, that is, extended Waves I–III, III–V, or I–V intervals, are commonly seen in patients with MS. Further, ABR findings can be influenced by the degree of involvement and the time of evaluation relative to an exacerbation of symptoms. During or close to a period of exacerbation, the ABR could be absent only to recover over a period of days.

TUMORS OF THE BRAINSTEM

Tumors of the brainstem are generally divided into two main groups: extra- and intra-axial. Extra-axial lesions are those that encroach on the brainstem from outside of this structure. For example, tumors of cranial nerves IV through VIII and of the cerebellum as well meningiomas can affect the brainstem and would be considered extra-axial lesions (Figure 13.7). Perhaps one of the more common extra-axial tumors noted by audiologists is the vestibular schwannoma

FIGURE 13.7 The top tracing is a normal ABR. The next two tracings are from a patient with a meningioma in the right cerebellopontine angle. Note the extended I–III [3.0 ms] and I–V [4.7 ms] interwave intervals on the involved side. [Reprinted from Musiek FE, Shinn JB, Jirsa RE. (2007) The auditory brainstem response in auditory nerve and brainstem dysfunction. In: Burkard RF, Don M, Eggermont JJ, eds. *Auditory Evoked Potentials: Basic Principles and Clinical Application*. Baltimore, CA: Lippincott Williams & Wilkins; pp 291–312 with permission.]

that grows large enough (usually 2 cm or greater) to affect the brainstem. There remains a paucity of data on extra-axial lesions and ABR sensitivity, but some analyses infer hit rates of around 80% or slightly less for a variety of extra-axial lesions (Musiek et al., 1994, pp 356–358). With the exception of an eighth nerve tumor, most extra-axial lesions, like MS, result in extended central conduction times, though the particular site of involvement does influence which of the specific ABR indices will be affected (see Figure 13.7).

Intra-axial tumors arise from within the brainstem with the most common being gliomas (see Hall, 1992, 2007). Again, there is not a wealth of data, but it appears that ABR is highly sensitive to intra-axial tumors (>90%) (Musiek et al., 1994). Similar to other brainstem lesions, IWI's are often abnormal when intra-axial tumors are present.

HYPERBILIRUBINEMIA

High bilirubin levels can be seen in 1 to 3 per 100,000 healthy newborns. If blood serum levels exceed 20 mg/dL it is of clinical concern even though this may not lead to a clinical problem. If bilirubin (unconjugated) is at high levels and crosses the blood–brain barrier, jaundice, HB, and even kernicterus (severe disease state) can occur. Most of the time HB can be easily managed by phototherapy. However, recently HB has become more of a problem because mother and infants are released from the hospital 1 day after giving birth and bilirubin levels generally peak on about the fourth day after birth. Because of this scenario, treatment is often delayed and bilirubin levels increase (see Musiek et al., 2012, pp 309–314).

Audiologists should be aware that high bilirubin levels can damage the CNS and the central auditory nervous system. Specifically, the CN is often damaged resulting in hearing difficulties (Dublin, 1985). Even though newborns with HB can be successfully treated, some manifest auditory problems. Though the incidence of abnormal ABR measures varies considerably (13% to 60%), there is no question that the ABR is a valuable test for detecting the central auditory problem at an early age (Kuriyama et al., 1986; Sharma et al., 2006). Increased absolute latency of Wave V appears to be a relatively common finding in patients with HB and ABR central conduction times (i.e., IWI's) are often abnormal in individuals with this disorder (Sharma et al., 2006). Since the HB lesion site is in the central auditory system, otoacoustic emissions may not be a prudent choice for screening these infants. It is also important to note that with the timely application of therapy, HB resolves and the ABR improves, often to within normal limits (Kuriyama et al., 1986).

HEAVY METAL EXPOSURE

Heavy metals such as lead, mercury, cadmium, and arsenic can compromise auditory function and the ABR can be useful in determining the effects from such exposures. Exposure to

heavy metals can slow nerve conduction, generally manifesting as CNS and central auditory system dysfunction. Clearly the greater the level of heavy metal found in the blood, the greater the possibility exists for cognitive and hearing disturbances (see Musiek et al., 2012, pp 311–317). Increased central conduction times during ABR testing are commonly noted in individuals exposed to heavy metals (Araki et al., 2000); however, interesting data from Counter (2002) showed little effect of lead exposure on the ABR in lead glaze workers in South America. These individuals experienced constant exposure to lead in their daily lives, yet normal or near-normal ABRs were found. (Perhaps their central auditory nervous system adapted to the lead exposure.) Nonetheless, in most situations, ABR should be one of the tests administered to evaluate the neurotoxic effect of heavy metals.

HEAD INJURY

It has become a common role for audiologists to be involved in the evaluation of individuals with a head injury. Key information relates that over half of the patients including children and adults with head injury (i.e., traumatic brain injury) may have central auditory deficits (Bergemalm and Lyxel, 2005). The pathophysiology of a head injury is related to the high acceleration and deceleration of the brain within the confines of the cranium. This can result in contusions, hemorrhage, and axon injury (including myelin damage). Also, secondary effects such as ischemia, hypoxia, edema, and increased intracranial pressure are seen (Musiek and Chermak, 2008). The ABR is commonly employed in the evaluation of head injury to check the physiological status of the brainstem (see Figure 13.8). This becomes even

FIGURE 13.8 The ABR from a patient with a head injury [pontine contusion]. This patient's symptoms of "difficulty in hearing" on the involved side resulted in a detailed audiologic evaluation including the ABR. [Reprinted from Musiek FE, Shinn JB, Jirsa RE. (2007) The auditory brainstem response in auditory nerve and brainstem dysfunction. In: Burkard RF, Don M, Eggermont JJ, eds. *Auditory Evoked Potentials: Basic Principles and Clinical Application*. Baltimore, CA: Lippincott Williams & Wilkins; pp 291–312 with permission.]

more important when the patient involved develops auditory symptoms after the event. Head injuries do not usually result in damage to the brainstem pathways; thus, normal ABRs should be obtained for many patients with head injuries. Therefore, normal ABR findings in head trauma cannot and should not be an indictment against the utility of ABR as an evaluation tool.

A review of significant studies shows ABR to be abnormal in about 50% of people with head trauma (Musiek et al., 2012), with the I–V interval of central conduction time being perhaps the most sensitive ABR index (Bergemalm and Borg, 2001). Also, increases in the latencies of Wave V and the I–V IWI of the ABR have been shown with increases in the severity of the head injury or traumatic brain injury (Munjal et al., 2010). The use of high rep rate ABRs may provide reliable assessment of patients with traumatic brain injuries (see Musiek et al., 2012, p 319); however, more studies are needed to determine if this is a clinically useful approach to detect auditory abnormalities associated with head injuries. Another ABR measure, the V–I amplitude ratio, as discussed earlier in this chapter, may also be of value in evaluating a head injury, although more research is also needed on this ABR measure.

EFFECTS OF COCHLEAR HEARING LOSS ON THE ABR

Degree and Configuration

The presence of a cochlear hearing loss is often encountered when a patient is being seen for a neurodiagnostic evaluation. If present, a peripheral hearing loss can potentially affect the response recorded, frequently resulting in test results that could be mistakenly attributed to the presence of a neural site of lesion. Unfortunately, the variable effects of a cochlear hearing loss are affected by a number of factors, such as the severity, slope and audiometric configuration of the hearing loss, age and/or gender, and complex interactions among these variables (Hall, 2007; Jerger and Johnson, 1988; Watson, 1999). As a result, many of the ABR diagnostic indices used to identify a retrocochlear hearing loss may not be available or their measurements may lead to a false-positive finding when the audiologist is attempting to render a clinical decision re: the presence of a retrocochlear lesion.

The one consistent observation is that the interwave latency (IWI) measures are largely unaffected by a peripheral hearing loss (both conductive and cochlear). Various studies have shown subtle effects of hearing loss on IWIs, but these effects have been subtle and often decrease the IWIs (see Fowler and Durrant, 1994; Shepard et al., 1992). Therefore, if Wave I of the ABR is present, decisions regarding the presence or absence of eighth nerve and/or brainstem abnormalities are relatively straightforward. Unfortunately, many patients with a moderate to severe

sensory/neural hearing loss lack an identifiable Wave I component, rendering the derivation of one or more of the typical IWI measures (I–III, III–V, I–V) impossible. In the absence of measureable IWIs, the audiologist must rely on other ABR measures, such as the absolute latency of Wave V, an ILD for Wave V, and/or the absence of ABR waves, all of which can be affected by a cochlear hearing loss or retrocochlear involvement.

When unfiltered click stimuli are used to derive an ABR the response is largely being generated by activity in the basal region of the cochlea since the signal reaching the basilar membrane is shaped by the filter effects of the outer and middle ears and the response characteristics of the transducer. Although there are some differences in the resonance peak of different transducers, the resonance peaks for most transducers used in electrophysiological assessments tend to occur in the higher frequency range (usually peaking around 3 to 4 kHz), which gives the stimulus reaching the cochlea a high-frequency emphasis. This transducer response (i.e., the high-frequency emphasis), coupled with the fact that the traveling wave stimulates the base of the cochlea before it stimulates the more apical regions of the basilar membrane, leads to an ABR response that is predominately affected by the status of the high-frequency neurons (Fowler and Durrant, 1994; Musiek et al., 2007). For these reasons, the effects of a cochlear hearing loss on the ABR can be quite variable and are highly dependent on the frequency range (low vs. high frequency), the slope or audiometric configuration (flat, mildly sloping, sharply sloping), and the severity of the hearing loss (see Rosenhamer, 1981).

In cases of low-frequency sensory/neural hearing loss, there tends to be little or no effect on the click-evoked ABR since the neurobiologic response is biased toward the high frequencies as discussed above. As the high-frequency cochlear region is not compromised or only minimally compromised in patients with hearing losses confined primarily to the low frequencies, the ABR waveform indices used for neurodiagnostic purposes typically fall within the normal range.

A high-frequency hearing loss will produce variable results. In a mid- to high-frequency hearing loss, Wave V latency is relatively stable up to 60 dB HL, but it increases as the degree of hearing loss at 4 kHz increases. However, the extent of the latency shift is affected not only by the degree of hearing loss, but also by the slope of the hearing loss (Fowler and Durrant, 1994). In cases of a relatively flat or a mildly sloping hearing loss of mild to moderate severity, the effects of hearing loss on the ABR derived at a high stimulus level (e.g., 80 dB nHL) are minimal or nonexistent. Although some reduction in amplitude may be seen, presumably related to the reduction of neural units, the other ABR indices are typically not affected.

With a sharply sloping severe high-frequency sensory/neural hearing loss, the earlier waves may be reduced in amplitude or absent, and any waves that are present are likely

to be delayed in their absolute latencies (Rosenhall, 1981; Rosenhamer, 1981). These changes in the earlier waves are related to (1) the increased travel time for the traveling wave to reach the healthy or active regions of the cochlea and (2) the effective reduction in the stimulus intensity caused by the compromise of the fibers of the basal end of the cochlea, that is, the fibers which respond with the shortest latencies. If Wave I is present and an I–V IWI can be determined, the measured IWI will typically fall within normal limits, contraindicating a retrocochlear lesion. However, if Wave I is not identifiable, the differentiation between a cochlear and retrocochlear lesion becomes more tenuous since both sites of lesion can result in abnormal Wave V latencies and potentially an abnormal ILD especially in cases of unilateral or asymmetrical hearing losses.

Watson (1999) conducted a relatively large-scale investigation designed to examine the effects of a cochlear hearing loss on the specificity and false-positive rates of the various ABR indices. He examined a number of hearing loss variables (including level, slope, and general shape of the hearing loss) in a large number of patients with unilateral or asymmetrical symptoms who were referred for ABR screening for potential retrocochlear involvement. His investigation of 566 ears from 306 participants showed that 85 ears (15%) failed the ABR test. On follow-up, retrocochlear hearing loss was confirmed by the author in seven participants and one additional individual showed an abnormal meatal narrowing (the method of confirmation was unspecified, but assumed to be imaging or surgical confirmation). It was also reported that MRIs were performed on an unspecified number of subjects with normal ABR results and that all ABR “passes” had been under review for at least 3 years (presumably without any additional identifications of retrocochlear lesions). The ABR results for all of the participants with confirmed retrocochlear hearing loss were abnormal, which indicated that the ABR diagnostic measures were highly sensitive for retrocochlear involvement. In patients diagnosed as free of retrocochlear problems, the I–V interval was found to be the most specific measure (>90%) and was relatively independent of degree of high-frequency hearing loss and slope of hearing loss. Although the degree of high-frequency hearing loss did not affect the specificity of the I–V IWI measure itself, there was an effect of the degree of hearing loss (measured at 4 kHz and also as an average threshold at 2 and 4 kHz) and the slope of the hearing loss on the detectability of Wave I, which if not detected precluded the derivation of the I–V IWI. The I–V interval was not measured in 68 of 550 ears (12%) and was found to be significant for the hearing loss at 4 kHz, the average hearing loss at 2 and 4 kHz, and the slope of the hearing loss defined as the difference in audiometric thresholds measured at 4 and 1 kHz.

Wave V specificity was high when hearing loss at 4 kHz was less than 70 dB HL, but was found to decrease with increasing hearing loss and increasing slope with the

specificity of this measure falling below 70% when hearing loss at 4 kHz exceeded 70 dB HL. Abnormal latency measures were found for 48 ears (9%) and Wave V was absent in another 8 ears (2%). Abnormalities of Wave V were found to be relatively low and independent of hearing loss at 4 kHz until this threshold exceeded 60 dB HL. Similar results were associated with increasing average hearing loss, with one in three subjects showing Wave V abnormalities when their 2- and 4-kHz average fell above 60 dB HL. Slope of the hearing loss was also found to affect the specificity of Wave V latency. Nearly half of the cases with Wave V abnormalities (24 of 56 ears) not related to retrocochlear pathology presented with hearing loss slopes measured between 1 and 4 kHz exceeding 30 dB.

A common practice among many professionals is to refer for imaging studies (MRI or CT scans) if asymmetrical or unilateral hearing losses or symptoms are noted during routine audiologic or otolaryngologic assessments, hence bypassing ABR testing in the process. The findings of this study raise questions about this common practice among some professionals. Only a very small number of individuals (~3%) were found to have retrocochlear lesions among the 330 patients who presented with asymmetrical or unilateral hearing symptoms, whereas normal ABR indices were found in the vast majority of the remaining patients. These results would suggest that ABR testing may avoid the need for more costly medical procedures where the incidence of retrocochlear involvement has been shown to be quite low, with cost savings to the healthcare industry.

Formulas to Account for High-Frequency Hearing Loss

The patient who is being evaluated with ABR for neurodiagnostic purposes will typically present with asymmetrical hearing loss. In such cases, an interaural Wave V latency difference may be noted since the absolute latency of Wave V in the affected ear may be delayed. However, a high-frequency sensory/neural hearing loss of cochlear origin may also result in similar delays of Wave V, especially if the hearing loss in the 4-kHz region falls within the moderate to moderately severe range. Under these circumstances, clinicians may be faced with the challenge of determining whether the delayed Wave V latency in the affected ear or poorer hearing loss ear, and the interaural asymmetry that results, is related to cochlear compromise or eighth nerve/auditory brainstem involvement.

A number of procedures have been proposed in an effort to control for latency shifts which may be caused by peripheral hearing loss. Some authors have proposed formulas based on the threshold measure at 4 kHz, whereas others have attempted to account for not only the extent of the hearing loss in the high-frequency range, but also the slope of the hearing loss as the basis for their adjustments Selters and

Brackmann (1977) recommended that 0.1 ms be subtracted from the absolute latency measure for Wave V for each 10-dB increase in a hearing loss above 50 dB HL. An ILD exceeding 0.2 ms following the correction for hearing loss above 50 dB HL would be considered abnormal. However, many individuals with a similar hearing loss at 4 kHz have differing Wave V latencies. As a result, the interpretation of an ILD difference following the application of adjustments to the latency of Wave V to account for a high-frequency hearing loss can result in inaccurate clinical decisions.

Prosser and Arslan (1987) proposed a diagnostic index (ΔV) to differentiate between a cochlear and a retrocochlear lesion when a sensory/neural hearing loss was evident. In this approach, a ΔV index is calculated based on the following formula: $\Delta V = L_p(90) - L_n(90-x)$, where $L_p(90)$ is the latency of Wave V derived at 90 dB nHL, $L_n(90)$ is the Wave V latency derived from a normal intensity function, and x is the average hearing loss at 2 and 4 kHz. These authors suggest that a negative ΔV would be consistent with cochlear hearing loss, whereas a positive ΔV would suggest a retrocochlear lesion. Further, a regression analysis on their cochlear hearing data with a 95% confidence interval for cochlear hearing loss was conducted and indicated that this measure was effective in differentiating cochlear and retrocochlear hearing losses.

Rosenhamer et al. (1981) offered a correction method for high-frequency hearing loss as a guideline for ABR interpretation when an asymmetrical hearing loss was present. These authors recommended that 0.1 ms be subtracted from the Wave V latency for every 10 dB of increased hearing loss above 30 dB HL; loss at 4 kHz greater than 50 dB HL. However, the authors noted the value of using sensation levels as opposed to hearing levels or sound pressure levels when evaluating patients with unilateral or asymmetrical hearing losses, which presumably eliminates the need for the application of a correction factor.

Building on this later concept, Jerger and Johnson (1988) offered the following guidelines for determining click stimulus intensity level for neurodiagnostic evaluations, which attempt to adjust for sensation level by increasing the stimuli intensity level based on the puretone average for high frequencies (1, 2, 4 kHz). Click intensity levels of 70, 80, 90, and 100 dB HL are recommended for male (but not female) patients with high-frequency averages in the following ranges, respectively: 0 to 19, 20 to 39, 40 to 59 and 60 to 79 dB HL. Other researchers (Hyde and Blair, 1981) have additionally suggested that different correction factors are needed for young versus older patients with comparable hearing losses.

Although many researchers support the use of correction factors to account for hearing loss, their application in neurodiagnostic assessments must be used with appropriate levels of caution as a number of factors can affect the latency of Wave V when cochlear hearing loss is present. For example, Wave V latency can vary considerably among patients with the same degree of hearing loss, and interactions between

factors such as age, gender, and hearing impairment have been shown to exist (see Rosenhall, 1981; Watson, 1999). These factors limit the universal application of correction factors.

As the I–V index has been shown to be largely unaffected by peripheral hearing loss, the best approach in addressing the challenges imposed by the presence of a potential cochlear hearing loss would be to take steps to increase the likelihood of deriving a Wave I. In many cases where Wave I is not observed using common procedures (e.g., surface electrodes placed at A1 and A2; stimulus intensity of 70 or 80 dB nHL), an identifiable Wave I can be elicited if the intensity of the eliciting stimulus is increased and/or extratympanic or intracanal electrodes are used. If Wave I can be derived, then an I–V IWI can be determined. As the I–V IWI has been shown to be highly sensitive to retrocochlear hearing loss and is not affected by cochlear and/or conductive hearing loss, the presence of an extended IWI would be a positive finding, which has been shown to be highly sensitive for retrocochlear involvement.

SUMMARY AND CONCLUDING COMMENTS

This chapter has reviewed the perspectives of ABR in reference to auditory nerve and brainstem disorders. The ABR remains a powerful and, in many cases, a necessary tool for shedding light on disorders of the brainstem and auditory nerve—especially from the audiologist’s point of view. The early investigators of ABR who pioneered the application of this then new procedure showed how it could be utilized in many ways and across many disciplines. The ABR in its diagnostic infancy triggered a focus on the importance of audiology and audiologists because of its impact on otologic and neurologic diagnosis. These interactions across disciplines benefitted patients as well as research into hearing disorders.

The diagnostic use of ABR is dependent on the anatomy of the generators of its various waves. Though some minor controversies still exist, the generator sites of ABR are known and because of this, the integrity of the auditory nerve and brainstem pathways can be assessed. Aage Møller’s work on ABR generators in humans in the 1980s was a key advance for not only auditory science, but also clinical applications. Without firm knowledge of the generator sites, clinical advances could not have been realized.

FOOD FOR THOUGHT

A segment of this chapter discussed a controversial issue related to referring directly for imaging and bypassing ABR for vestibular schwannoma detection. This practice has its advantages, but recently it has become clear that there is an over-referral for expensive imaging testing with a poor ratio of “hits” compared to negative findings. The ABR, if applied

appropriately, could help resolve this problem. This issue sorely needs to be revisited again, especially in light of increasing healthcare costs. The model offered by Urben et al. (1999) deserves more attention regarding this issue.

To optimize the use of ABR in retrocochlear diagnosis, an accurate perspective on various ABR measurements or indices needs to be realized. Interwave latency intervals (I–III, III–V, I–V) are solid indicators of auditory nerve and brainstem function. In addition, they are essentially unaffected by hearing loss, a situation that does not exist for other ABR indices. The ILD though influenced by hearing loss still remains highly applicable and very sensitive to eighth nerve involvement, but interestingly not brainstem involvement. Vestibular schwannomas and brainstem disorders that affect the auditory pathways yield various ABR patterns that are helpful in measuring the integrity of the neural auditory tracts. For example, Waves I–III extensions are often indicators of eighth nerve or low brainstem involvement. Absent late waves or extended Waves III–V intervals argue strongly for brainstem compromise. It is also important for the clinician to realize that there are a variety of auditory nerve and brainstem disorders for which ABR testing can be applied. In many instances, imaging may not be helpful in defining a disorder, whereas ABR becomes the best and perhaps the only avenue for effective diagnosis. How can the audiologist participate in the identification of ANSD, head injury with auditory involvement, various neurotoxic effects, and some subtle early auditory degenerative diseases if they do not utilize the ABR?

Auditory Brainstem Response: Estimation of Hearing Sensitivity

Linda J. Hood

INTRODUCTION

Early identification of hearing loss is now well established in the evaluation and care of newborn infants. The positive impact of identification of hearing loss in infants on language outcomes has been definitively demonstrated (e.g., Yoshinaga-Itano et al., 1998). Timelines that include identification of hearing loss before 1 month of age, thorough evaluation of an infant by 3 months of age, and implementation of management before 6 months of age are incorporated into widely recognized recommendations (e.g., JCIH, 2007; see Chapter 23). For early identification to be effective, test methods that can accurately quantify auditory threshold sensitivity in infants must be available to provide adequate follow-up of those who do not pass newborn hearing screening.

Objective measures are key components in a test battery for young children in whom, for reasons that might include developmental delays, the ability to obtain reliable responses through behavioral testing is not possible. Auditory-evoked potentials (AEPs), when used and interpreted properly, also provide a powerful method of obtaining reliable estimates of auditory sensitivity in individuals of all ages who either cannot or will not provide reliable results on behavioral hearing tests.

AEPs in general provide objective assessment of auditory function with two broad areas of application: (1) Identification of neurologic abnormalities of the VIII cranial nerve and auditory pathways and (2) estimation of hearing threshold sensitivity. Applications in both of these general areas exist across AEPs obtained from the cochlea to the cortex and in patients of all ages.

The auditory brainstem response (ABR) is an evoked potential used to both assess neural response integrity and obtain estimates of hearing thresholds. Although the ABR is not a test of hearing per se, the information obtained can be useful in estimating or predicting hearing thresholds. To accurately characterize threshold sensitivity, information must be obtained for defined frequency regions, as is standard practice in behavioral testing via puretone audiometry. Presently, there are two approaches that are considered appropriate objective measures for obtaining responses to

frequency-specific stimuli in infants and young children. These methods are the ABR and the auditory steady-state response (ASSR). This chapter will focus on the ABR as it can be applied to threshold prediction; the ASSR is thoroughly described in Chapter 15.

A HISTORICAL PERSPECTIVE

AEPs from the cochlea to the cortex have been studied as possible methods to assess hearing. Indeed, Hallowell Davis' pioneering work with cortical potentials first reported in 1939 was, in part, directed toward the development of a technique to assess auditory function without the need for patient participation. Cortical responses and middle latency responses, studied in the 1950s and 1960s, proved useful in acquiring the necessary information about threshold sensitivity (e.g., Davis, 1976). However, these responses generally require patients to be awake, cooperative, and alert during testing to maintain response amplitude. Steady-state responses, recorded with a slower rate of 40 Hz and primarily cortical in origin (Galambos et al., 1981; Kuwada et al., 2002), are also an efficient method of obtaining estimates of hearing sensitivity; however, this response again is affected by sleep and sedation which limit its application in infants and young children. Thus, whereas cortical responses have higher face validity in that they evaluate a greater proportion of the auditory pathway, the applications in infants and young children are limited in the population most in need of an objective method of assessing hearing sensitivity.

If the goal of hearing testing is to determine peripheral hearing sensitivity, then measurement of responses directly from the cochlea would seem ideal. In fact, electrocochleography proved a very useful technique in the 1960s and 1970s. However, the somewhat invasive nature of transtympanic or eardrum recording sites limited its widespread clinical application, particularly in infants and young children. The relative ease of recording the ABR and its resistance to the effects of sleep and sedation have facilitated widespread use of this AEP in prediction of hearing thresholds in infants and children, as well as adults.

WHAT THE ABR TESTS

Although AEPs have proven useful in estimating hearing thresholds, it is important to remember that the ABR is NOT a test of hearing! The ABR and other evoked potentials assess neural synchrony, that is, the ability of the peripheral and central nervous system to respond to external stimulation in a synchronous manner. A synchronous neural response results from simultaneous firing of a group of neurons. Since clinical recording of responses is completed in a far-field manner via electrodes placed on the scalp, away from the source of the response, a sufficient number of neurons must fire together to yield a response of sufficient amplitude to be recorded at this distance.

When the auditory nervous system pathways are functioning normally, we can use evoked potentials to record neural responses to stimuli presented at various intensity levels. Thus, by presenting stimuli at a series of intensity levels above and below threshold, one can infer sensitivity at the periphery based on whether or not sound was able to pass through the ear and cause the sources of the neural response to respond in a synchronous manner. For individuals who do display synchronous neural responses, we can find the lowest stimulus intensity level that yields the neural response and relate that to a threshold for hearing. A limitation, in relation to patients with auditory neuropathy/dys-synchrony, will be discussed later.

ABRs can be obtained at intensities very close to behavioral thresholds if a sufficient number of responses are averaged to adequately reduce the background physiological noise (Elberling and Don, 1987). This requires a greater number of stimuli, on the order of 10,000 sweeps per test level and smaller intensity step sizes, and thus a longer time than is clinically feasible. In routine clinical procedures where fewer responses are averaged, responses can generally be obtained near, but not at, behavioral thresholds in a quiet subject.

WHEN TO USE THE ABR TO ESTIMATE AUDITORY FUNCTION

AEPs are best utilized when the clinician desires a noninvasive, objective approach to assessment of auditory function in infants, children, and adults who cannot participate in voluntary behavioral audiometric procedures. AEPs are espe-

cially useful when one wishes to know the sensitivity of each ear separately, to compare responses by air and bone conduction with or without masking, and to estimate auditory function in various frequency regions. Since AEPs are a test of the neural system, insight into the integrity of the neural pathways should also be considered. AEPs should not be used in lieu of a behavioral audiogram in patients who can provide reliable behavioral responses. An ultimate goal in all patients, where possible, should be to obtain behavioral responses and use this information in combination with physiological responses. In infants and young children, behavioral responses may be obtained at a later time, but, in the meantime, appropriate management can and should begin based on AEP results. Comparisons of evoked potential and behavioral responses provide a valuable clinical cross-check and confirmation of results on each measure individually.

WHY ARE FREQUENCY-SPECIFIC STIMULI NECESSARY?

Although broadband stimuli, such as clicks, are useful for evaluation of patients with suspected neurologic disease and for establishing neural synchrony, clicks are not considered appropriate for threshold testing. Because clicks are broad band in nature and also stimulate more basal regions of the cochlea, it is not possible to know the exact frequency range being tested. This is particularly problematic in patients with sloping (either positively or negatively) hearing losses. Furthermore, behavioral puretone audiometry is completed at multiple frequencies, not just one frequency. Figure 14.1 shows two hearing losses where clicks or other broadband stimuli will underestimate or miss a hearing loss. In Figure 14.1A, clicks will **underestimate** or **miss** this high-frequency hearing loss. The latency may be longer since lower frequency regions are stimulated. In Figure 14.1B, a click will **underestimate** or more likely **miss** this low-frequency hearing loss. Responses to clicks will be dominated by cochlear basal responses and will not reflect a hearing loss in more apical regions of the cochlea.

Types of Frequency-Specific Stimuli

A 100-microsecond electrical pulse, impressed on an earphone, generates a broadband signal whose primary

FIGURE 14.1 Example audiograms depicting puretone thresholds for right (dark gray) and left (light gray) ears that are consistent with a downward sloping hearing loss in **(A)** and an upward sloping hearing loss in **(B)**.

frequency emphasis is determined by the resonant frequency of the transducer. With earphones typically used in clinical evaluation, the maximum energy peaks of these clicks are focused in the frequency region between 1,000 and 4,000 Hz (e.g., Don et al., 1979). The greatest agreement with puretone thresholds is in the 2,000- to 4,000-Hz frequency range (Bauch and Olsen, 1986).

Several types of stimuli and recording methods have been proposed to obtain responses from narrower frequency regions. Some alternative stimuli and methods include tone bursts or tone pips, filtered clicks, tone bursts in notched noise, and high-pass masking of clicks or tone bursts. Each type of stimulus appears to have advantages and limitations, and stimulus selection is dependent on frequency specificity, the amount of time available for testing, and the equipment available.

Techniques of masking test stimuli, in an effort to obtain greater control and precision related to the frequency content of the stimulus, have been the focus of several investigations. In a method pioneered by Teas et al. (1962), the cutoff frequency of a high-pass masker is progressively decreased and click ABRs at adjacent cutoff frequencies are subtracted from the filtered ABR and/or from the preceding ABR. This method allows separation of frequency-specific wave components and has been shown to be useful in audiogram reconstruction (Don et al., 1979). A modification of this method uses tone bursts presented in the presence of a high-pass masker (Kileny, 1981). By presenting stimuli simultaneous with a masker, the higher frequency response regions of the cochlea are blocked and the resulting responses reflect activity in frequency areas outside of the masker region.

Presentation of stimuli in notched noise narrows the stimulation to limited regions of the basilar membrane through presentation of a noise masker with components above and below the frequency range of interest (e.g., Picton et al., 1979). The presence of the notched noise masker restricts the cochlear region able to contribute to the ABR to those frequencies within the band of the notch. Although the utility of this method has been clearly demonstrated, additional special equipment or software may be needed to create and present the noise. Further, studies have demonstrated similar results with and without notched noise masking for most cases of hearing loss, with exception being very steeply sloping losses (e.g., Johnson and Brown, 2005).

Presently, tone bursts or tone pips, without high-pass or notched noise masking, are the most widely accepted and preferred stimulus for frequency-specific ABR evaluation. This chapter focuses on the use of tone bursts centered at various frequencies in recording frequency-specific ABRs.

Frequency Specificity versus Neural Synchrony

When using frequency-specific stimuli there is a trade-off between frequency specificity and neural synchrony. Tone

bursts with longer rise times will be more frequency specific, but will generate poorer neural synchrony which will affect the quality of the ABR. As already emphasized, the goal of using ABR for threshold prediction is to stimulate isolated regions of the basilar membrane to analyze function in distinct frequency regions. Thus, control of spread of acoustic energy to surrounding frequencies works in opposition to the ability to activate a large number of neural units and obtain a clearly synchronous ABR. The more abrupt the acoustic onset of the stimulus, the more synchronous the neural discharge and the clearer the resulting ABR. However, as noted previously, abrupt onset, broadband stimuli have poor frequency specificity.

Although the ideal stimulus for frequency-specific ABR would be a puretone, this is not possible because stimuli with long rise times (needed to maintain integrity of a puretone) will not yield sufficient neural synchrony to obtain an ABR at the surface of the head. Thus, the stimulus used in ABR testing has a shorter onset (rise time) than a puretone, but longer than a click (which is essentially instantaneous). This results in some spectral spread of the tone burst stimulus, compared to a puretone. However, the spectrum of the tone burst is considerably narrower than a click and thus stimulation along the basilar membrane is restricted and reasonably frequency specific. In interpreting results, it is important to remember that the use of tone bursts results in stimulation of the cochlea at frequency regions surrounding the target frequency as well as at the desired frequency.

Frequency Specificity versus Place Specificity

There is a difference between frequency specificity and place specificity. Frequency specificity refers to the characteristics of the stimulus whereas place specificity reflects a region of the cochlea. Although the frequency regions activated may be relatively narrow at low intensities, there is considerable spectral spread for moderate-to-high-intensity signals. When presented at higher intensities, on the order of 60 to 80 dB HL or higher, even puretones can activate wider frequency ranges on the basilar membrane surrounding the center frequency of the stimulus (Moore, 2004).

Spread of excitation can be particularly problematic in underestimating hearing loss in individuals with steeply sloping hearing losses. A tone burst presented to an ear with a steeply sloping high-frequency hearing loss may yield a response, but that response may be generated from stimulation of a lower frequency responsive region where thresholds are better. Although latencies may be longer because of more apical stimulation, it can remain difficult to determine the source of the response and there is risk of underestimating a hearing loss. Thus, caution must be exercised in interpreting ABRs, particularly as in the case of infants where behavioral thresholds are unknown.

STIMULUS CONSIDERATIONS IN ABR THRESHOLD TESTING

Characteristics of the ABR will change as a result of a number of stimulus, recording, and patient factors. The effects of these factors must be considered when designing test protocols for various clinical populations, determining appropriate stimulus parameters, setting recording parameters, and interpreting ABRs. Stimulus, recording, and subject factors will be discussed in regard to applications in ABR threshold prediction in the following sections. We begin with stimulus factors.

Changes in the settings used in creating test stimuli can affect the latency and the amplitude of the ABR. An understanding of the effects of parametric changes in the stimulus is necessary to correctly interpret test results. And, importantly, understanding the results of adjusting various stimulus settings can be used to the examiner's advantage in obtaining the best possible responses.

Tone Burst Envelope Characteristics and Gating Functions

Whereas puretones have long rise times, in the range of 20 to 200 ms, tone bursts must have shorter rise times to achieve needed synchronous neural responses. As noted earlier, shortening the onset time of a stimulus results in broadened spectral characteristics. The optimal stimulus will maintain as much frequency specificity as possible while allowing activation of a sufficient number of neurons to record a far-field response. Characteristics needed to achieve this goal have been derived from studies that compare various stimulus rise times and durations across frequency and intensity.

Davis et al. (1985) recommended a tone burst with two cycles of rise time, a one-cycle plateau, and two cycles of decay, known as a "2-1-2 envelope." Changes in envelope characteristics affect the spectrum of the stimulus, the intensity (and the loudness because of durational changes and temporal integration), and the latency of the response because a longer rise time results in increased latency. By holding the number of periods in the stimulus constant across different frequencies, the power spectrum is held constant.

To create appropriate stimuli, one needs to recall the duration of a single cycle for various frequencies. For example, one cycle of a 500-Hz tone is 2 ms in duration. Therefore, to create a 2-1-2 envelope, the rise time would be 4 ms (two cycles at 2 ms per cycle), the plateau would be 2 ms (one cycle), and the fall time would be 4 ms (two cycles). This would add up to a total envelope duration of 10 ms. As another example, a 1,000-Hz tone burst would have a total envelope duration of 5 ms (2 ms rise, 1 ms plateau, and 2 ms decay). These stimulus parameters have generally held the test of time with some minor modifications. For example, since the ABR is an onset sensitive response, the plateau contributes little to the utility of the stimulus. Thus,

envelopes now used often have no plateau and are referred to as 2-0-2 cycle envelopes.

The envelope of a stimulus is constructed using various types of windowing or gating functions, in other words the way in which stimuli are turned on and off. A linear envelope involves an abrupt change from no signal to the rise (or ramp) of the signal. A nonlinear windowing function, such as a Blackman window, has a curvilinear onset. Although differences in spectra have been observed with linear versus nonlinear functions, studies have shown similar ABR results using either linear or Blackman windowing functions (e.g., Johnson and Brown, 2005; Oates and Stapells, 1997). Thus, although some prefer to use a nonlinear, such as Blackman, function, either can be used. Most current clinical ABR equipment uses the Blackman or nonlinear functions as the default setting.

A caution is needed related to equipment settings for stimulus durations and windowing functions. The way in which these are set varies across ABR systems. Some systems will differentially ask for duration settings in either cycles or milliseconds depending on the type of envelope requested. Further, some systems require information about the total duration of the stimulus whereas others set stimuli according to rise and fall times separately. The key here is to understand the desired and appropriate characteristics and know how to calculate those according to the specific ABR system requirements. Knowing this will avoid errors that could result in stimuli with poor frequency specificity (rise time or envelope too short) or poor neural responses (rise time or envelope too long).

Stimulus Frequency

Higher frequency stimuli elicit shorter ABR latencies than lower frequency stimuli. These latency differences occur because high-frequency stimuli activate more basal portions of the basilar membrane, resulting in earlier neural activation and shorter latencies compared to stimuli centered at lower frequencies. Since lower frequency stimuli have to travel further toward the apex of the cochlea, latencies for these stimuli will be longer. Because all components of the ABR are dependent on cochlear processing, all waves of the ABR (e.g., Waves I, III, V) will display shorter latencies for higher frequency tone bursts and longer latencies for lower frequency tone bursts. (For reference, a sample of a normal ABR, obtained with click stimuli, is shown in Figure 11.1 in Chapter 11.) ABRs obtained to tone bursts centered at 500, 1,000, 2,000, and 4,000 Hz are shown in Figure 14.2. Here it can be seen that latencies for Wave V at comparable intensities are longer for low-frequency tone bursts than for high-frequency tone bursts.

Stimulus Intensity

As stimulus intensity decreases from 70 or 80 dB nHL to the threshold of detectability, all waves of the ABR show a

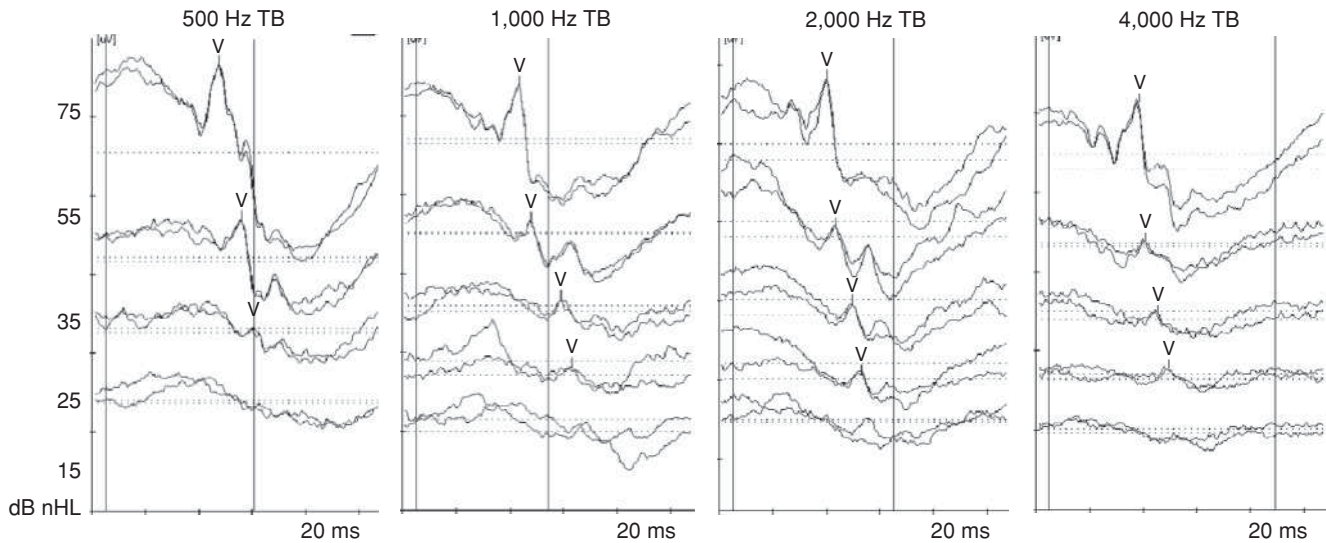

FIGURE 14.2 ABRs to tone bursts centered at 500, 1,000, 2,000, and 4,000 Hz recorded from an individual with normal hearing. The latencies of Wave V at 75 dB nHL are 8.53 ms for a 500-Hz tone burst, 7.70 ms for a 1,000-Hz tone burst, 7.03 ms for a 2,000-Hz tone burst, and 6.53 ms for a 4,000-Hz tone burst, demonstrating the latency decrease as center frequency of the tone burst increases.

systematic increase in latency and decrease in amplitude (Picton et al., 1974; Starr and Achor, 1975). This is illustrated in Figure 14.2. Wave V is most visible at lower intensity levels whereas the earlier components tend to become indistinguishable at lower intensities. The intensity at which earlier waves become less apparent also depends on tone burst frequency. Changes in Wave V latency with intensity are nonlinear with shifts on the order of approximately 0.2 to 0.3 ms per 10 dB through mid-intensity ranges and more rapid changes in latency at lower intensities and near response thresholds.

The amplitude of the ABR is rarely greater than 1 microvolt and no consistent trend in amplitude growth as a function of intensity has been reported (Hecox and Galambos, 1974; Jewett and Williston, 1971). This is most likely related to the considerable variation in amplitude within and among subjects, as amplitude is more highly influenced by noise than latency. The amplitude of Wave V is less affected by intensity decreases than earlier components (Pratt and Sohmer, 1976; Terkildsen et al., 1975).

It is important to note that the actual intensity and frequency information reaching the cochlea is dependent on the acoustic properties of the transducer, the volume of the external ear canal, and middle-ear transmission characteristics. This can be particularly problematic in infants and young children whose ear canals are small. It is possible that technologic advances will facilitate use of a transducer containing a probe microphone to monitor the sound pressure level in the ear canal and a method to account for intensity differences as a function of ear canal volume. This should be especially useful in neonatal screening and testing of infants and young children.

Stimulus Rate

The rate at which test stimuli are presented affects both the latency and the amplitude of the various components of the ABR. In general, at stimulus rates above approximately 30 stimuli per second, the latency of all components of the ABR increases and the amplitude of the earlier components decreases (e.g., Don et al., 1977; Terkildsen et al., 1975). Latency does not increase by the same amount for all components. With increasing stimulus rate, the later components (e.g., Wave V) show a greater latency increase than the earlier components, which results in a prolongation of the Waves I–V interwave interval. Wave V also shows less of an amplitude decrease at high rates, which can facilitate the use of higher stimulus rates in evaluation.

Stimulus rate is an important consideration in testing infants and young children. Faster stimulus rates may help in decreasing test time since more stimuli can be presented in a shorter period of time. Faster stimulus rates may be useful, with some caveats discussed later, in threshold-seeking procedures where only the presence or absence of Wave V is of interest. However, faster stimulus rates may also reduce the clarity and reproducibility of responses, particularly for the earlier components. As noted later, this can be problematic if response amplitude is reduced and thus the signal-to-noise ratio is compromised. Here, results could suggest the presence of a hearing loss when, in fact, hearing thresholds are normal.

Stimulus Polarity

Stimulus polarities for ABR testing can be selected as rarefaction, condensation, or alternating between rarefaction

and condensation stimuli. Because latencies of the various components in the resulting response are dependent on the polarity of the test stimuli, both consistent use of a particular polarity when comparing results to normative data or previous tests and knowledge of the effects of polarity are critical.

A rarefaction stimulus produces an initial outward movement of the earphone diaphragm that generally leads to an outward movement of the footplate of the stapes and an upward motion of the more basal structures of the organ of Corti. Because the upward motion of the basilar membrane is the depolarizing motion for the hair cells, latency is slightly shorter and amplitude is higher for the early components of the ABR for rarefaction pulses in comparison to condensation pulses in the majority of subjects (e.g., Stockard et al., 1979). Condensation stimuli produce an initial inward movement, followed by outward movement and depolarization of the hair cells. Thus the early components of the ABR may be slightly longer in latency than those produced using rarefaction pulses. Wave V amplitude tends to be larger in response to condensation stimuli for normal-hearing subjects. There is no significant latency difference in Wave V latency to rarefaction or condensation stimuli (e.g., Stockard et al., 1979).

At high intensities and for bone-conduction testing, use of alternating polarity reduces stimulus artifact. Alternating polarity stimuli for air-conduction testing, particularly in the lower frequencies, can be a problem as responses in some subjects to condensation versus rarefaction stimuli can be out of phase, as described below. Use of insert earphones, with an inherent delay of 0.9 ms that separates the stimulus generation from the time it reaches the ear, results in reduced interference of stimulus artifact with the response. Therefore, the need for alternating polarity stimuli may be less of an issue for air-conduction testing. Alternating polarity stimuli are recommended when using a bone-conduction transducer where large electrical artifacts from the bone oscillator are problematic.

POLARITY CONSIDERATIONS

When the polarity of a stimulus is reversed, latency shifts in the peak of the response may be observed. Typically, higher frequency tone bursts (e.g., 2,000 or 3,000 Hz and above) tend to show little or no latency shift with polarity reversals. However, tone bursts centered at lower frequencies, such as 250 or 500 Hz, can show large latency shifts in some individuals that can degrade the waveform and even be out of phase with the opposite polarity (Gorga et al., 1991; Orlando and Folsom, 1995). Thus, whereas it may seem intuitively desirable to alternate polarity to minimize stimulus artifact, in fact the use of alternating tone bursts for lower frequencies can be detrimental in some cases.

Consistent with the observation of greater latency differences between condensation and rarefaction polarity stimuli for lower frequencies, studies of patients with high-

frequency hearing loss show considerable latency changes within individuals as a function of polarity. Simulation of high-frequency hearing loss through high-pass masking indicates that the polarity effects are primarily because of lower frequency contributions to the response that would be particularly apparent in person with high-frequency hearing loss (Schoonhoven, 1992). Large latency differences between polarities are observed in individual subjects whereas there do not seem to be systematic trends when comparisons are made on a group basis (Schoonhoven, 1992; Sininger and Masuda, 1990). Because phase reversals can degrade an ABR sufficiently to interfere with accurate interpretation and reversals appear to have a detrimental effect in some individuals, use of single polarity stimuli is recommended in patients with high-frequency hearing loss and patients, such as infants and young children, where hearing threshold configuration is not known.

There also is a group of patients in which ABRs appear to be present when in fact the acquired waves represent the cochlear microphonic (CM; e.g., Berlin et al., 1998). In these patients, described as having auditory neuropathy/dys-synchrony, the peak latency does *not* increase as the intensity of the stimulus is decreased; the first indication that this is not a neural response. When the polarity of the stimulus is reversed, the waves also invert, consistent with the characteristics of the CM. Present CMs are seen in infants with no ABR but present otoacoustic emissions (OAEs). CM is also seen in infants with present ABRs which is a normal observation, providing evidence of intact cochlear and neural function. Comparing separate averages of both rarefaction and condensation stimuli will aid in identification of patients with auditory neuropathy/dys-synchrony and, as discussed later, this procedure is now a part of our standard ABR protocol.

Chirps

As noted earlier, a click stimulus is theoretically broad in bandwidth because of its rapid onset. Although clicks stimulate broad regions of the cochlear partition, in cases of normal hearing or a flat hearing loss, the resulting ABRs are generally attributed to responses from more basal, or higher frequency, regions of the cochlea. The tonotopic design of the cochlea results in temporal delays because basal portions are activated earlier in time than more apical regions. These cochlear delays can result in phase cancellations based on the accumulation of responses from individual neural units that contribute to the total ABR (Don and Eggermont, 1978). Such phase cancellations can have a detrimental effect on the amplitude of the averaged response of the ABR.

Recently, stimuli that are called “chirps” have been applied to ABR testing (e.g., Fobel and Dau, 2004) and, more recently, frequency band limited chirps have drawn considerable interest as a stimulus for frequency-specific ABR testing (Elberling and Don, 2010). Use of chirp stimuli

FIGURE 14.3 Example of a broadband chirp, plotted with time on the *x*-axis and amplitude on the *y*-axis. Note that lower frequencies [toward the left] precede higher frequencies [toward the right] in time. In this way, theoretically, more apical portions of the cochlea are stimulated earlier than more basal regions, resulting in increased synchronous neural firing.

results in ABRs that theoretically allow simultaneous contribution of neural activity from all cochlear frequency regions. In creating a chirp stimulus, higher frequency components contributing to the stimulus are delayed in time relative to the lower frequency components (Dau et al., 2000). Through this stimulus generation, chirps are designed to offset cochlear delays and increase synchronous neural firing, resulting in increased response amplitude (e.g., Fobel and Dau, 2004). An example of a chirp stimulus is shown in Figure 14.3.

Several studies have demonstrated higher ABR amplitude with broadband chirps in comparison to clicks (e.g., Elberling and Don, 2008; Fobel and Dau, 2004; Maloff and Hood, 2014). With the need for frequency-specific stimuli in using ABR to estimate hearing sensitivity in pediatric populations, frequency-specific chirp stimuli have been created. A type of frequency-specific chirps, known as octave-band chirps, may provide a more sensitive frequency-specific metric through generation of higher amplitude responses and thus lower response thresholds (Elberling and Don, 2010). Reports are beginning to appear that systematically compare broadband and frequency-specific stimuli in patients of various ages.

Stangl et al. (2013) compared physiological response amplitudes and thresholds for stimuli currently used in clinical settings (click, tone burst) to broadband and frequency-specific chirp stimuli (CE-Chirp, octave-band chirp). ABR Wave V amplitudes were significantly greater for broadband chirp than click stimuli at 60, 40, and 20 dB nHL, consistent with previous studies (Kristensen and Elberling, 2012; Maloff and Hood, 2014). For frequency-specific stimuli, ABR Wave V amplitudes were generally greater for octave-band chirps than for tone burst stimuli, though the amplitude differences varied with stimulus frequency and level. An example of an intensity series for a 2,000-Hz octave-band chirp is shown in Figure 14.4. Greater differences occurred at higher intensities and no significant differences were found for 500-Hz stimuli. Higher amplitudes for frequency-specific stimuli have also been reported by Ferm et al. (2013) and Wegner and Dau (2002).

Higher amplitude responses can result in improved signal-to-noise ratios. With similar noise levels and higher amplitude responses for chirp stimuli, lower ABR thresholds and better agreement with behavioral thresholds would be predicted. With the desire to utilize the most efficient and sensitive paradigms in pediatric applications where ABR is used to obtain estimates of hearing sensitivity, frequency-specific chirp stimuli may offer advantages for accurately determining hearing sensitivity and hearing loss configuration.

RECORDING CONSIDERATIONS IN ABR THRESHOLD TESTING

Infants differ from adults in many ways and this includes characteristics affecting recording of ABRs. For example, differences in head size and shape should be considered in placing electrodes to obtain optimal responses. Infants have longer ABR wave latencies than adults which translate to lower frequency content of infant ABRs. Both longer latencies and lower frequency characteristics require changes in the recording window and the filter settings, respectively, to be sure to encompass the response of interest.

FIGURE 14.4 Examples of ABRs to octave-band chirps in the **left panel** and tone bursts in the **right panel** centered at 2,000 Hz recorded from an individual with normal hearing.

Electrode Montages

Placement of electrodes at the vertex (C_z) and ears (A_1 and A_2) and recording between vertex and ear (C_z-A_1 for the left side and C_z-A_2 for the right side) are optimum for recording the ABR in most conditions. Waves I–III are more prominent in ipsilateral recordings whereas Waves IV and V are better separated in contralateral recordings. Earlobe sites tend to result in less muscle potential than mastoid recording sites and greater Wave I amplitude. Use of a noncephalic site (recording from the vertex to the nape of the neck, C_7) can enhance the amplitude of Wave V.

In infants, the recommended electrode montages differ from adults. A contralateral montage (vertex or high forehead to the ear contralateral to the stimulus ear) is not recommended in infants as the response is poor in newborns in this channel. In a comparison of two electrode montages in infants, thresholds were lower when recorded from the vertex to the nape of the neck (Sininger et al., 2000). Although amplitude was higher at this location, noise levels were also higher than for a vertex to mastoid montage. This may be attributed to proximity of the nape electrode to the torso and additional physiological noise sources. Both electrode montages appear to work well in threshold estimation application.

Filter Settings

When speaking of filtering and filter characteristics related to the recording of the ABR, one is describing the filter band through which the physiological response is recorded from the electrodes. This is distinguished from any filtering of a stimulus transduced through an earphone or bone oscillator. Filtering of the physiological response is used to eliminate as much internal noise (e.g., unrelated muscle potentials, general physiological activity) and external electrical noise (e.g., 60 Hz, other equipment in the environment) as possible. The filters are set to pass the signal of interest, in this case the ABR.

Changes in the frequency band through which the physiological response is filtered affect waveform latency and amplitude. Changing the filter so that there is more high-frequency information in the biologic signal generally decreases the latency of the response. Allowing more low-frequency information into the average typically results in more rounded peaks and longer latencies. Interference from electrical sources and muscle activity increases as more low frequencies are included. Wave V amplitude may increase because it is dependent on the amount of low-frequency energy included because of the low-frequency components of Wave V. Use of very narrow filters and steep filter slopes is discouraged because phase shifting may occur in frequency regions near the cutoff frequencies.

As noted earlier, infant ABRs have longer latencies and contain more lower frequency energy. Therefore, when testing

infants, lowering the low-frequency filter setting from 100 to 30 Hz will often enhance the amplitude of infant ABRs (Sininger, 1995; Spivak, 1993).

Time Window

The recording time window, or analysis time, should be set to encompass all components of the response. The duration of the time window will vary with the age of the patient and the intensity and type of stimulus used. For presentation of click stimuli in adult patients, a time window of 10 to 12 ms is usually sufficient to record the ABR since Wave V occurs in normal individuals within 5 to 6 ms of the stimulus at high intensities and within 8 ms for intensities near threshold. Use of insert earphones will delay the response by slightly less than 1 ms which is still within this time frame. In infants, however, ABR waves are longer, on the order of 1 ms or more; therefore, a time window of at least 15 ms is recommended when testing patients below 18 months of age or in patients older than 18 months where delays in neuromaturation are suspected.

Whereas a 10- to 15-ms time window is usually sufficient when presenting click stimuli, ABR testing with tone bursts requires a time window of at least 20 ms. This is particularly true when using 250- or 500-Hz tone bursts where the stimuli have a longer onset time and activate more apical portions of the cochlear partition. In practice, when testing low frequencies at low intensities in an immature system, a window of 25 ms may be desired.

One- versus Two-Channel Recordings

Recording two channels simultaneously allows acquisition of both ipsilateral and contralateral (or midline) recordings simultaneously. In infants, ipsilateral and midline channel recordings are recommended. For diagnostic testing and threshold prediction there are several reasons to obtain two-channel recordings that include:

1. To monitor the ear that was stimulated by the amplitude of the artifact in the response and the position of the trace containing Wave I.
2. To determine the presence and location of the CM and Wave I by comparison to a contralateral recording. The CM and Wave I should not be present, or be diminished, in the contralateral tracing.
3. To obtain better definition of Waves IV and V since they tend to be more separated in contralateral recordings.

Number of Averages and Noise Quantification

The number of averages required varies according to the inherent amplitude of the evoked potential and the amount

of background noise that includes muscle artifact, 60-Hz noise, and EEG activity. For the ABR, usually 1,000 to 2,000 sweeps are used to obtain clear responses in quiet patients when using higher intensity stimuli. At lower intensities where the response is lower in amplitude and in cases where patients are more active and noisier, more averages may be necessary because of the reduced signal-to-noise ratio.

Use of objective estimates of the signal-to-noise ratio, such as F_{sp} , based on the F -ratio statistic, is very helpful in determining when a sufficient number of responses have been averaged (Don et al., 1984). Using methods such as F_{sp} can allow, in an objective manner, for averaging of fewer responses at higher stimulus intensity levels where the response has high relative amplitude whereas more responses can be averaged to improve accuracy for low intensity stimuli (i.e., close to response threshold) where the ABR amplitude is low. Point-optimized variance ratio (POVR) is another statistically based signal and noise estimation method, which is implemented in a newborn hearing screening system (Sininger, 1993). In addition to requiring fewer averages, these methods reduce the need to replicate the response and provide objective estimate of response presence.

SUBJECT CONSIDERATIONS IN ABR THRESHOLD TESTING

Age

The ABR changes as a function of age, particularly during the first 12 to 18 months of life, as the auditory neural system continues to mature. These changes have been attributed to continuing myelination of the auditory pathway after birth. Characteristics of ABRs obtained in premature and term infants vary from each other and from those obtained in adults (e.g., Hecox and Galambos, 1974; Salamy, 1984). Reliable ABR components for 65-dB nHL clicks have been reported in newborns of approximately 28 weeks gestational age (Starr et al., 1977). Waves I, III, and V are most visible in infant recordings and the normal Wave V absolute latency for click stimuli in a newborn approximates 7.0 ms at 60 dB nHL. Responses obtained from infants 12 to 18 months and older should resemble those acquired from adults (Hecox and Galambos, 1974).

Wave I may be prolonged in infants, but generally not as much as Wave V, generating longer interwave latencies on the order of 5.0 ms compared to 4.0 ms in adults (Hecox and Galambos, 1974; Starr et al., 1977). This may be related to cochlear maturation, neuronal maturation, reduced efficiency in external and/or middle-ear sound transmission, and occasionally collapsing ear canals. Neural maturation of the auditory system is complex with conduction time adult-like by term birth, pathway lengthening continuing to mature until about age 3 years, and different aspects of myelin development contributing to changes in ABRs in infants (Moore et al., 1996).

Amplitude of the ABR also changes with age. Peak amplitudes (typically measured from the peak to the following negative trough) increase over the first 1 to 2 years of life (e.g., Salamy, 1984). In infants, the amplitude of Waves I and/or III may be greater than Wave V, which is in contrast to higher Wave V amplitude in adults. This changes to more adult-like patterns over the first few years of life.

Gender

Females tend to have shorter latency and higher amplitude ABRs than males. Wave V latency averages about 0.2 ms shorter in females, and amplitude is higher in females, particularly for Waves IV, V, VI, and VII. Females may also show shorter interwave latencies than males. It has been suggested that the source of the differences in latency and amplitude in the ABR between males and females may be related to the observation that cochlear response times are shorter in females than males (Don et al., 1994).

PROTOCOLS AND PROCEDURES FOR PEDIATRIC PATIENTS

A pediatric test protocol includes multiple measures to provide a cross-check among results and to maximize efficiency (e.g., Gravel and Hood, 1999). The combination of middle-ear measures that includes immittance and middle-ear muscle reflexes, OAEs, and ABR provides a comprehensive view of middle-ear, cochlear, and peripheral neural function (Berlin and Hood, 2009). Once it is possible to obtain reliable behavioral information, at around 6 months of age in typically developing children, a combination of physiological and behavioral test results provides important test cross-checks.

Our pediatric protocol utilizes a combination of measures, as described in Table 14.1. We measure either transient (TEOAE) or distortion product (DPOAE) otoacoustic emissions, tympanograms using a 1,000-Hz carrier tone, and a minimum of ipsilateral middle-ear muscle reflexes at 1,000 and 2,000 Hz. We recommend completing these tests prior to the ABR, as pressure may change in the middle ear over the course of a deep sleep or sedation period and this can affect accurate assessment and interpretation of OAEs and middle-ear tests. All air-conduction testing is completed in each ear individually.

Approaches

For ABR testing, one can complete all ABR testing with tone bursts or can use tone bursts in combination with a brief neural integrity screening that uses a click stimulus. It must be emphasized that click stimuli in pediatric testing are *not* used for threshold prediction; clicks are only used to establish the presence of neural synchrony. Thus clicks are only briefly included and are presented at a moderate to high

TABLE 14.1

Suggested Tone Burst ABR Test Parameters

Parameter	Comments
Stimulus	
Type	Tone burst
Polarity	Condensation for AC, alternating for BC
Intensity	Begin at 75 dB nHL, decrease in 20-dB steps, refine to 10-dB steps
Rate	27.7/s; 39.1/s for 500 Hz
Transducer	Earphone, bone oscillator
Recording	
Time window	20–30 ms
Filter band	High pass 30 or 100 Hz; Low pass 1,500 or 3,000 Hz
Number of sweeps	1,500–2,000 at high intensities, more sweeps nearer threshold
Electrode montage	Noninverting at vertex or high forehead; inverting at mastoid or earlobe; second channel recommended with inverting electrode at nape
Subject	
State	Sleeping, resting quietly, sedated for older infants

intensity where responses to rarefaction and condensation polarity stimuli are compared. If responses are present to clicks, then testing proceeds immediately to determine the response thresholds for tone bursts.

When the ABR protocol utilizes tone bursts for all aspects of testing, then testing begins with tone bursts. Click stimuli may be used later in the test sequence if there is any question about the integrity of the tone burst responses that might suggest a neural synchrony problem and possible auditory neuropathy/dys-synchrony.

Neural Integrity

To test neural integrity, we present clicks at a single high intensity (e.g., 75 dB nHL or higher if there is no response at 75 dB nHL) using both condensation and rarefaction polarity, presented or collected separately, so that results can be compared to differentiate the CM from neural response components. The CM (which will reverse in phase as the stimulus does) is distinguished from Wave I of the ABR (which will not show a phase reversal with clicks). It is emphasized that testing with click stimuli is completed *only* at a single high intensity as a method of checking neural response integrity. When it is documented that an ABR is present, then testing proceeds immediately to tone bursts to obtain estimations of frequency-specific thresholds. Figure 14.5 shows examples of an infant with good neural synchrony and an infant with poor neural synchrony. The infant with poor neural synchrony was found to have auditory neuropathy/dys-synchrony.

ABRs to Air-Conducted Tone Burst Stimuli

A key in ABR testing for threshold estimation involves using well-defined frequency-specific stimuli. Typical stimulus durations utilize a minimum of two cycles rise and fall times (Davis et al., 1985; Gorga et al., 1988), which provide both sufficient frequency specificity and neural synchrony. We prefer condensation polarity tone bursts as these provide higher Wave V amplitude in the majority of individuals. We do not recommend using alternating polarity signals (unless each polarity is separately averaged), particularly in the lower frequencies (Orlando and Folsom, 1995). Suggested tone burst ABR parameters are shown in Table 14.2.

Four frequencies are tested in each ear: 500, 1,000, 2,000, and 4,000 Hz. The test order is 2,000, 500, 1,000, and 4,000 Hz *if* OAEs are present at all frequencies. This order was determined based on obtaining key information for management of and monitoring hearing loss along with the

FIGURE 14.5 A patient demonstrating good neural synchrony is shown in the **left panel** where the recording contains a CM at the beginning of the response and Waves I, III, and V of the ABR, with good replication. The patient depicted in the **right panel** has poor neural synchrony and the tracing only shows the reversing CM with no ABR present. Two tracings with condensation clicks and one tracing with rarefaction clicks are shown in each panel.

TABLE 14.2

Suggested Test Protocol for ABR Threshold Testing

Procedure	Comments
Otoacoustic emissions	
TEOAE or DPOAE	Assess aspects of cochlear function, compare to ABR to identify AN/AD For DPOAE, test at 2, 3, 4 kHz with pass criteria of responses >0 dB SPL and at least 6 dB SNR for all three frequencies
Middle-ear measures	
Tympanogram	For infants <7 months, use probe tone >660 Hz
Middle-ear muscle reflex	Minimally screen at 1 and 2 kHz; must be present at normal levels for both frequencies to pass
Checking neural integrity	Condensation and rarefaction clicks at 75 dB nHL Conduct two runs with condensation polarity and at least one run with rarefaction polarity. If ABR obtained, proceed to tone burst testing If no response, increase intensity If no response persists, clamp earphone tube to distinguish stimulus artifact
Threshold prediction	
Tone burst stimuli	Test order: 2,000, 500, 1,000, 4,000 Hz unless OAEs absent at 4,000 Hz; then test 4,000 Hz before 1,000 Hz
Air conduction	Increase or decrease intensity in 20-dB steps, then refining to 10-dB steps
Bone conduction	Alternating polarity; care in placement of bone oscillator

additional consideration that testing at all frequencies may not be possible if a patient wakes up prior to test completion. If no OAE energy is present above 2,000 Hz, the order of the tone burst center frequencies is 2,000, 500, 4,000, and 1,000 Hz to acquire higher frequency information at 4,000 Hz that could be useful in monitoring possible high-frequency progressive hearing loss. The ideal approach is to assess each frequency in each ear and alternate between ears for each frequency (e.g., 2,000 Hz in the right then the left ear). This approach allows the opportunity to obtain at least some information from each ear in the event that the entire test sequence cannot be completed (i.e., infant becomes too

active). However, if insertion of an earphone in the opposite ear would result in awakening a sleeping baby, then testing is completed in one ear before testing the opposite ear.

Testing typically begins at a reasonably high intensity, such as 75 dB nHL, or at a level where a response is likely to be present based on history, observation, and so on. Intensity is then increased or decreased by 20-dB steps with replications at each level until no response is obtained. If there is no response at 75 dB nHL, then the stimulus intensity is increased. Each of these responses is obtained twice to judge replicability and assist in determination of threshold. Once the threshold range has been bracketed, the step size is decreased to 10-dB steps. Intensity is lowered until Wave V disappears or a response is observed within the predicted normal range. If the patient is quiet and we predict that sufficient time will be available to complete all parts of the test battery, then the intensity level is increased 10 dB to determine the presence of a response at an intermediary level. For example, if responses are obtained at 75, 55, and 35 dB nHL, but no response is observed at 15 dB nHL, then stimuli are presented at 25 dB nHL. At higher intensities where response amplitudes are higher and thus more easily seen over the noise, fewer sweeps, such as 1,000 or 1,500, may be sufficient. Closer to threshold, averaging of more than 2,000 responses may be necessary.

Lower frequency tone bursts are typically more difficult to discern as they generally do not have the familiar five- to seven-wave complex associated with ABRs to clicks or higher frequency stimuli. For 500-Hz tone burst ABRs, we adjust the filters to 30 to 1,500 Hz to accommodate lower frequency physiological activity. Tone bursts with 4-ms (two cycles) rise and fall times, Blackman envelopes, and either condensation or rarefaction polarity are typically used. The time window is extended to 20 or 25 ms since these responses have longer latencies than responses to clicks. Tone bursts centered at 500 Hz are presented at a rate near 40 per second (we use 39.1 per second) to each ear individually beginning at 75 dB nHL and then decreasing in 20-dB steps until no response is obtained, with the 10-dB step filled in if time allows. If there is no response at 75 dB nHL, then the stimulus intensity is increased.

When interpreting the responses obtained to 500-Hz tone bursts, we look for a single replicable peak that represents Wave V of the ABR. We generally observe a single peak that may have a sinusoidal overlay at high intensities. The latencies obtained range from 8 to 10 ms for high-intensity stimuli to 14 to 16 ms nearer threshold (Gorga et al., 1988). In infants, these latencies may be even longer. In our experience, ABR thresholds to 500-Hz tone bursts obtained from normal-hearing individuals using the test parameters described here are generally between 25 and 35 dB nHL.

ABR to Bone-Conducted Stimuli

When responses to air-conducted auditory stimuli are seen at predicted normal threshold levels, there is no need

to obtain bone-conducted responses, as is true in behavioral audiometry. However, when tone burst responses are not present at predicted normal levels, then ABRs should be completed using bone-conducted stimuli. Criteria for obtaining bone-conduction thresholds are (1) if any of the air-conduction thresholds were not within the normal range; (2) if OAEs, immittance, or reflexes are abnormal; or (3) for subsequent visits, if there is a reason to believe there has been a sensory change.

The test parameters used are the same as those for air-conducted stimuli except that alternating polarity is used to reduce the electrical artifact emitted from the bone oscillator. Tone bursts are presented at progressively decreasing intensities via bone conduction to determine whether there is a discrepancy in intensity levels at which responses are obtained between air- and bone-conduction stimuli. If such a discrepancy does exist, this suggests the presence of an air-bone gap and a conductive or mixed hearing loss.

Care must be taken in the placement of the bone oscillator in infants to assure appropriate response amplitude and test accuracy. Oscillator placement in infants should be at the mastoid since stimuli from the bone oscillator are conducted across the scalp less efficiently in infants than in adults. Stuart et al. (1994) demonstrated that bone oscillator placement in infants has a significant effect on Wave V amplitude. Placement of the oscillator directly behind the ear canal is recommended as placements higher on the mastoid result in lower amplitude. Coupling of the bone oscillator also takes special consideration. The procedure described by Yang and Stuart (1990) provides an excellent method. They recommend coupling the bone oscillator using an elastic headband held in place by a Velcro closure that can be adjusted. The tension of the headband can be adjusted to a recommended coupling force of 400 to 450 g using a spring scale.

The dynamic range for bone-conducted stimuli is different than that for air-conducted stimuli, as is true in audiometric applications. The dynamic range typically does not exceed 50 to 60 dB and the relationship between the output of the oscillator and the “dial reading” on the equipment may vary with different instruments. Stimuli are presented beginning at the highest output level and then decreasing in 20-dB steps as in the other tests. Responses are first obtained without masking and then, if response thresholds are better than those obtained by air conduction and/or there is an asymmetry between ears, masking is used.

Because the output in bone conduction is limited, the responses obtained by bone conduction will rarely show the familiar five-wave complex seen at high intensities in standard air conduction ABRs. Responses will resemble those obtained with air-conducted clicks in the threshold-to-50 or 60 dB nHL range. The latency of waves may vary slightly from those acquired by air conduction based on slight spectral differences among bone-conduction transducers. However, since the primary goal in bone-conduction testing in infants is determination of ABR threshold, this is rarely an issue.

Relation of ABR Thresholds to Behavioral Thresholds

In the final step for predicting behavioral thresholds, the threshold of the ABR (i.e., the lowest level where a physiological response is obtained) is adjusted to relate the physiological (ABR) thresholds to behavioral puretone thresholds. This information is helpful in planning management, fitting amplification, counseling, and reporting results. The term “estimated hearing level” (eHL) is used (e.g., Bagatto et al., 2005). In the case studies presented later in this chapter data are used from the Ontario Infant Hearing Program (OIHP) in Canada where adjustments are 20 dB at 500 Hz, 15 dB at 1,000 Hz, 10 dB at 2,000 Hz, and 5 dB at 4,000 Hz.

The eHL values used in the OIHP as well as grossly similar corrections that are used in other programs were derived from studies that directly compared ABR thresholds and behavioral thresholds in the same subjects. An excellent study by Stapells et al. (1995) recorded ABR thresholds to air-conducted stimuli in infants and children with normal hearing and various degrees of hearing losses. Relationships between ABR and behavioral thresholds were approximately linear across a relatively wide range of intensities (20 to about 90 dB nHL). Across the subject dataset, ABR thresholds averaged (with rounding to the nearest 5 dB) 15, 5, and 0 dB above behavioral thresholds at 500, 2,000 and 4,000 Hz, respectively. In another study, Stapells (2000) reviewed studies meeting test criteria and containing data for ABR and behavioral thresholds. Although some differences existed among studies included in this meta-analysis, based on techniques and calibrations, data were available for infants, children, and adults with normal hearing and with SNHL. Results of this analysis indicated overall approximate differences of 15, 10, 5, and 0 dB for 500, 1,000, 2,000, and 4,000 Hz, respectively, though there was variation between children and adults and between those with normal hearing and with SNHL.

ADDITIONAL CONSIDERATIONS

Maximizing ABR Test Accuracy and Efficiency

There are modifications of ABR procedures that can be used to improve test efficiency and decrease test time. This is particularly important since, when sedation is used, there is a finite time period during which a patient will be asleep and, thus, a limited amount of time to obtain all necessary information.

Picton (1978) recommended the use of faster stimulus presentation rates to reduce test time. He suggested the use of a slow rate at a relatively high intensity for accurate identification of the latencies of Waves I, III, and V. Then, when in the threshold-seeking mode of testing, stimuli can be presented at rates on the order of 50 to 70 clicks per second, or faster. Although Wave V latency is prolonged, the amplitude of Wave V in normal adults is not reduced as much as

earlier components, making acquisition of responses near threshold possible. Slower rates at all levels are indicated if the response disappears when stimulus rate is increased.

Other methods use very high stimulus rates (on the order of 500 to 1,000 stimuli per second) with randomized presentation sequences, known as maximum length sequences (MLS; e.g., Picton et al., 1992) and continuous loop averaging deconvolution (CLAD; Delgado and Özdamar, 2004). Presentation of different sequences to each ear allows testing of both ears simultaneously which, when coupled with fast presentation rates, could decrease overall test time. Limitations in testing immature or compromised systems at very high rates and noise levels need to be considered. Caution should be exercised when testing in infants as responses to faster rates may result in decreased amplitude. In cases where no or poor responses are obtained at high rates, testing with slower rates should follow.

Test Protocol for Older Children and Adults

The test protocol used for older children, over approximately 8 to 10 years of age who are not sedated, and adults may vary from that used for infants and young children. Frequency-specific stimuli remain necessary to adequately complete threshold estimation; however, there are additional paradigms in which tone bursts can be presented. For example, 40-Hz ASSR techniques may be added to tone burst ABR and other ASSR methods (see Chapters 15 and 17). Although the 40-Hz response has not been found useful in young patients, it is quite useful in older patients for estimating auditory function using frequency-specific stimuli (Stapells et al., 1984).

Use of Masking

When using tone bursts or tone pips, as with other stimuli, masking should be used when sensitivity differences between ears could create crossover of sound to the nontest ear. With insert earphones the intensities where crossover occurs during air-conduction testing is higher than with supra-aural earphones. The bandwidth of the masking stimulus should be sufficiently wide to encompass the tone burst stimulus being used. The masking stimulus can be generated via sources other than the ABR equipment, such as an audiometer, as long as effective masking levels for the tone burst stimuli are established.

CAUTIONS AND CONSIDERATIONS

There are a number of factors to keep in mind to assure accurate recording of ABRs and correct interpretation of results. Some of the many factors that we consider when using ABR to predict threshold sensitivity are the following.

Neural Abnormalities

Measuring AEPs requires an intact neural system. Thus, abnormalities that can affect the neural system must be considered in interpreting test results. For example, in the presence of hydrocephalus, the ABR can be obliterated despite normal hearing (Kraus et al., 1984). Patients with auditory neuropathy/auditory dys-synchrony (AN/AD) are characterized by absent or highly abnormal ABRs and present OAEs (Starr et al., 1996). Thus, it is particularly important to obtain OAEs in patients who fail to show an ABR at any intensity. Presence of an ABR at high intensities but not to lower intensity stimuli is consistent with a peripheral hearing loss. Absence of an ABR to high and low intensities may mean either a more severe peripheral hearing loss or a neural disorder. OAEs are useful in distinguishing these two groups and therefore we always obtain OAEs in patients who fail to show an ABR response.

Subject Noise

Improper subject preparation can result in noisy or difficult-to-interpret recordings. Poor electrode impedance or dissimilar impedances among electrodes may yield poorly defined, difficult-to-interpret responses. Subjects who are fussy or tense or placed in an uncomfortable position may produce excessive muscle artifact.

Collapsing Ear Canals

Ear canal collapse or earphone slippage can reduce signal intensity at the ear without the examiner's knowledge. We always use insert earphones to avoid the possibility of collapsing ear canals, a common problem in infants when using supra-aural earphones. Insert earphones are also more comfortable which may enhance the patient's state of relaxation or sleep.

Middle-Ear Function

Part of our test battery always includes middle-ear immittance and middle-ear muscle reflexes as well as OAEs. If a patient requires sedation (as in the case of infants over about 4 to 5 months of age and young children) or sleeps deeply, then it is important to obtain these measures *before* doing the ABR. During sedated or natural deep sleep, positive pressure may build up in the middle ears that will compromise the results of middle-ear measures and OAEs if completed at the end of testing.

The ABR Is Not a Hearing Test

Finally, it is always important to remember that the ABR and other AEPs are not hearing tests. In those patients who do not have good neural synchrony, other means of estimating auditory function must be sought. In addition, passing an ABR as an infant does not preclude the possibility

of acquired or later onset hereditary hearing loss. Thus, in reporting test results, we always inform parents and referral sources of the importance of monitoring a child's speech and language development and observing a child's responses to his/her auditory environment. If a child fails to develop speech and language, parents are advised to seek appropriate evaluation and management.

AUDITORY NEUROPATHY/ AUDITORY DYS-SYNCHRONY

The term auditory neuropathy/auditory dys-synchrony (AN/AD), also referred to as auditory neuropathy spectrum disorder (ANSD), describes patients who demonstrate intact outer hair cell function/active cochlear processes shown by OAEs and/or CMs and poor VIII nerve/brainstem responses as a consequence of disturbed input from the inner hair cells, abnormal synaptic function, or peripheral neural pathology (Berlin et al., 1993; Starr et al., 1991, 1996). Further evidence of effects on neural function are demonstrated by generally absent or sometimes elevated middle-ear muscle reflexes (Berlin et al., 2005) and abnormal medial olivocochlear reflexes, measured via efferent stimulation effects on OAEs (Hood et al., 2003). Most AN/AD patients show bilateral symptoms, though function may be asymmetric between ears, and cases of unilateral AN/AD have been documented.

Despite fairly similar findings from current physiological measures, there is considerable variation in characteristics and functional communication abilities across patients (e.g., Berlin et al., 2010; Starr et al., 2000). Clinical presentation typically, but not always, includes difficulty listening in noise, may include fluctuation in hearing ability, and, in the case of infants and children, most often involves delayed or impaired development of speech and language. AN/AD may or may not be accompanied by neural problems in other systems. Patients with AN/AD typically demonstrate timing problems (Zeng et al., 1999), which suggest a disturbance in neural synchrony. This variation impacts both evaluation and management of AN/AD.

Estimates of the incidence of AN/AD suggest that it occurs at a rate of about 10% in those individuals who have a dys-synchronous ABR (see Figure 14.5 for an example of poor synchrony) or an ABR result consistent with a severe or profound estimate of hearing sensitivity. This rate is based on evidence from studies of school-aged children with severe–profound hearing losses (e.g., Berlin et al., 2000) and infant populations (e.g., Rance et al., 1999; Sininger, 2002). Some studies and populations report higher incidence of AN/AD. For example, in the NICU, Berg et al. (2005) observed that about 24% of 477 infants failed their ABR in one or both ears, while passing OAEs bilaterally. To detect AN/AD in newborns, hearing screening must include ABR. If only OAEs are tested, then AN/AD will be overlooked.

Clinical findings in patients with an AN/AD are most accurately described with physiological measures that assess

cochlear hair cell and peripheral neural function. On behavioral measures, patients with AN/AD show puretone thresholds ranging from normal sensitivity to the severe or profound hearing loss range (e.g., Berlin et al., 1993; Starr et al., 1996). Speech recognition is variable across individual patients in quiet and generally poorer than expected with ipsilateral competing stimuli (e.g., babble, noise) in all patients with AN/AD.

In infants and young children, ABR is used as the definitive measure in determining AN/AD. ABRs are typically absent in patients with AN/AD, although some patients demonstrate small responses for high-level stimuli. In the germinal paper defining auditory neuropathy, Starr et al. (1996) reported absent ABRs in 9 of 10 patients (aged 4 to 49 years) and the 10th patient had an abnormal ABR characterized by Wave V responses only to high-intensity stimuli. The Berlin et al. (2010) review of ABR data for 186 patients with AN/AD ranging in age from infants through adults indicated that 138 (74%) patients had absent ABRs whereas 48 (26%) showed abnormal responses characterized by presence of low-amplitude Wave V only at high stimulus levels of 75 to 90 dB nHL. This distribution of responses is very similar to that reported by Starr et al. (2000) for 52 patients where 73% had no ABR and 27% had abnormal responses.

The absence or abnormality of all components of the ABR including Wave I suggests that the most distal portions of the VIII nerve are affected, either directly or indirectly, in AN/AD. This characteristic distinguishes AN/AD from space-occupying lesions affecting the VIII nerve, where Wave I of the ABR may be seen in recordings obtained with surface electrodes. Results of radiologic (MRI and CT) evaluation are characteristically normal in AN/AD patients.

Several distinct differences exist between cochlear responses, such as the CM, and neural responses, such as the ABR. These responses can be distinguished by using appropriate recording methods. The most direct method of separating the CM and ABR is to compare responses obtained with rarefaction polarity stimuli to those obtained with condensation stimuli. CM follows the characteristics of the external stimulus; thus, the direction of the CM reverses with a change in polarity of the stimulus. For higher frequency stimuli and clicks, neural responses such as the ABR in normal individuals may show slight latency shifts with polarity changes but do not invert. Therefore, cochlear and neural components can be distinguished based on whether or not the peaks invert with reversing stimulus polarity. Refer to Figure 14.5 that shows ABRs obtained to both condensation and rarefaction polarity stimuli. In the left panel, the CM inverts at the beginning of the tracing whereas the ABR (neural response) does not invert. In AN/AD, the entire response inverts with polarity changes confirming that it is completely CM and not ABR activity.

An important consideration in evaluating ABRs in newborns and infants is neuromaturation of the ABR after birth that continues through 12 to 18 months of age. Although the ABR is typically present at birth, it is possible that factors

such as premature birth, risk factors, or other trauma surrounding birth may delay development of synchronous neural responses. More information is needed to adequately understand the reasons for poor synchrony and the factors that may contribute to later development of the ABR in some infants who initially present with the signs of AN/AD. At present, estimates of the number of newborn infants who present with dys-synchronous ABRs and later develop a normal ABR are unclear. In the meantime, it is important to closely monitor infants over the first year of life both with ABR and with other indices of auditory development, continually modifying management plans as needed.

CASE STUDIES

Two case studies are shown here to exemplify the use of tone bursts in ABR testing. Responses to tone bursts centered at frequencies ranging from 500 to 4,000 Hz, as described in this chapter, provide the information needed to make predictions about the degree and configuration of hearing thresholds. When predicted thresholds are not normal, sufficient information is obtained to proceed directly with appropriate management.

Case Study 1: Normal Hearing

Case study 1 is an 18-month-old female who was referred for testing based on delayed speech and language development. Development was otherwise normal. There was history of hyperbilirubinemia and the possibility of AN/AD was considered, prompting the recommendation of an ABR.

Middle-ear tests and OAEs were within the normal range for each ear. Following a check for neural synchrony, as described above, in each ear, tone burst ABRs were completed. Testing began with tone bursts centered at 2,000 Hz, followed by 500 Hz and 4,000 Hz. Testing of tone bursts centered at 1,000 Hz was not completed because of patient restlessness. However, with information in both ears at three frequencies, sufficient information was available to make threshold predictions.

Replicated responses were obtained at several intensity levels for each tone burst stimulus. Not all responses are shown; rather those used to determine response threshold are displayed. As shown in Figure 14.6 and in Table 14.3, ABR threshold was 40 and 30 dB nHL for the left and right ears, respectively, for tone bursts centered at 500 Hz, 30 dB

FIGURE 14.6 ABRs obtained for tone bursts centered at 500, 2,000, and 4,000 Hz for the pediatric patient described in case study 1. The time window for all responses is 20 ms.

nHL in each ear for tone bursts centered at 2,000 Hz, and 20 dB nHL in each ear for tone bursts centered at 4,000 Hz. Correction factors, based on the Ontario program guidelines, were used to obtain estimated hearing levels. Predicted thresholds for all frequencies were within normal limits for both ears. Therefore, test results ruled out AN/AD and also suggested that peripheral hearing loss was not a factor in this child’s speech and language delay. This child and her family were referred for speech/language intervention.

Case Study 2: Moderate Hearing Loss

Case study 2 is a 2-year-old male who was referred for testing based on a history of middle-ear problems and a family history of hearing loss. Parents were concerned with speech and language development and lack of responses to sound in some situations. Development was otherwise normal.

Middle-ear tests were within the normal range for each ear at the time of ABR testing. OAEs were absent in both ears. Following a check for neural synchrony, as described above, in each ear, tone burst ABRs were completed. Testing

TABLE 14.3

Case Study 1: Normal Hearing

	L-500	L-2000	L-4000	R-500	R-2000	R-4000
dB nHL	40	30	20	30	30	20
Correction	20	10	5	20	10	5
dB eHL	20	20	15	10	20	15

FIGURE 14.7 ABRs obtained for tone bursts centered at 500, 1,000, 2,000, and 4,000 Hz for the pediatric patient described in case study 2. The time window for all responses is 20 ms.

began with tone bursts centered at 2,000 Hz, followed by 500, 1,000, and 4,000 Hz.

Replicated responses were obtained at several intensity levels for each tone burst stimulus. As with the previous case presented, not all responses are shown; rather those used to determine response threshold are displayed. As shown in Figure 14.7 and in Table 14.4, ABR threshold was 50 dB nHL in each ear for tone bursts centered at 500 Hz, 50 dB nHL in each ear for tone bursts centered at 1,000 Hz, 60 dB nHL for each ear for tone bursts centered at 2,000 Hz, and 50 dB nHL in each ear for tone bursts centered at 4,000 Hz. Correction factors, based on the Ontario program guidelines, were used to obtain estimated hearing levels. Predicted air-conduction thresholds were consistent with a mild-to-moderate hearing loss bilaterally. Because air-conduction thresholds were not normal, bone-conduction ABRs were completed using alternating polarity tone bursts. Bone-conduction ABR thresholds were similar to air-conduction thresholds, consistent with a sensory/neural hearing loss. Based on the air- and bone-conduction test results, this child and his family were referred for speech/language intervention and management with amplification.

SUMMARY

A number of considerations to increase accuracy and efficiency of the ABR in pediatric threshold prediction have been presented through discussion of normal characteristics, considerations in improving test sensitivity and accuracy, and in the context of a clinical test protocol. Use of a test battery and cross-check principles is important in all assessments. History, physiological, and behavioral test results need to make sense (agree). Efficiency is needed in minimizing time and prioritizing information. It is important to use strict criteria and technically correct methods in both physiological and behavioral testing. Finally, whereas the ABR is *not* a hearing test per se, the information related to auditory function and hearing threshold sensitivity obtained from physiological measures *can* and *should* be used in implementing management programs.

There is no dispute that the ABR is an objective, indirect method of estimating hearing sensitivity based on the presence of responses at various intensity levels. This is particularly valuable in infants and young children. Ear-specific and frequency-specific information can be obtained and directly applied to management of identified hearing losses. Using ABR in estimating hearing sensitivity can be challenging in assuring accuracy of responses while also obtaining the needed information in a timely manner, a necessity in pediatric patients. Key goals include maximizing the signal, in this case the amplitude of the ABR, while controlling and minimizing noise as much as possible. Although the ABR is well established as a method of predicting hearing thresholds, areas remain for investigation and refinement. Such areas include refinement of stimuli and stimulus paradigms, accurate calibration of signals in infants (e.g., Lightfoot et al., 2007), methods of accurately assessing and controlling noise levels, and removing subjectivity from determination of response presence.

FOOD FOR THOUGHT

1. What do you think is the “most ideal” stimulus or stimulus set for predicting hearing thresholds in infants and young children? Consider the current state of the art, what you want to know when testing an infant, the characteristics of an auditory system that is still maturing, and what might yield the most accurate information.
2. Noise is an issue in evoked potential testing, as electrodes cannot select the response from the noise. Several methods

TABLE 14.4

Case Study 2: Moderate SN Hearing Loss

	L-500	L-1000	L-2000	L-4000	R-500	R-1000	R-2000	R-4000
dB nHL	50	50	60	50	50	50	60	50

dB eHL	30	35	50	45	30	35	50	45

hold promise for providing specific information about noise levels that can help in response determination. Some methods have been touched on in this chapter. Think about the noise problems in recording ABRs in infants and discuss (1) what you would do to try to control the noise and (2), more importantly, what approach you might use to assess noise levels in an objective manner.

3. There is subjectivity in ABR related to marking latencies of waveforms and, in the context of this chapter, in deciding the threshold of a response, that is, when a response is present and when there is no response. Discuss the criteria that you would use to decide if a response is present and how you would try to make your decisions as objective as possible.

Auditory Steady-State Response

Andrew Dimitrijevic and Barbara Cone

OVERVIEW

Auditory steady-state responses (ASSRs) are rhythmic brain potentials evoked by regularly repeating stimuli such as clicks, amplitude-modulated (AM) noise or tones, or frequency-modulated (FM) tones.

Imagine the waveform of an auditory brainstem response if two toneburst stimuli were presented within an averaging epoch. Each toneburst would be expected to produce a response, and so the response waveform would be repeated twice, within the averaged epoch. Now, imagine a 125-ms train of 2-1-2 cycle tonebursts, say at 2,000 Hz (carrier frequency [CF]), with an interstimulus interval between each burst at 12.5 ms (80 Hz). Imagine that the response averaging epoch is also 125 ms in duration. One thousand 125-ms trains are presented, and the response to each train is averaged. There are 10 responses represented in the time-averaged waveform for the 125-ms sample. The time-averaged waveform appears as a series of peaks or a periodic wave, with a 12.5-ms interpeak interval (Figure 15.1A). This is one way of conceptualizing an ASSR. The ASSR, furthermore, can be

obtained for a wide range of modulation frequencies (MFs), although rates between 10 and 200 Hz have been most often investigated. For example (Figure 15.1B), the 40-Hz ASSR is obtained using clicks or tonebursts presented every 25 ms, or puretones or noise amplitude modulated at 40 Hz. Because the ASSR is periodic (repeating at the same rate as the MF), it can be analyzed using frequency-domain methods. The spectrum of the response will show a peak at the repetition rate, that is, at the MF. The latency of this periodic waveform can be expressed as a phase delay (360 degrees), relative to the onset of the start of the stimulus train, or onset modulation of tones or noise. When a response is present, the phase of the response is consistent (phase coherent) across subaverages and is “phase-locked,” occurring at a specific phase relative to the MF. The phase coherence (PC)/phase-locking can be tested for statistical significance in addition to, or in place of, the statistical test of response spectral peak amplitude. The presence of an ASSR is dependent on the integrity of the auditory periphery (external, middle, and inner ear, auditory nerve) for the CF, as well as the integrity of higher levels of the auditory pathway.

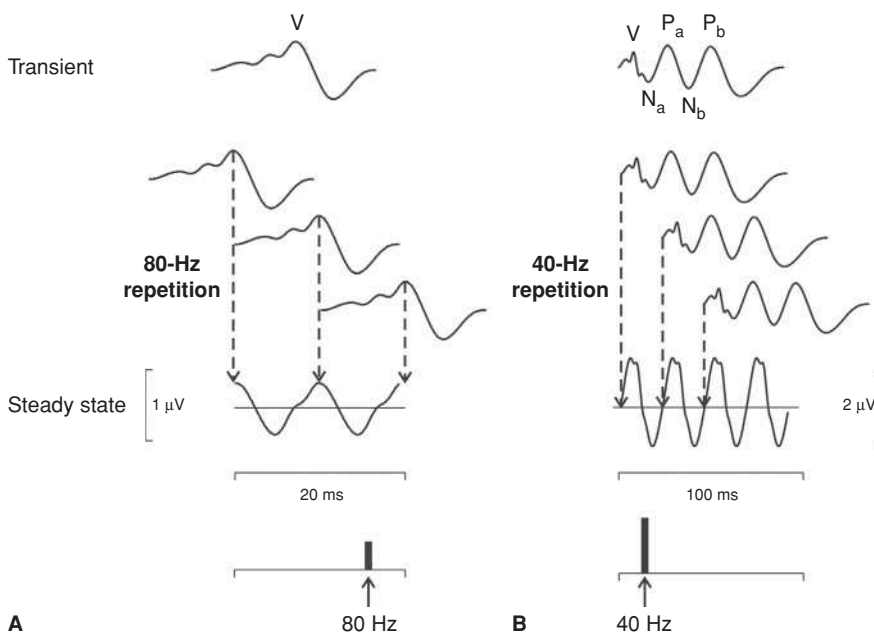

FIGURE 15.1 Examples of transient-evoked potentials and how they are related to steady-state potentials. **[A]** With a modulation frequency of 80 Hz, there are brainstem responses occurring every 12.5 ms, the same period as the modulated [tone] stimulus. **[B]** With a stimulus modulation frequency of 40 Hz, the responses occur every 25 ms, the same period as the stimulus modulation.

Since the first inclusion of ASSRs in the fifth edition of the *Handbook of Clinical Audiology*, there has been a significant increase in the clinical application of ASSRs. The primary clinical application of ASSR during the past two decades has been for estimating hearing thresholds in infants and children, which is the focus of this chapter. The ASSR is also a tool for investigating responses to complex stimuli at suprathreshold levels. These emerging applications will be highlighted in this chapter.

FUNDAMENTALS

Knowledge of neural generators, stimulus–response relationships, subject-related response factors, signal processing, and detection algorithms is necessary for interpreting ASSR results. Each of these areas will be reviewed.

Neural Generators

The generation of the ASSR at the level of the cochlea and nerve is schematized in Figure 15.2 (after Lins et al., 1995). An AM tone is the stimulus. The first step in sensory transduction occurs at the level of the inner hair cells. As the basilar membrane vibrates, the stereocilia on the inner hair cells move back and forth following the sound stimulation. This symmetric movement is shown in the figure as a sinusoid. Integrity of the outer and inner hair cell transduction systems is needed to obtain a normal response to the tone. The transmission of information from the inner hair cells to the auditory nerve involves the release of glutamate when the stereocilia move in one direction thereby initiating

FIGURE 15.2 A model of ASSR generation at the level of the cochlea and eighth nerve. The modulated tone creates a basilar membrane vibration at the “best place” for the carrier frequency. There is no energy present at the modulation frequency. Inner hair cells release neurotransmitters to the peripheral processes of the spiral ganglion cells. This provides a half-wave rectification of the stimulus providing energy for the neural response at the modulation frequency.

an action potential. Because the action potentials are generated by movement of stereocilia in only one direction, the stimulus (tone) undergoes half-wave rectification. Half-wave rectification provides energy at the modulation frequency. There is no stimulus energy at the modulation frequency, yet the half-wave rectification introduces energy at the modulation frequency. It is this energy at the modulation frequency that evokes the ASSR. Supporting evidence of this model is seen in recordings from auditory nerve made by Khanna and Teich (1989a, 1989b), who showed that presenting AM or FM stimuli evoked responses in the auditory nerve at the MFs, at the harmonics of the MFs, and at the CF.

Neurons of the eighth nerve (Ruggero, 1992), cochlear nucleus (Rhode and Greenberg, 1992), inferior colliculus (IC; Irvine, 1992), and primary auditory cortex (Clarey et al., 1992) are responsive to AM and FM signals, and so could be involved in the generation of the ASSR. One line of evidence that points to a relationship between MF and the underlying neural generator is that of ASSR latency. Measurement of the response phase spectrum (relative to the MF) can be used to estimate response latency. The predominant phase is used to characterize the latency of the response, and hence the generators are assumed to be the same as those for the transient-evoked response of similar latency. Modulation rates of 20 Hz or less will result in a response dominated by those generators that are responsible for the late cortical-evoked potential, specifically primary auditory cortex and association areas. For modulation rates higher than 20 Hz but lower than 50 Hz, the response characteristics are similar to those found for the middle latency auditory-evoked response (MLAER), with generators generally thought to be auditory mid-brain, thalamus, and primary auditory cortex (Kraus et al., 1994). Modulation rates higher than 50 Hz will be dominated by evoked potentials from brainstem sites, including those for Wave V and its subsequent negative trough, sometimes identified as SN-10 (Møller, 1994).

Chemical lesions of the auditory pathway were used by Kuwada et al. (2002) to determine neural generators of the ASSR. Using a rabbit model, they administered pharmacologic substances that reduced activity at selected levels of the auditory system, while recording ASSRs as MF was varied. As MF was increased, phase delay (latency) decreased. Estimated latency for MFs <100 Hz was 27 ms, suggesting a cortical generator. At rates above 100 Hz, latencies of 5 ms or less were more consistent with brainstem generators. When potassium chloride was administered topically to the cortex (to depress cortical activity), the ASSRs for MFs <100 Hz were significantly decreased, whereas those for MFs >100 Hz were stable. Szalda and Burkard (2005) recorded ASSRs from the IC and auditory cortex sites in awake and nembutal-anesthetized chinchillas, as the modulation frequency of a 2,000-Hz tone was varied from 29 to 249 Hz in 20-Hz steps. The IC responses were largest at modulation rates of 109 and 170 Hz. A different result was

obtained from the auditory cortex. In the awake state, the auditory cortex had large responses at 29 and 70 Hz, but when anesthetized, the amplitude of the ASSR was greatly reduced and the amplitudes were largest at 29 Hz. These results are consistent with those of Kuwada et al. (2002), in that more robust responses were found for higher modulation rates at the IC compared to auditory cortex, whereas the cortex had more robust responses to lower modulation rates.

Studies in human subjects, using the techniques of multichannel EEG/MEG for brain source analysis, functional magnetic resonance imaging (fMRI), and positron emission tomography (PET), indicate both brainstem and cortical neural generators of the ASSR. Herdman et al. (2002a) investigated the neural generators of ASSR for modulation rates of 12, 39, and 88 Hz in adults using dipole source modeling techniques. The results showed that the brainstem source was active for all three rates of stimulation, whereas the cortical sources were predominant for the two lower rates, although the ASSRs at 12 Hz were very low in amplitude. Estimated latencies of the ASSR were also consistent with a brainstem site of generation for the 88-Hz ASSR, and cortical site(s) for the 39- and 12-Hz modulation rates. PET was used to study the generators of the 40-Hz ASSR in adults (Reyes et al., 2004). The investigators distinguished the cortical areas activated by an AM tone from those activated by a puretone. They showed that bilateral activation of primary auditory cortices, left medial geniculate, and right middle frontal gyrus, as well as the right anterior cingulate gyrus and an area of right auditory cortex, was specifically by the AM stimulus. The PET technique used in this study would not be sensitive to brainstem sites of activation, so these cannot be ruled out. A recent study (Steinmann and Gutschalk, 2011) examined the use of fMRI and MEG for ASSR localization in the same adults on different testing days. A blood oxygen–level–dependent (BOLD) activation in the fMRI contrast between puretones and AM tones indicated medial Heschl gyrus activation with ASSRs. In the same subjects, there was a close correspondence between ASSR dipole source location and BOLD activation in the same group of subjects. This provided good correspondence with previous results showing medial activation of Heschl gyrus (more medial than for a transient-evoked response) with ASSRs (Herdman et al., 2002a).

In summary, the ASSR has multiple generators, although the contributions of the generators vary with MF. In humans, MFs >80 Hz are thought to be generated predominantly by brainstem sites, although the contribution of cortical generators is still present. At lower MFs, the medial geniculate body, auditory radiation, and primary auditory cortex are thought to contribute to the ASSR. As for other cortical-evoked responses, ASSRs at low modulation rates show laterality toward the hemisphere contralateral to the stimulated ear, although 40-Hz ASSRs show evidence of right hemispheric dominance (Ross et al., 2005).

Stimulus Factors

CARRIER FREQUENCY

Auditory sensitivity varies as a function of CF, as does ASSR threshold. The difference between ASSR and behavioral threshold also varies with CF. In general, the ASSR threshold is lowest in the mid-frequency range, at 1.5 and 2.0 kHz, in comparison to thresholds at lower or higher CFs. Phase delays decrease systematically with CF, reflecting the tonotopic organization of the cochlea, and in support of the data demonstrating that the ASSR is somewhat place specific (Herdman et al., 2002b).

The data about the effect of CF on ASSR are from experiments in which ASSR threshold was measured. Variability in the methods used in these studies contributes to the variability in the results. Some investigators report ASSR threshold in dB HL, for which thresholds are “normalized” to an audiometric calibration, and others report thresholds in dB SPL. Another consideration is that ASSR threshold is determined using algorithms based on an estimate of the signal-to-noise ratio (SNR). Longer averaging times decrease the background noise level, thus improving the SNR, yielding lower (better) thresholds. A further consideration is that there are relatively little threshold data for those with normal hearing; the bulk of published threshold data are for those with hearing loss. Table 15.1 includes ASSR threshold data as a function of frequency in adults and infants with normal hearing. The estimation of perceptual threshold for puretones from ASSR threshold is discussed in a later section of this chapter.

AM AND FM DEPTH

John et al. (2001b) evaluated the effect of AM and FM depth on ASSRs obtained from adults with normal hearing. A sinusoidal function at 82 Hz was used to amplitude modulate a 60-dB SPL 1,000-Hz tone at 100%, 50%, 20%, 10%, and 5%. Then, the 1.0-kHz carrier was frequency modulated (at 82 Hz) at depths of 50%, 20%, 10%, 5%, and 2%. ASSR amplitude decreased with modulation depth by 0.5 nV/% over a 20% to 100% AM change, but the AM change was almost twice as steep for a change in FM depth. ASSR amplitudes in response to a 20% FM tone were larger than those for a 100% AM tone. There was no change in phase delay (latency) as modulation depth was varied. Fewer than 50% of responses reached statistical significance for AM depths less than 20% and for FM depths less than 5%.

John et al. (2001b) studied the advantage of using both AM and FM (called mixed modulation [MM]) for the same CF. ASSR amplitudes were significantly larger in response to MM tones in comparison to responses to AM alone. Part of the reason is the spread of spectral energy for the MM signal. Sidebands for the AM will be at the $CF \pm MF$, and for FM at $CF \pm$ integer multiples of the MF. The interaction of

The number of subjects, stimulus type, and threshold level are given for each study. AM is a sinusoidally modulated puretone and MM is an amplitude- and frequency-modulated tone. AM modulation depth is 100% and FM modulation depth varies between 10% and 25% in various studies. There are considerable differences in ASSR recording methodology represented in these studies, with some using a single-frequency, sequential test strategy, whereas the others used multiple carriers presented simultaneously. Differences in averaging time, signal processing, and detection algorithm also vary between studies. “80-Hz ASSR” refers to modulation rates in the 70–110-Hz range.

FIGURE 15.3 A model of combined AM and FM response activation. **[A]** The tuning curves for auditory nerve fibers and how the AM activates the fibers slightly apical to the best frequency and FM, slightly basally. **[B]** The area of the basilar membrane activated by both types of modulation. **[C]** The time course of response to each type of modulation and the time course of the response to combined [mixed modulation [MM]] AM and FM tones.

AM and FM accounts for increased MM responses. John et al. suggest that the benefit of MM is governed by the different responses of AM and FM. An FM response maximally stimulates neurons that are slightly higher in frequency than at the CF and therefore occurs slightly earlier than the AM response (Figure 15.3). If the FM phase is adjusted relative to the AM component, so that it is delivered slightly after the AM, the resultant ASSR will be optimized because the “peaks” of AM and FM occur at the same time. This results in a larger ASSR response in comparison to AM or FM alone, or when the phase relationships between AM and FM are not phase adjusted. The researchers demonstrated that when the phase of FM was varied with respect to AM, ASSR amplitude plotted as a function of FM phase delays varied in a sinusoidal fashion, with amplitude crests observed at relative phases of 0 and 270 degrees. Stimulus level and CF were also varied in this experiment, and phase delays decreased with increasing level and CF; this is homologous to the latency changes observed in ABR for changes in stimulus level and toneburst frequency.

This parametric study showed that MM stimuli yield larger ASSR amplitudes, and hence, a greater number of responses are detected, in comparison to results with pure AM stimuli. The study also showed the importance of the phase relationship between the AM and FM stimulus components, to obtain the largest, most easily detected responses. Of course, the spectrum of the stimulus is considerably broader for an AM + FM tone than for AM alone. This would be expected to affect the frequency specificity or cochlear place specificity of the ASSR.

MODULATION TYPE

Clicks, modulated broadband, high-pass, or low-pass noise, will yield large-amplitude ASSRs with low detection thresholds. John et al. (2003) used noise and tones modulated with exponential functions to obtain ASSRs. In all cases, the ASSRs for the exponential modulations were larger than those for conventional, sinusoidal, and MM tones. This is

predictable, given that exponential modulation results in steeper rise times that will broaden the stimulus spectra and, in fact, the shape approaches a toneburst. They suggest that high-pass- and low-pass-modulated noise or clicks could be used to quickly estimate threshold in the low- and high-frequency ranges of hearing. This could then be followed by using frequency-specific MM tones, to make more definitive puretone threshold estimates. If threshold can be estimated quickly using less frequency-specific stimuli, then more time can be spent acquiring ASSRs for frequency-specific stimuli at levels closer to threshold. Figure 15.4 shows time- and frequency-domain representations of sinusoidal AM, FM, MM tones, and tones modulated with an exponential function and modulated noise.

CHIRPS

ASSRs using chirps have been studied (Elberling et al., 2007) to create a stimulus that maximally excites the cochlea and produces a large ASSR. The chirp is an AM and FM stimulus designed to create a cochlear traveling wave that produces synchrony in response to the neural elements innervating the low-, mid-, and high-frequency portions of the cochlea. The chirp stimulus compensates for the normal phase delays introduced by the traveling wave by systematically presenting high frequencies slightly later than low frequencies. These frequency-specific time delays can occur over a broad frequency range (activating the entire cochlea) or be constrained to a narrow range (e.g., near 500 Hz). Stürzebecher et al. (2006) described a stimulus composed of cosine waves ranging from 270 to 810 Hz (average near 500). The phases of the individual components were adjusted so that neural activation would occur synchronously. These chirp stimuli evoked ASSRs with larger SNRs and that were detected earlier compared to those in response to nonadjusted stimuli. The advantage of the chirp stimulus is particularly important for ASSRs in response to low-frequency carriers (i.e., near 500 Hz) that have relatively low SNRs for conventional stimuli.

FIGURE 15.4 Time- and frequency-domain representation of stimuli used for ASSR. Waveforms and spectra are shown for [sinusoidal] amplitude modulation [AM], frequency modulation [FM], mixed modulation [(MM), AM+FM], exponential sine-wave modulation [\sin^3], toneburst [linear ramp], and modulated noise.

MULTIPLE MODULATION AND CARRIER FREQUENCIES

It is possible to present multiple AM CFs simultaneously and perform a separate analysis for each modulation frequency used in the complex stimulus. Lins and Picton (1995) were the first to show that it was possible to present up to four CFs in both ears and obtain multiple ASSRs. The CFs were 0.5, 1.0, 2.0, and 4.0 kHz and there were eight different modulation frequencies, with the modulation frequency varied for both ear and CF. When suprathreshold-level (60-dB SPL) stimuli were used, there was no difference in response amplitude for the single tone-alone condition, four stimuli combined in one ear, or four stimuli combined in both ears. ASSR threshold was also estimated using two CF tones (500 and 2,000 Hz) in each ear. In normal ears, there does not appear to be a difference in ASSR threshold for four CFs presented simultaneously, compared to when they are presented singly, as long as the CFs are separated by an octave, and the MFs (at 70 Hz or greater) are separated by 3 Hz. An illustration of this multifrequency stimulus is shown in Figure 15.5, with both time (waveforms) and fre-

quency (spectra) domain representations of the stimulus components. Lins et al. (1996), using four simultaneously presented CFs to normal hearing adults, showed that the mean behavioral ASSR threshold difference was 12 dB.

Lins and Picton (1995) also showed that it was possible to measure ASSRs using the same CF (1.0 kHz) and up to four different modulation rates presented simultaneously, with modulation rates in the low (39 and 49 Hz) and high (81 and 97 Hz) ranges. This would appear to be a beneficial technique for testing patients who may be in a variable state of arousal, from alert to deep (stage 4) sleep, as might occur during a typical clinical test session. When adults were tested during an awake state, the amplitudes of the responses to the low MFs (presented individually) were up to three times those of the responses for high MFs (presented individually). When two different MFs were used in each ear, the responses to each MF were decreased by about 20%. In sleeping adults, when four different MFs were presented simultaneously (39, 49, 81, and 97 Hz), the amplitudes of the low MF response components decreased with sleep stage, whereas the amplitudes of the high MF response components remained unchanged. Although only a small group of adults

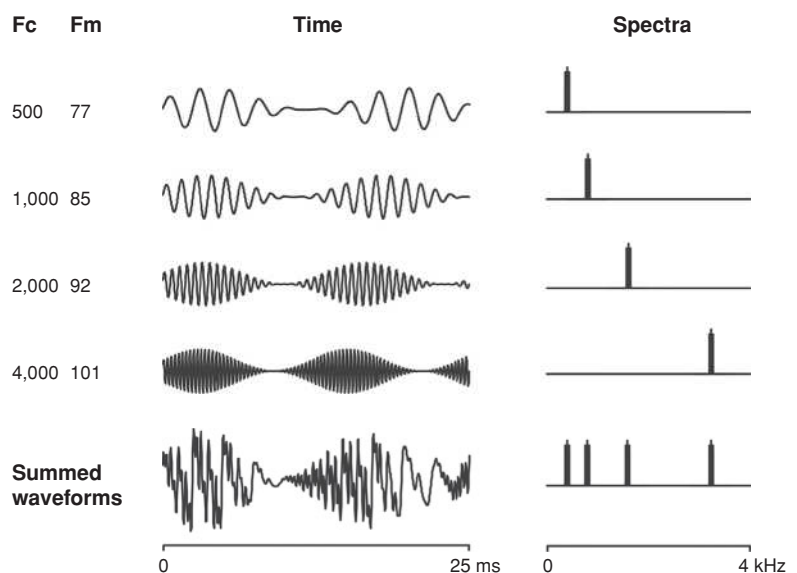

FIGURE 15.5 Time waveforms and spectra for each component of a multifrequency stimulus, consisting of simultaneously presented modulated tones. F_c is the carrier [tone] frequency, F_m is the modulation frequency [rate]. F_c s should be separated by an octave, and F_m s by at least 3 Hz to avoid interaction.

were tested in each of these conditions, and the 1,000 Hz CF was at a suprathreshold level, the implications for a clinical test protocol are compelling. That is, if threshold estimates are needed and the patient is in an awake state, the low MF components might be best, but at the same time, high MF components can also be tested. If the patient is drifting from wakefulness to drowsiness and sleep, the stability of the high MF components will yield adequate information.

COCHLEAR PLACE SPECIFICITY

The cochlear place specificity of the ASSR evoked by MM tones, the most commonly used stimuli for ASSR tests, was evaluated by Herdman et al. (2002b), using the classic high-pass masking derived-band technique. In this method, cochlear response areas are delimited by using masking noise in which the high-pass edge of the filter is systematically lowered, for example, from 8 to 20 kHz, to 4 to 20 kHz, then 2 to 20 kHz, and so forth. An ASSR is obtained for each masker setting. Cochlear response areas are “derived” by subtracting the response obtained for adjacent masking bands, that is, the 4- to 20-kHz ASSR from the 8- to 20-kHz condition. The derived or difference wave represents the response attributed to the 4- to 8-kHz cochlear area. Details about this technique can be found in Chapter 11. Herdman et al. used this technique, with masker high-pass cutoffs at 0.5 octave intervals between 0.250 and 16 kHz. The derived bandwidths for cochlear place of excitation varied from 1.02 to 1.21 octaves. These results indicate slightly narrower derived bandwidths compared to those obtained when a toneburst is used to evoke the ABR, or middle latency response (MLR). Even though the stimulus spectrum of an AM tone may have a narrower, more “frequency-specific” spectrum than does the spectrum of a toneburst, the response “place specificity” appears to be about an octave wide for modulation envelopes or tonebursts that are less than 10 ms in duration. Place specificity is better (narrowest in terms of octaves) for high-frequency CFs (>1.0 kHz) in comparison to low-frequency CFs. Picton et al. (2003) remind us that it is the cochlea that is the limiting factor for place specificity, not the stimulus. Audiogram estimates derived from ASSR tests using MM stimuli appear to be accurate, even when such steep audiometric slopes exist (Herdman and Stapells, 2003), and thus additional masking does not appear to be necessary.

Subject Factors

AGE: INFANTS

ASSR threshold decreases with age during infancy. Rickards et al. (1994) were the first to establish ASSR thresholds in newborns. ASSR threshold was estimated from the results of over 480 tests conducted at 500, 1,500, and 4,000 Hz, using MFs of 72, 85, and 97 Hz, respectively. A statistical criterion of $p < 0.03$ was used to determine when a response was present, using a PC algorithm. The mean thresholds were 41,

24, and 34 dB HL (or 52.5, 30.5, and 44.5 dB SPL) for 500, 1,500, and 4,000 Hz, respectively. The ASSR in newborns shows stimulus–response characteristics, and derived latencies similar to those of the toneburst-evoked ABR.

The 4-CF combined MF technique was applied to infants aged 1 to 10 months by Lins et al. (1996). The MFs were between 75 and 110 Hz. All infants were considered “well-babies,” tested during sleep, and assumed to have normal hearing. The mean ASSR thresholds found for the infants tested in a quiet room were within 10 dB of ASSR threshold in adults and were 45 dB SPL for 500 Hz, 29 dB SPL for 1,000 Hz, 26 dB SPL for 2,000 Hz, and 29 dB SPL for 4,000 Hz. The response amplitudes and phases were also measured and compared to those of adults. On average, response amplitudes were less than 50% of those found in adults, but phase measurements were similar.

Savio et al. (2001) showed that ASSR threshold improved with age in the first year of life. In the 0 to 1 month age group, ASSR thresholds were, on average, 13 dB higher than those obtained from infants aged 7 to 12 months. John et al. (2004) measured ASSR amplitude and detectability for AM, FM, MM, and exponentially modulated tones in neonates and also in older infants (3 to 15 weeks) using stimuli at a fixed level of 50 dB HL. ASSR amplitude and detectability increased with age, suggesting that threshold might also improve with age. Responses were largest for MM and AM tones with exponential modulations, suggesting that these stimuli would be best for testing threshold in very young infants.

Rance and Tomlin (2006) performed longitudinal ASSR threshold measures over the first 6 weeks of a life in a cohort of full-term infants with normal hearing. They found an improvement in ASSR threshold of 11 dB at 0.5 kHz and 10 dB at 4.0 kHz when comparing thresholds measured in the newborn period to those measured at 6 weeks of age. These threshold differences were obtained after taking into account the level differences owing to the ear canal acoustics (obtained from in situ stimulus calibration).

Unlike the ABR, there have been no large-scale parametric studies of ASSR development in infants and young children, the population most likely to undergo testing of this nature to estimate threshold. Indeed, most of the published ASSR results in infants and children concern those who have hearing loss, and it is difficult to infer normal development from results obtained in pathologic ears. ASSR tests utilize modulation rates much higher than toneburst presentation rates typically used to evoke the ABR, rates at which considerable neural adaptation in both premature and full-term neonates is known to occur (Lasky, 1984). Optimization of ASSR test parameters for very young infants, particularly for threshold estimation applications, requires further research.

AGE: ADULTS

Although there is experimental evidence that there is an increase from 38 to 46 Hz in the peak of the function

relating ASSR amplitude to modulation rate that occurs in middle age (Poulsen et al., 2007), the 40-Hz ASSR does not change significantly with increasing age in adulthood (Boettcher et al., 2001), although even slight-mild hearing loss among older adults may be a confounding variable. Larger amplitudes for the ASSR have been found among the elderly who have hearing levels at the “lower” end of normal (e.g., 20 to 25 dB HL), likely because of a recruitment-like phenomenon (Muchnik et al., 1993). Picton et al. (2003) report no age-related changes in the amplitude or phase of ASSRs for a 1,000-Hz puretone modulated at 3, 43, and 95 Hz in a group of normal hearing adults aged 20 to 81 years. They do, however, report high intersubject variability in amplitude and phase measures that may have precluded finding statistically significant age-related differences. Grose et al. (2009) found some decrement in ASSR amplitudes for older adults but only for high (>100 Hz) modulation frequencies.

Stimulus × Subject Interactions

MF × SUBJECT STATE

The modulation frequency, modulation type(s), and CF are the primary determinants of ASSR properties. There are, however, some interactive effects of subject consciousness with MF and CF on the ASSR. These were first evaluated by Cohen et al. (1991). CFs of 250 to 4,000 Hz (octave steps) presented at 55 dB HL were used to evoke steady-state responses in awake adults at MFs of 30 to 185 Hz. MFs of 60 Hz or lower resulted in response latencies (calculated from phase delay data) in the range of 28 to 33 ms, clearly similar to the range for auditory MLRs. For modulation frequencies at 90 Hz and above, the latencies ranged from 11.6 ms for a CF of 250 Hz to 8.9 ms for a CF at 4.0 kHz, indicating a likely homology to toneburst-evoked ABRs. In both waking and sleeping adults, for CFs at 1.0 kHz or lower, an MF of 45 Hz yielded larger ASSR SNRs; however, this SNR advantage for a 45-Hz MF was not obvious for sleeping subjects tested with CFs at 2.0 or 4.0 kHz. At CFs of 2.0 and 4.0 kHz, MFs of 80 Hz and above yielded SNRs that were equivalent to those at lower MFs in sleeping subjects. The study by Cohen et al. established the efficacy of recording ASSR in sleeping subjects, using high (>80 Hz) MFs, for CFs in the audiometric frequency range.

Dobie and Wilson (1998) also determined the detectability of ASSRs in adults tested both in the awake state and during sedated sleep. MFs of 40 and 90 Hz yielded peaks in the detection function for both awake and sedated sleep states for the low-frequency (640-Hz) CF presented at a moderate level, but less than 75% of the trials conducted at 38 dB SPL resulted in a detectable response, regardless of MF. MFs at 50 Hz or lower detectability were considerably reduced in the sedated sleep state compared to the awake state. The results obtained by Dobie and Wilson indicate

that both low (40 to 50 Hz) and high (90 Hz) MFs are effective in evoking an ASSR for a CF below 1.0 kHz in awake or sleeping adults.

Aoyagi et al. (1994a) tested adults with normal hearing during natural sleep using MFs of 20 to 120 Hz, and CFs of 0.5, 1.0, 2.0, and 4.0 kHz all presented at 50 dB HL at MFs of 20 to 120 Hz. Results were similar to those of Cohen et al. (1991), with peaks in the detectability versus MF functions found at 40 and 80 Hz for CFs at 0.5 and 1.0 kHz and at 80 Hz or higher for CFs at 2.0 and 4.0 kHz. It should be noted that responses were detected at all MFs except for 20 Hz.

Lins et al. (1995) conducted a parametric study of ASSR using MFs of 67 to 111 Hz and CFs of 0.5, 1.0, and 2.0 kHz. Adult subjects were tested as they read or slept, but the effects of subject state were not evaluated as a variable. For a CF of 1.0 kHz presented at 60 dB SPL, MFs at 83 and 91 Hz yielded the largest ASSR amplitudes, significantly different from amplitudes measured at MFs of 71 and 111 Hz. Holding MF constant at 91 Hz, and level constant at 60 dB SPL, they showed no significant difference in ASSR amplitude for CFs varied at 5.0, 1.0, and 2.0 kHz. Increasing the level of a 1.0-kHz (CF) tone modulated at 91 Hz from 20 to 90 dB SPL resulted in a systematic increase in amplitude, and a decrease in phase, equivalent to a 1.3-ms decrease in latency.

In summary, for CFs of ≤ 1.0 kHz, at near threshold levels, there may be some advantage to using MFs at around 40 Hz in awake or sleeping adult subjects. MFs at 80 Hz or higher are suitable for CFs greater than 1.0 kHz.

STIMULUS × SUBJECT INTERACTIONS IN INFANTS AND CHILDREN

Findings of Levi et al. (1993) indicate that modulation frequencies above 40 Hz, and particularly at 80 Hz, are preferable for testing young infants with AM tones. Using AM tones at 500 and 2,000 Hz, presented at 60 dB HL (~ 78 dB SPL), they measured response coherence, an estimate of response power relative to overall response plus noise power, as a function of MF. The largest coherence values were obtained at 80 Hz, regardless of CF. When a 500-Hz CF was used, statistically significant responses were obtained only for MFs of 40, 50, and 80 Hz, but not at 10, 20, or 30 Hz. Using a 2,000-Hz CF, only the 80-Hz MF yielded statistically significant responses for infants. Aoyagi et al. (1994b) showed that MFs in the 80-Hz range resulted in the most stable and reliable ASSR results among normal hearing infants and children (aged 4 months to 15 years), tested while sedated. Although only one CF (1,000 Hz) was used, the MF was varied from 20 to 200 Hz. Measures of PC were highest for 80 Hz, although peaks were also found at 120 and 160 Hz for infants and children less than 4 years of age; these additional peaks in the coherence functions were not clear for older children, nor for a group of normal hearing adults. There was a clear advantage for the 80-Hz MF compared to the 40-Hz MF for all except children older than 9 years or for adults.

A large-scale study of newborns completed by Rickards et al. (1994) provides compelling evidence for the efficacy of modulation rates higher than 60 Hz for obtaining responses to tones with both AM (100%) and frequency modulation (20%). CFs of 500, 1,500, and 4,000 Hz (at 55 dB HL) were used to obtain ASSRs at MFs ranging from 35 to 185 Hz. As CF increased, so did the best MF for response detection. MFs in the range of 65 to 100 Hz yielded the best detection efficiencies in sleeping newborns. In addition, latencies calculated from the response phase were in the 11- to 14-ms range, with a systematic decrease in latency with increased frequency. Both the range and the type of latency change suggest that the ASSR recorded at high MFs in sleeping newborns are generated by the brainstem.

These studies indicate that MF should be varied with CF to get the largest amplitude responses. They further show that for CFs <1.0 kHz, ASSRs obtained with MFs of 30 to 50 Hz are larger than ASSRs at MFs >80 Hz. This may be because at lower MFs, the modulation envelope is of longer duration, allowing greater temporal summation, and thus, a larger response. It is also likely because of the fact that the ASSRs from the cortex, that is, at the lower MFs, are larger than those from the brainstem (at the higher MFs). The relationship between MF and ASSR amplitude is illustrated in Figure 15.6. Although Levi et al. (1993) were able to obtain ASSRs for low-frequency MF–CF combinations in very young infants, the ASSRs for the 0.5-Hz CF at 80-Hz MFs were more consistently present and of larger amplitude than were those obtained at lower MFs. Previous research in sleeping infants and young children using MFs at 40 Hz indicates that the ASSR is unstable (Stapells et al., 1988). This is not the case, however, for adults, in whom ASSRs for low (<1.0 kHz) CF and low (<50 Hz) MF stimuli are present during either sleep or wakefulness.

FIGURE 15.6 ASSR amplitude as a function of modulation frequency. Data are modeled from adults tested awake or asleep. ASSR amplitudes at 40 Hz are two to three times the amplitudes of ASSRs at 80 Hz. ASSR amplitudes for MFs <20 Hz are variable in wakefulness, and even more so during sleep.

Signal Processing and Acquisition Variables

FILTERING

Filtering is a crucial tool that is used in recording any type of evoked response. Filtering can be in either analog (online) or digital (offline), or a combination of both. Filtering increases the SNR by removing unwanted activity at frequencies that are not of interest, and allowing focus on the frequencies at which the responses are located.

The choice of filter cutoff frequencies depends on the frequency of the intended recorded signal. If a filter's cutoff frequency is placed too close to the MF used to obtain the ASSR, then correction factors must be applied to compensate for the attenuation of the signal because of the filter. Common high-pass filter settings used in ASSR studies are 1 Hz up to 30 Hz, with low-pass filters of 300 Hz. As the major energy of the ASSR is at the MF, and the FFT acts as a narrow-band filter centered on the MF, the filter cutoff points are largely unimportant, unless there is a danger of saturating the bioamplifier.

ELECTRODE MONTAGE

ASSRs are readily recordable using electrode configurations similar to those used for the ABR. A number of factors contribute to the optimal placement of electrodes. Some of these include location of the ASSR generator and noise sources.

The magnitude of a scalp-recorded evoked response varies depending on the orientation of the equivalent dipole of the underlying generator. The 80-Hz ASSRs have a major component in the brainstem oriented vertically and therefore yield large responses when using centrally placed noninverting electrodes such as Cz, Fpz, or Fz, with inverting electrodes placed at the mastoid, inion, or nape of neck (C7). The 40-Hz ASSR has neural generators that are both at the brainstem and at the primary auditory cortex levels and therefore will also have large responses recorded from the midline. A study by Van der Reijden et al. (2004) evaluated the effect of electrode placement on ASSRs obtained from young infants. They recorded ASSRs from an array of 57 scalp electrodes and determined the montages that yielded the best ASSR-to-noise ratios. They showed a Cz-Mi (vertex-ipsilateral mastoid) montage resulted in the largest ASSR-to-noise ratios. The practical result is that using the Cz-Mi montage will result in time-savings during an ASSR evaluation, because criterion SNRs are reached more quickly. More recently, Van Dun et al. (2009) recorded ASSRs with six scalp electrodes and combined ASSRs across electrodes in various combinations. They showed that in quiet, "clean" EEG recordings, the addition of multiple recording electrodes does not provide an SNR advantage for the ASSR. However, in situations of higher EEG noise, as is typical in the clinic, a clear SNR advantage was obtained with "spatial averaging" across the Oz, P3, and Mi electrode sites, when Cz was used as reference.

Noise Sources

Every electrode placed on the scalp will have noise sources, either electrical or physiological. Electrical noise can most often be reduced by ensuring that the contact between electrode and skin has low impedance (under 5 k Ω). One source of physiological noise results from placing an electrode over a muscle. Tonic muscle activity is particularly problematic because it contains energy at frequencies (20 to 50 Hz) that are close to those of the ASSR. For example, a large amount of tonic neck muscle activity is present in an otherwise quiet subject sitting upright. If an electrode is placed at the nape of neck, the recording will be contaminated with this muscle noise. In such cases, placing head supports behind the subject's neck often relieves the strain on neck muscles ensuring less muscle activity and increased comfort for the subject.

AVERAGING

Just like every other evoked response, the ASSR becomes more easily detected through the process of averaging (see Chapter 11). By definition, an ASSR has a stable amplitude and phase. The ASSR detection algorithms (see the next section) are based primarily on the SNR; that is, the ASSR signal must be significantly larger than the noise for the ASSR to be detected. ASSRs near threshold have very low amplitudes, and averaging for a substantial time period is required so that the ASSR can be detected.

Another assumption of averaging, and of the ASSR detection algorithms, is that the background noise is stationary; however, biologic noise (coughing, sneezing, blinking, yawning, swallowing) is anything but. Invariably, when recording at near threshold levels, the subject transiently generates muscle noise (i.e., swallowing, or gross limb movements), creating a large "noise burst" that significantly alters the SNR, thus resulting in the detection algorithm indicating no response. A couple of options exist for such cases. One is to simply record for a longer period of time until the transient noise has been "averaged out." Another option is to use artifact rejection. Simply, if the voltage of an EEG sample exceeds a predetermined value (i.e., 80 mV), that sample is discarded. The disadvantage of artifact rejection is that the response is discarded along with the noise, so that longer test times are needed to obtain a result.

Weighted averaging (Elberling and Wahlgreen, 1985; John et al., 2001a) is another signal processing method used to reduce the effect of transient noise in evoked potential recordings. The general concept in weighted averaging is that noisy sections of the recording, that is, noisy EEG samples, contribute proportionally less to the overall average. Using online calculations, the "weight" of each sample can be determined by considering its variance. Noise will increase the variance of a sample. A weighted-averaging algorithm will assign the higher variance samples lesser weights, and the low-variance samples higher weights. Samples with large (noise) variance will contribute proportionally less to the overall average.

DETECTION METHODS

One of the major reasons that ASSRs are gaining widespread use is the fact that "real-time" statistical methods may be used for response detection. It is only when an evoked response is detected using statistical methods that the technique is truly "objective."

Time- and Frequency-Domain Methods

Most modern techniques of ASSR detection involve transformation of the response from the time domain to the frequency domain. These transformations are usually accomplished using the Fourier transform. In the frequency domain, the ASSR can be represented as an addition of sinusoids each with its own frequency, amplitude, and phase.

The Fourier transform can be implemented in either analog or digital form. In analog form, the EEG sample is fed into a Fourier analyzer and is multiplied by the sine and cosine of the modulation frequency. After multiplication, the ASSR at the modulation frequency is observed as a sustained or DC output, whereas noise yields an oscillatory or AC output. The Fourier analyzer output is further low-pass filtered and yields values x (from the cosine multiplication) and y (from the sine multiplication). The ASSR amplitude, a , is calculated using the formula (Stapells et al., 1984)

$$a = (x^2 + y^2)^{0.5}$$

Response phase, θ , is calculated using the formula

$$\theta = \tan^{-1}(y/x)$$

The output of the Fourier transformation for a particular (modulation) frequency of interest is two-dimensional, with real and imaginary components in rectangular coordinates, or as a magnitude and phase in polar coordinates; that is, a Fourier coefficient is a complex number. These two dimensions may be graphed on a polar plot with response amplitude shown by the length of the vector and response phase (latency) as the angle of the vector in either radians (from 0 to 2π) or in degrees (from 0 to 360).

There are two general strategies for objective statistical analyses of the ASSR. One strategy involves repeated measures of ASSR phase and amplitude as obtained from the Fourier transformation. The other strategy evaluates the variability of the ASSR and adjacent noise amplitudes in the spectrum of the response.

Phase Coherence Measures

PC is related to the signal (response)-to-noise (background EEG and myogenic) ratio. The basic concept is that the phase delay of the response is measured relative to the MF. Each averaged response can be subjected to a fast Fourier transformation (FFT). For PC, the phase of the major peak at the MF frequency can be plotted in polar coordinates. The sine and cosine of the angles formed by each phase

vector (for each sample) are calculated.* The general idea for detecting ASSRs using PC is that measurements of phase (from the Fourier transformation) are taken for a number of EEG samples. If an ASSR is indeed present, then its phase will be consistent, phase-locked to the MF, across the samples. If sample phases are random, then the ASSR cannot be distinguished from background noise.

PC values vary from 0.0 to 1.0. When the sample phases are in phase with one another, there is high coherence and the values will be closer to 1.0. When the sample phases are random, there is low coherence (values close to 0), as would be found if the samples contained only noise, with no ASSR. The statistical significance of the resulting PC value can be determined. That is, the probability that the samples come from a distribution of phase values that are randomly distributed can be tested using a variety of statistics. Usually when a significance level of $p < 0.05$ is obtained, the null hypothesis (samples of phases and sample of noise are equal) is rejected, and the samples can be considered phase-locked or phase coherent, and an evoked response is deemed to be present. The amplitude, or length, of the phase vectors is not used in this statistical test. Very small amplitude responses that demonstrate high PC will be detected as easily as large-amplitude responses with the same degree of PC.

Dobie and Wilson (1989a, 1989b, 1993, 1995) have employed magnitude-squared coherence[†] (MSC) methods for detecting and defining the ASSRs. This method uses both the amplitude and phase information from the FFT. MSC (γ^2) estimates the power of the averaged response divided by the average power of the individual responses. γ^2 will vary from 0 (no response) to 1 (high SNR). Since the response consists of both signal (response) and noise, the MSC can be viewed as a signal plus noise-to-noise estimate. Theoretical distributions of MSC have been determined, so that it is possible to determine critical values to be used in the objective detection of an ASSR. When a critical value of MSC is exceeded by the EEG samples obtained in response to an AM tone, the null hypothesis (sample containing only noise) can be rejected and an ASSR has been detected. Another method for determining the significance of the ASSR phase and amplitude distribution employs the Hotellings T^2 test, which is similar to a t -test, except that it calculates significance in two dimensions (amplitude and phase). Victor and Mast (1991) introduced the T^2_{circ} , which assumed equal variances in both real and imaginary dimensions. This results in confidence

*Phase coherence is

$$PC = [(1/n \sum \cos \phi_i)^2 + (1/n \sum \sin \phi_i)^2]^{1/2}$$

where n is the number of successive samples and ϕ is the phase of the i th frequency component in the Fourier series.

[†]Magnitude-squared coherence, γ^2 , is

$$MSC = ((1/n \sum A_i \phi_i)^2 + (1/n \sum \sin A_i \phi_i)^2)^{1/2} / (1/n \sum A_i^2)$$

where n is the number of subaverages and ϕ is the phase and A the amplitude of the i th frequency component in a Fourier series.

limits with a circular shape. Mathematically, the T^2_{circ} and γ^2 are equivalent (Dobie and Wilson, 1993).

If amplitude information is ignored, that is, if all amplitude vectors are set to a value of 1, then $MSC = PC^2$, or $PC = (MSC)^{1/2}$. The advantage of MSC is that amplitude increases in the evoked potential will serve to increase the MSC value obtained, and enhance detection, as compared to methods that measure phase alone. The disadvantage of MSC is that fluctuations in background noise will have a greater effect on the MSC value compared to PC or PC^2 (PCS).

Dobie and Wilson (1995) compared MSC at two alpha levels, 0.01 and 0.10, to human visual detection of the time-domain waveform for a 40-Hz auditory-evoked potential. The sensitivity and specificity of each method were determined, and a d' calculated. Values for d' were higher for MSC at both alpha levels, compared to human observers. Although thresholds were not estimated, it is clear from their data that the alpha level for MSC would have an effect on estimated threshold. In general, as the statistical criterion is relaxed, the estimated threshold decreases, but at the expense of decreased specificity (more false positives, or responses detected when there is no stimulus).

Spectral Measurements

The basis for spectral measurements of ASSR detection comes from performing an FFT on a grand averaged recording. The result is a frequency spectrum of the entire EEG. The peaks in the resulting spectrum, and the amplitude and phase of the spectral peak, can be measured. A steady-state response evokes activity at the MF, and, therefore, the stronger the signal the more power there is at the MF. In this measurement, the noise is defined as activity that is not at the MF. The significance of the signal is determined by comparing the power (voltage squared) of the signal to the power of the noise (a few Hertz above and below the MF). An F -test can then be calculated, where the numerator is the power of the signal and the denominator is the power of the noise.

Picton et al. (2003) have described the method of spectral analysis for ASSR detection:

“The level of the background noise in a recording can be estimated by measuring the activity at frequencies in the spectrum other than that of the stimulus and response. Comparing the power of the signal to the powers at other frequencies is the basis of the F -test for hidden periodicity (Dobie and Wilson, 1996; Lins et al., 1996). The procedure calculates an F ratio of the power in the signal frequency bin (s) to the mean power in N adjacent bins:

$$F = N(x_s^2 + y_s^2) \left/ \sum_{\substack{j=s-N/2 \\ j \neq s}}^{s+N/2} (x_j^2 + y_j^2) \right.$$

This is distributed as F with degrees of freedom 2 and $2N$. The F -test is essentially the same as the magnitude

FIGURE 15.7 Examples of phase coherence, circular T^2 , and F -tests for a statistically significant response [signal] versus no response [noise]. Each dot in the phase coherence quadrant represents the end-point of a phase vector, which emanates from the 0,0 point of the vertical and horizontal axes. Similarly, the position and size of the circle drawn on the T^2 quadrant represents the presence of a statistically significant response. A result containing only noise [no response] is indicated by a circle that is at or close to the crossing of the X- and Y-axes. For the F -test, the amplitude of the response spectrum peak at the MF will be significantly larger than the amplitude at adjacent frequencies.

squared coherence when the number of individual measurements for calculating the coherence equals one less than the number of adjacent points used in the F -test, i.e., the degrees of freedom are the same (Dobie and Wilson, 1996).

The F -test has several advantages over tests based on repeated measurements of the response. First, the number of adjacent frequency-bins to which the signal response is compared can be increased beyond any easily obtained number of separate measurements of the signal response. Second, the technique can easily be adapted to omit certain frequency bins from the calculation. In this way a noise estimate can be obtained that is uncontaminated by line noise or by responses at other frequencies (if one is recording responses to multiple simultaneous stimuli.)”

Figure 15.7 shows the results for PC, circular t -tests, and F -tests for trials in which responses are present compared to those in which only noise is present.

CALIBRATION

Calibration of modulated tones is straightforward. The common practice is to measure the SPL of the modulated tone in the same way as for a puretone. Commercially available test instruments allow the user to select levels using dB SPL or dB HL levels. In the latter case, the 0 dB HL at each frequency would have the same SPL as a puretone at 0 dB HL, for exam-

ple, using published audiometer standards such as ANSI S3.6-2004 American National Standard Specification for Audiometers, or equivalent international standards (ISO-389-2: 1994; ISO-389-1:1998). For example, using ANSI 3.6-2004, the SPL of a 2.0 kHz at 0 dB HL is 2.5 dB when presented through insert phones (calibrated in an H1 A coupler).

It must be recognized that the power of a modulated tone is less than that for a puretone of the same peak amplitude. The long-term average power of a sinusoidally amplitude-modulated (SAM) waveform is $(1 + m^2/2)I_0$, where I_0 is the average power when m , the modulation index, = 0 (Viemeister, 1979). The relative increment in power, $\Delta I/I_0$, for a modulated tone is $m^2/2$. Viemeister’s classic study of temporal modulation transfer functions (1979) addressed the issue of modulation detection thresholds by measuring modulation thresholds for power-compensated wide-band noise $[(1 + m \sin \omega_m t)/(1 + m^2/2)^{1/2}]$ compared to those obtained with no compensation $[(1 + m \sin \omega_m t)]$. At modulation frequencies below 560 Hz, there was no effect of power compensation on modulation thresholds. Although the threshold of modulation detection is different from the threshold for a stimulus with modulation, it is worth keeping in mind that the power of modulated versus unmodulated signals is different, and that there will be a discrepancy of around 2 to 3 dB when thresholds for 100% AM tones are compared to those for unmodulated tones. These differences are not compensated for when using dB HL calibration.

CLINICAL APPLICATIONS OF ASSR

The primary application of ASSR in audiology is for hearing threshold estimation in those at risk for hearing loss, that is, the prediction of the audiogram. To this end, a number of studies have compared ASSR thresholds and behavioral thresholds in infants, children, and adults with hearing loss and published regression formulae that relate ASSR threshold to puretone threshold. Alternatively, the difference between ASSR and puretone thresholds has been calculated, and these “correction” factors have been used to interpret the ASSR thresholds. In addition, ASSR thresholds to bone-conducted stimuli can be used to determine the presence and extent of a conductive impairment. The determination of a sensory versus neural hearing loss, another element of site-of-lesion evaluation, is possible, under some circumstances. ASSRs have also been employed in hearing aid and cochlear implant (CI) evaluations. Experiments with ASSR tests employing complex and dynamic suprathreshold stimuli hold some promise for estimating psychophysical and speech perception abilities. These applications are reviewed below.

Audiogram Prediction/Hearing Threshold Estimation

A driving concept in ASSR research is the objective determination of the puretone audiogram. The goal of objectivity

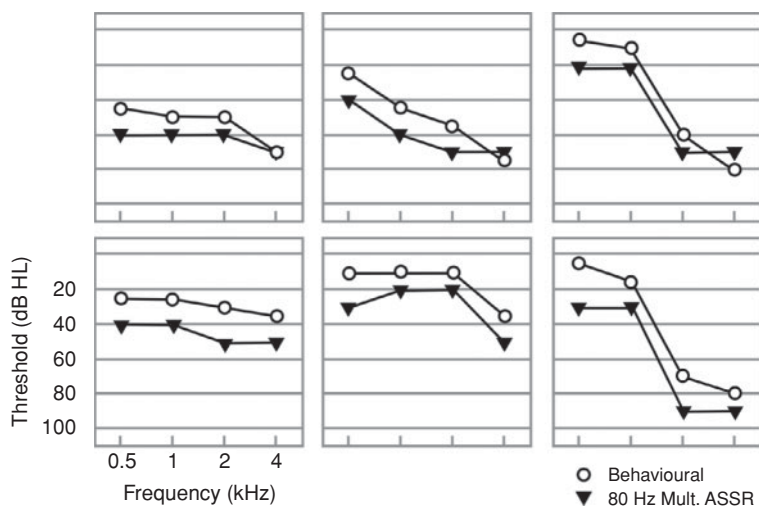

FIGURE 15.8 ASSR results from Van Maanen and Stapells [2005] showing a variety of audiometric configuration can be estimated using ASSRs. *White circles* represent behavioral thresholds whereas *black triangles* are ASSR thresholds derived using multiple ASSRs.

should be met in three ways. First, the threshold determination is based on a physiological response, not on a subjective perception of the subject. Second, the presence of a response is determined by the use of statistical tests, or “objective” detection algorithms. Third, the interpretation of the results is also bound by objective methods and decision-making rules.

Figure 15.8 illustrates how different audiometric configurations can be predicted using ASSRs (data adapted from Van Maanen and Stapells, 2005).

A comprehensive study of hearing threshold prediction using ASSR, in a sample that included hearing impaired children and adults, was reported by Rance et al. (1995). Participants had hearing losses that were moderate or worse, including some with profound hearing loss. These hearing losses were purely sensory/neural; those with conductive loss were specifically excluded from the study. ASSR threshold estimates were made using CFs at 250, 500, 1,000, 2,000, and 4,000 Hz, all presented at an MF of 90 Hz. Pearson product-moment correlations between puretone and ASSR threshold were at 0.96 for 250 Hz and as high as 0.99 for 2,000 and 4,000 Hz. Regression formulae were developed, to predict behavioral thresholds from ASSR thresholds. Table 15.2 shows these formulae for each CF. The Y-intercepts demonstrate that subjects with normal hearing (e.g., 10 dB HL) have ASSR thresholds elevated by as much as 40 dB with respect to puretone threshold in the low frequencies, whereas in mid and high frequencies, ASSR thresholds are closer to puretone thresholds. This is similar to reports of ABR thresholds to toneburst stimuli in normal hearing subjects (Stapells, 2000). As hearing loss increases and as CF increases, there is less discrepancy between behavioral and ASSR threshold, shown by an analysis of the standard deviations of the regressions by degree of hearing loss and by CF (Rance et al., 1995). Errors in prediction of behavioral thresholds from ASSR thresholds show standard deviations ranging from 3.6 dB for severe-profound losses

at 2 kHz, to 11.9 dB for mild-moderate losses at 250 Hz. These findings are very similar both qualitatively and quantitatively to the findings of Stapells et al. (1995), who developed regression formulae relating toneburst ABR threshold to puretone threshold in infants and young children.

In a related study, the Melbourne group (Rance et al., 1998) demonstrated the advantages of using ASSRs to determine residual hearing thresholds for those infants and children from whom ABRs could not be evoked (at 100 dB nHL) using click stimuli. Again, ASSRs were obtained using CFs of 250 to 4,000 Hz with an MF of 90 Hz. In a sample of 109 children, whose hearing losses ranged from moderate to profound, the average discrepancy between ASSR and behavioral thresholds was only 3 to 6 dB (although the standard deviations were 6 to 8 dB), with larger discrepancies and standard deviations found at 250 and 500 Hz, as in the previous study. ASSR thresholds were within 20 dB of puretone threshold for 99% of the comparisons and less than or equal to 10 dB for 82% of the comparisons. The findings demonstrated the efficacy of ASSRs for estimating the audiogram in infants and children who can benefit from the amplification of their residual hearing.

More recently, Rance et al. (2005) published a large series of ASSR and behavioral thresholds in infants. Clinical findings from seven audiology centers within the state of Victoria, Australia, were pooled. All centers used the GSI-Audera (GSI-Nicolet) or its predecessor, the ERA System (ERA Systems), in the collection of ASSR thresholds. Only those infants who had ASSR thresholds measured at ≤ 3 months of age, who subsequently yielded reliable conditioned behavioral audiometric thresholds, and who had evidence of normal middle-ear function at the time of ASSR and behavioral tests were included. This sample was composed of 575 infants (1,091 ears), whose ASSR thresholds were obtained at a mean age of 2.6 months and behavioral thresholds obtained at a mean age of 9.8 months. There were 285 (of 575) infants who demonstrated normal hearing

TABLE 15.2

**Regression Formulae Relating ASSR Threshold to Behavioral Threshold,
Where x = ASSR Threshold**

Carrier Frequency	500 Hz	1,000 Hz	2,000 Hz	4,000 Hz
Cone-Wesson et al. [2002a]	$1.39x - 35$	$1.24x - 15$	$0.94x + 5$	$1.34x - 24$
Dimitrijevic et al. [2002]	$0.88x - 9$	$0.92x - 1$	$0.89x - 0$	$0.99x - 8$
Herdman and Stapells [2003]	$0.77x - 6$	$0.91x - 4$	$0.92x - 6$	$1.04x - 5$
Rance et al. [1995]	$1.30x - 40$	$1.18x - 26$	$1.05x - 19$	$1.19x - 24$
Rance and Rickards [2002]	$1.39x - 49$	$1.35x - 44$	$1.28x - 36$	$1.31x - 39$
Rance et al. [2005]	$1.37x - 45$	$1.33x - 40$	$1.23x - 28$	$1.32x - 37$
Van der Werff and Brown [2005]	$1.12x - 23$	$1.03x - 13$	$1.11x - 14$	$1.11x - 13$

Regression formulae: [1] Cone-Wesson et al. [2002a] based on a sample of 51 infants, mean age 16 months, 16 with near normal or mild loss, 18 with moderate loss, and 17 with severe-profound loss. Whereas 31 were SNHL, 10 were conductive and the remainder had normal hearing or mixed-type loss. [2] Dimitrijevic et al. [2002] based on a sample of 45 adults, 31 with hearing loss and 14 with normal hearing. In the hearing loss group, there were 17 ears with mild, 19 with moderate, and 16 with severe loss. [3] Herdman and Stapells [2003] based on a sample of 27 adults with SNHL ranging from mild to severe. [4] Rance et al. [1995] based on a sample of 25 children with moderate to profound SNHL and 35 adults with hearing ranging from normal to profound SNHL. [5] Rance and Rickards [2002] based on a sample of 211 infants with a mean age of 3.2 months at the time of ASSR and a mean age of 7.9 months at the time of behavioral hearing tests. Infants with evidence of conductive or progressive losses were excluded. [6] Rance et al. [2005] based on 575 infants tested at a mean age of 2.6 months, with behavioral tests completed at a mean age of 9.8 months. Whereas 285 infants had normal hearing thresholds (by behavioral tests) 271 had SNHL. [7] Van der Werff and Brown [2005] based on 30 subjects, 10 with normal hearing, 10 with sloping hearing losses, and 10 with flat hearing losses.

(thresholds ≤ 15 dB HL). The mean ASSR thresholds in this group were 32.3, 32.5, 23.3, and 28.1 dB HL for CFs at 0.5, 1.0, 2.0, and 4.0 kHz, respectively, with standard deviations ranging from 6.3 dB (2.0 kHz) to 7.5 dB (0.5 and 4.0 kHz).

For the infants with sensory/neural hearing loss ($N = 271$), regression formulae were developed to relate the ASSR and behavioral thresholds. These are shown in Table 15.2 and are similar to those published by Rance et al. (1995) and Rance and Rickards (2002). In general, the slope of the regression function indicates that as hearing loss increases in severity, and CF increases in frequency, there is a closer correspondence of ASSR and behavioral threshold.

Several studies have demonstrated that ASSR thresholds have a strong relationship with puretone thresholds in adults with well-defined hearing losses. Dimitrijevic et al. (2002) tested 59 ears of 31 adults with primarily sensory/neural hearing impairments ranging in severity from mild to severe, with nearly equal representation among mild, moderate, and severe degrees of loss. The ASSR thresholds showed a high correlation with the puretone thresholds, with $r = 0.92$ for carriers in the range of 500 to 4,000 Hz. The differences between ASSR and puretone threshold ranged from 13 ± 11 dB at 0.5 kHz and 5 to 8 dB ± 8 to 11 dB for carriers at 1.0 to 4.0 kHz. Herdman and Stapells (2003) tested 31 male adults with sensory/neural hearing losses, some with very steep configurations, and demonstrated that the ASSR versus puretone threshold differences were, on average, 14, 8, 10, and 3 dB for CFs at 0.5, 1.0, 2.0, and 4.0 kHz, respectively. Van der Werff and Brown (2005) and Picton et al. (2005) obtained ASSRs from adults with normal hear-

ing and those with sensory/neural hearing loss. Both studies showed that the difference between ASSR and puretone threshold was smaller in those with sensory/neural hearing loss than in the normal hearing subjects. This is in agreement with Rance et al. (1995). Furthermore, the amplitude-growth functions were steeper in those with sensory/neural hearing loss, indicating a physiological recruitment-like phenomenon (Picton et al., 2005). Van der Werff and Brown (2005) showed ASSR–puretone differences in the range of 8 to 18 dB HL at 0.5 and 1.0 kHz, but only 6 to 8 dB HL at 2.0 and 4.0 kHz, among adults with sensory/neural hearing losses. On the other hand, Picton et al. (2005) obtained ASSR–puretone differences of less than 5 dB HL in their group of elderly adults with sensory/neural hearing loss. One reason for these differences may be that Van der Werff and Brown (2005) averaged ASSRs for about 4 minutes, whereas Picton et al. (2005) averaged for greater than 9 minutes, thus allowing resolution of responses with smaller SNRs.

Regardless of stimulus procedure, whether it be single frequency (Rance et al., 1995) or multiple frequencies (Dimitrijevic et al., 2002; Herdman and Stapells, 2003; Picton et al., 2005; Van der Werff and Brown, 2005) or averaging time (as short as 90 seconds in Rance et al., 1995, as long as 9 minutes in Picton et al., 2005), it is clear that the ASSR provides a clinically useful estimate of puretone thresholds, even in sloping audiometric configurations. The largest discrepancies between ASSR and puretone threshold are obtained in those with normal cochlear function (i.e., normal or conductive hearing loss), which are on

the order of 25 to 40 dB for low-frequency carriers and 10 to 20 dB for mid- and high-frequency carriers. The size of the ASSR–puretone difference is not really the issue, as this can be accounted for with a correction factor; it is the variability that is troublesome. For example, even if the ASSR–puretone difference was 45 dB at every frequency, if there was little variability (± 5 dB), puretone threshold would be easy to estimate. What is observed, however, is that both the ASSR–puretone difference and the variability are dependent on CF and degree of hearing loss. As the CF and degree of hearing loss increase, the ASSR–puretone difference and the variability decrease. That is, predictive error decreases with increases in severity of hearing loss and CF. Both subtractive and regression formulae methods of estimating puretone thresholds from ASSR thresholds can take this into account. Table 15.3, after Picton et al. (2003), updated with studies published since 2003, summarizes 80-Hz ASSR threshold data from multiple clinical laboratories.

Comparison of ASSR with ABR

Because a primary application of ASSR is in the estimation of threshold, it is appropriate to compare the results

obtained from ASSR to those obtained from ABR tests using tonebursts. There are, however, a number of differences in methodology that could lead to fairly substantial differences, including stimulus spectrum, modulation envelope/toneburst shape, rate, and response detection methods.

Aoyagi et al. (1999) directly compared toneburst-evoked ABR threshold estimates to ASSR threshold estimates, primarily in hearing impaired children tested during sedated sleep. They used a 1,000-Hz tone modulated at 80 Hz to evoke the ASSR and a 1,000-Hz toneburst (2 ms rise/fall time, 1 ms plateau) with a 53-ms interstimulus interval to evoke an ABR. Puretone thresholds ranged from 10 to 110 dB HL in the group of children tested with ABR and ASSR. The correlation of puretone threshold (in dB HL) with ABR threshold (in dB nHL) was 0.83, whereas for ASSR the correlation with behavioral threshold was 0.86. The difference in correlation coefficients was not statistically significant. The mean difference between behavioral and ASSR threshold was 3.8 dB (12.9 s.d.) and for ABR the difference was 6.8 dB (14.1 s.d.). It is not known if the dB nHL reference was the same for the AM tone and the toneburst.

TABLE 15.3

ASSR Threshold–Behavioral Hearing Threshold Difference, in Adults, Children, and Infants with Hearing Loss

Study	Subjects	Stimulus	500 Hz	1,000 Hz	2,000 Hz	4,000 Hz
Van der Werff and Brown [2005] (flat loss)	10	MM	11 \pm 5	8 \pm 4	7 \pm 5	6 \pm 5
Van der Werff and Brown [2005] (sloping loss)	10	MM	18 \pm 8	10 \pm 7	8 \pm 6	5 \pm 4
Picton et al. [2005]	10	MM	11 \pm 18	–4 \pm 9	2.5 \pm 11	5 \pm 12
Luts and Wouters [2005] (“Master”)	10	MM	17 \pm 12	12 \pm 8	17 \pm 8	19 \pm 12
Luts and Wouters [2005] (“Audera”)	10	MM	20 \pm 8	14 \pm 7	13 \pm 7	14 \pm 13
Herdman and Stapells [2003]	29	AM	14 \pm 13	8 \pm 9	10 \pm 10	3 \pm 10
Dimitrijevic et al. [2002]	31	MM	13 \pm 11	5 \pm 8	5 \pm 9	8 \pm 11
Rance and Briggs [2002]	184	MM	6 \pm 9	6 \pm 7	4 \pm 8	3 \pm 11
Van Maanen and Stapells [2005]	23	MM	17 \pm 11	15 \pm 7	19 \pm 9	4 \pm 10
D’haenens et al. [2009]	21, 18, 13, 4 [mild]	MM	14 \pm 11	13 \pm 8	14 \pm 7	13 \pm 6
	11, 15, 20, 27 [mild]	MM	14 \pm 7	10 \pm 10	9 \pm 6	11 \pm 9
Lin et al. [2009]	142	AM	17 \pm 14	15 \pm 9	14 \pm 8	11 \pm 87
Ishida et al. [2011] ^a	13 [flat]	MM	6 \pm 12	4 \pm 13	3 \pm 13	2 \pm 11
	10 [gradual slope]	MM	18 \pm 8	7 \pm 10	4 \pm 13	0 \pm 9
	15 [steep slope]	MM	25 \pm 13	16 \pm 11	11 \pm 12	2 \pm 10

The number of subjects and stimulus type are given for each study. AM is a sinusoidally modulated puretone and MM is an amplitude- and frequency-modulated tone. Rance and Briggs [2002] is the only study in which ASSR – PT differences were published for infants and children. All other studies report differences in adults. All studies used multiple carrier frequencies presented simultaneously, except Rance and Briggs [2002] and Luts and Wouters [2004] “Audera,” in which single-frequency, sequential testing was used.

^aBone conduction.

Cone-Wesson et al. (2002a) performed a direct comparison of toneburst-evoked ABR and ASSR threshold measures in a group of 10 normal hearing adult subjects. ABRs were evoked using 0.5- and 4-kHz tonebursts, with (Blackman window) onset and offset ramps of two cycles, and a one cycle plateau, presented with an interstimulus interval of 40 ms. ASSRs were evoked using CFs of 0.5 and 4 kHz, tested at 41 Hz, and also at 74 Hz for the 0.5-kHz CF and at 95 Hz for the 4-kHz CF. Sampling for each ABR trial proceeded until an Fsp criterion of 3.1 ($p < 0.01$) was met, or 6,000 artifact-free samples were obtained. Visual detection by an expert observer was used as an additional measure of ABR presence. For each ASSR trial 64 samples of 1.486 seconds duration were obtained and subjected to PC analysis using a filter centered at the MF. A response was considered present if the PC statistic reached a criterion of $p < 0.01$. Thresholds for the 46-Hz ASSR and toneburst ABR thresholds were not statistically different. Thresholds for the 74-Hz MF–0.5-kHz CF were elevated with respect to the ABR threshold for a 0.5-kHz toneburst (and 46-Hz ASSR), but thresholds for the 95-Hz MF–4-kHz toneburst were 15 dB better than those for the 4.0-kHz toneburst ABR.

This study is the only one that attempted to compare threshold estimates using both ABR and ASSR methods and also employed similar statistical criteria for judging a response to be present. There is no difference in evoked potential threshold (expressed as dB SL) when adults are tested with tonebursts (for ABR) or CFs modulated at 41 Hz (for ASSRs), and when both ABR and ASSR are detected using an appropriate statistical technique. These results are in agreement with Cohen et al. (1991) and Dobie and Wilson (1998), who show that a low MF (in this case 41 Hz) is generally advantageous testing *adults* at low CFs (1,000 Hz or lower) whereas the higher MFs (above 60 Hz) are generally better for high CF tones. In normal hearing adults, furthermore, ABRs and ASSRs can generally be detected within 20 dB of behavioral threshold.

Van der Werff et al. (2002) obtained click and toneburst ABR and ASSR thresholds from 32 infants and young children, all tested during sedated sleep. All the participants in the study were being evaluated as candidates for CIs, and so they were known to have significant hearing losses. They found a 0.97 correlation between click ABR thresholds and those found for ASSRs at 2.0 and 4.0 kHz. The correlation between the 500-Hz toneburst ABR and the 500-Hz ASSR thresholds was statistically significant, but lower (0.86) than the correlations between click ABR and high-frequency (2- and 4-kHz) ASSR. In 33% of cases, when the toneburst ABR was absent for stimuli presented at the highest stimulus level available, an ASSR was present, albeit at elevated levels consistent with a moderately severe or greater hearing loss. Also, 58% of ears with absent click-evoked ABRs had an ASSR response. This result replicates the findings of Rance et al. (1998) that ASSR thresholds may reveal some residual hearing when click or toneburst ABRs are absent.

This property has helped to establish ASSR as a valuable test for infants and young children undergoing evaluation for cochlear implantation.

Johnson and Brown (2005) measured ASSRs and toneburst-evoked ABRs at 1.0, 1.5, and 2.0 kHz in adults with normal hearing and those with flat or sloping sensory/neural hearing losses. ASSR thresholds were determined as the lowest level at which a statistically significant response was obtained, whereas ABR thresholds were determined by visual inspection of the time-domain waveforms. Overall, ABR thresholds were “closer” to behavioral thresholds than ASSRs, except in the case of steeply sloping sensory/neural hearing losses, for which ASSRs were better estimates of threshold. Both ASSR and ABR provided accurate estimates of threshold among those with sensory/neural hearing loss.

In summary, the experience of those who use the ASSR technique for predicting audiometric threshold in hearing impaired infants and children appears to be comparable to that of those who use toneburst-evoked ABRs. Comparisons between the two techniques can be made to help formulate the most efficient and sensitive methods for this purpose. Each technique has particular strengths and limitations. An advantageous feature of the ASSR technique is that objective detection algorithms rather than visual detection methods are always used to determine the presence or absence of a response. This is a particular advantage for techniques claiming to be “objective” measures.

It is difficult to determine whether or not the ASSR is detected at lower SPLs than a toneburst-evoked ABR response at the same center frequency, owing to differences in stimulus calibration and response detection method. In normal hearing subjects, visual detection of the toneburst-evoked ABRs yielded lower thresholds, although when both toneburst ABR and ASSR were detected with automatic detection algorithms, the thresholds were equal (Cone-Wesson et al., 2002a).

40-Hz ASSR Threshold Tests

The bulk of the literature concerning audiometric applications of the ASSR employs modulation frequencies of 80 Hz or higher. When it was shown that ASSR responses to 40 Hz were unstable or absent in sleeping infants and children, much of the interest in its audiometric applications diminished. Thus, there is limited data on the use of the 40-Hz ASSR for puretone threshold estimation. Aoyagi et al. (1993) showed that 40-Hz ASSR was present at 11 to 18 dB above puretone threshold in normal hearing adults and at 8 to 13 dB for adults with hearing loss. There is reason to believe that the 40-Hz ASSR threshold estimates would be as good, if not better, than those for the 80-Hz ASSR, but this has not been carefully determined. The 40-Hz ASSR has a larger amplitude than the 80-Hz ASSR; however, background EEG and other biologic noise are larger in that

TABLE 15.4

40-Hz ASSR Threshold–Puretone Threshold Difference (Adults)

Study	Subjects	Stimulus	500 Hz	1,000 Hz	2,000 Hz	4,000 Hz

	38 H	MM	8 ± 6	9 ± 6	9 ± 7	14 ± 10

The number of subjects and their hearing status, and stimulus type are given for each study. For stimulus type, TB is the toneburst, AM is the sinusoidally modulated puretone, and MM is the amplitude- and frequency-modulated tone. For hearing status of subject group, N is normal hearing, H means subjects had hearing loss, and M indicates the group tested had members with hearing loss and normal hearing.

frequency region as well, so that achieving a criterion SNR may require as much averaging as for a smaller amplitude response. Table 15.4 summarizes 40-Hz ASSR threshold as a function of CF in adults.

A study by Van Maanen and Stapells (2005) performed the first comparison of 40-Hz ASSRs, 80-Hz ASSRs, and the slow cortical potential (N1/P2) in adults with normal hearing and sensory/neural hearing loss. Their results demonstrated that multiple 40-Hz ASSRs showed the smallest difference between physiological and behavioral thresholds compared to the other two measures. Moreover, the recording time for the 40-Hz ASSRs and the slow cortical potential was less than for the 80-Hz ASSRs. The authors concluded that the method of choice for estimating threshold in adults was 40-Hz ASSRs.

A growing trend in ASSR research, although not for threshold testing, has been to evaluate brain function using rates below 40 Hz. The general trend from the early work (Picton and Skinner, 1987; Rees et al., 1986) has demonstrated that ASSRs with AM rates from 2 to 35 Hz could be reliably recorded; however, the recordings had high levels of background EEG noise. Also noted was that the lower modulation rates had responses at the modulation rate harmonics. This effect was recently explored by Tlumak et al.

(2012) in both children and adults. ASSRs were elicited by tone bursts ranging from 0.75 Hz all the way up to 80 Hz. Children showed larger responses at harmonics of the modulation rate than at the primary modulation frequency. This effect was most prominent at low modulation rates. It is possible that these harmonics represent the auditory system responding to the modulation change in both directions, in effect responding twice for one cycle of the stimulus. For example, with a low AM rate of 10 Hz, the rise time of the stimulus would be 50 ms (half modulation cycle) and 50 ms fall time (the second half of the modulation cycle), 50 ms being likely enough time for the auditory system to respond before the next half cycle of modulation.

Tlumak et al. (2007) performed a meta-analysis of the literature to test six assumptions about threshold estimation with ASSR. The first was that threshold differences between ASSR and behavioral thresholds decrease with the degree of hearing loss and CF. Second, that threshold estimates are expected to be better with MM stimuli compared to SAM tones. Third, that longer test duration or a greater number of sweeps are associated with lower threshold estimates because of the improvement in the response to noise ratio. Fourth, that there are no differences in the accuracy of threshold estimation for monaural compared to binaural stimulation.

Fifth, that there are no differences in threshold estimation owing to electrode montage; and sixth, that threshold differences for 80-Hz versus 40-Hz ASSR are similar to those found for ABR versus MLR. Meta-analyses were performed for studies that had participants with normal hearing, those with hearing loss, and then by combining the two samples. Assumptions that held true for the group with hearing loss were not always the same for the normal hearing group. In the normal hearing population, the threshold differences between ASSR and behavioral measures were smallest at 1.0 and 2.0 kHz, differences in threshold for MM versus SAM were significant at 1.0 kHz only, and there were no differences for the number of sweeps required to reach threshold for MM versus SAM tones. There was no difference in threshold for stimuli delivered monaurally versus binaurally nor did electrode montage have an effect. The analogy with ABR and MLR was confirmed for both normal hearing and hearing impaired groups. For the hearing impaired group, both modulation type and number of sweeps had significant effects on threshold, as did monaural versus binaural stimulation. As in the normal hearing group, there were no differences in threshold owing to electrode montage for the hearing impaired group.

Bone Conduction

The mainstay of audiometry is the determination of puretone air- and bone-conduction thresholds, for the purpose of determining whether a conductive component exists and its severity. In general, an air–bone gap of >10 dB is considered indicative of a conductive hearing loss. There are a number of studies that have explored the techniques for and the results of ABR BC threshold tests (for review, see Cone-Wesson, 1995). The results of these studies are relevant to the problem of estimating BC threshold with ASSR, for which there are fewer published results. In general, there are two methods for obtaining BC thresholds. First, the stimuli used for the AC test are presented through a bone vibrator, and the difference in threshold for AC and BC test conditions is measured. The second method is to present masking noise by a bone vibrator and to determine the noise level needed to mask the response to an AC stimulus. This is known as the “sensory/neural acuity level” (SAL) technique. The level of effective BC noise needed to mask the response to the AC signal is used as the BC threshold (Ysunza and Cone-Wesson, 1987). The air–bone gap is calculated as the difference between the AC threshold and the BC effective masking level. Both techniques require careful calibration. The first requires determination of psychophysical threshold for the stimuli used for the BC test. The SAL technique requires physiological calibration of the BC noise masker for a panel of normal hearing listeners. Both conventional BC thresholds (Dimitrijevic et al., 2002; Lins et al., 1996; Small and Stapells, 2005) and the SAL technique (Cone-Wesson et al., 2002c) have been used to estimate air–bone gaps from ASSR

threshold tests. The advantage of the first “direct” method is that the procedure mimics that which is typically done during behavioral testing, and so has the comfort of face validity. A disadvantage of obtaining ASSRs to BC stimuli is that the electromechanical artifact of the BC stimulus is “steady state” and is present during the entire recording and so can obscure the neural response or, worse, cause the detection algorithm to return a “false positive,” that is, an artifactual response (Small and Stapells, 2004). An artifactual response may arise if the sampling rate of the signal is a harmonic of the CF. There are two methods for reducing or eliminating this artifact: (1) Change the digital-to-analog conversion rate so that it is not a harmonic of the CF or (2) use a steep antialiasing (low-pass) filter (Picton and John, 2004). Some commercially available instrumentation may not allow these procedures, in which case the chance of artifact during BC testing is very high.

The advantage of the SAL method is that the stimulus for both the AC and BC threshold tests is the same, that is, the AC stimulus. There is no difference in transducer. Also, the artifact produced by the BC oscillator is noise, and so should not be mistaken for the response. The level of the artifact would be expected to diminish with averaging. The disadvantage is that the effective masking levels must be measured physiologically, not psychophysically. Table 15.1 summarizes the studies which established ASSR threshold for BC signals. The real conundrum in BC ASSR (or ABR) tests is not really the stimulus or masker, but the fact that the skulls of infants less than 1 year of age transduce BC stimuli much differently than in adults. Studies (Cone-Wesson and Ramirez, 1997; Yang et al., 1987) have shown that the immature skull appears to “focus” the BC signal at the temporal bone, leading to higher effective stimulus levels than in an adult. Thus, infants exhibit very low ABR thresholds compared to adults, and air–bone gaps exceeding 10 to 15 dB are not uncommon. Furthermore, there are only case reports of how ASSRs for air- and bone-conducted stimuli may be used to detect hearing loss because of middle-ear pathology, and there are no controlled cohort studies demonstrating the clinical efficacy. There are only two studies (Hulecki and Small, 2011; Casey and Small, 2014) that undertook measurement of psychophysical air- and bone-conduction puretone thresholds in infants under the age of 1 year and compared them to ASSR threshold estimates. The range of behavioral versus ASSR threshold estimates was very large (–10 to 30 dB) limiting clinical applicability until the sources of variability can be determined and controlled.

Hearing Aid Fitting and Cochlear Implant Mapping

There is considerable interest in using “objective” measures to fit and demonstrate benefit from amplification, particularly in preverbal infants and toddlers. It is possible to

measure ASSR thresholds in the unaided and then aided conditions (Dimitrijevic et al., 2004; Picton et al., 1998) and demonstrate functional gain. One advantage of using ASSRs for this purpose, compared to ABR, is that the AM (or MM) tones appear to be transduced by hearing aid microphones and circuitry more accurately than are click or toneburst stimuli, at least when used in a linear mode. It is still necessary, however, to measure the fidelity of this transduction and to calibrate the sound field, before making this type of measurement. At the present time, measures of functional gain, using either behavioral or electrophysiological measures, are not recommended (Scollie and Seewald, 2002). Rather, the careful determination of threshold as a function of frequency, and verification of target gains (based on the threshold data) using in situ electroacoustic measures, is preferred. The ASSR test, then, has a role in hearing aid fitting, by providing an accurate estimate of threshold on which hearing aid targets can be based. Yet, to quote Picton et al. (2003):

...demonstrating that the hearing aid is causing sounds to activate responses in the brain at intensities where there was no response without the aid is an important confirmation of the benefit of the aid. This is essential in patients who do not have clear or reliable thresholds (either behavioral or physiologic) without aids. (pg. 211)

ASSR methods for the estimation of the loudness discomfort levels, another crucial variable in hearing aid fitting, have not yet been developed. ASSRs may be present at higher stimulus levels (when toneburst-evoked ABRs are absent at the upper limits of the instrumentation), and thus can more accurately indicate the severity of a hearing loss and residual hearing levels. This is always a consideration when cochlear implantation is being considered. As in the case of hearing aids, the ASSR provides the audiometric data on which implantation decisions can be made.

There are a limited number of studies examining the use of ASSRs in evaluating CI function in humans (Hoffman and Wouters, 2010, 2012; Menard et al., 2004; Yang et al., 2008). Recording an ASSR in subjects with CIs is problematic because the CI itself creates a large electrical signal that can obscure the ASSR. The CI artifact problem arises because the CI extracts the envelope of an incoming signal and uses that derived envelope to modulate electrical pulses stimulating the auditory nerve. Therefore, the stimulus modulation frequency used to elicit the ASSR becomes part of the CI electrical artifact. The algorithms used to detect the ASSR are not able to distinguish between the ASSR and the CI electrical signal. It is not unreasonable to assume that the CI artifact will be larger with greater stimulus intensities (assuming “automatic gain” functions are switched off) and therefore it is difficult to interpret studies that report ASSR thresholds similar to behavioral

thresholds (e.g., Yang et al., 2008) if no measures are taken to reduce CI artifacts. Menard et al. (2004) examined the feasibility of recording ASSRs in the presence of CI artifacts by manipulating the CI pulse train duration and amplitude. To hear a sound, there must be sufficient charge density (pulse amplitude and duration) required to stimulate the auditory nerve. It was assumed that the amplitude of the CI artifact grew as a function of stimulus intensity and was linearly related to CI pulse amplitude. By varying the CI pulse duration and different pulse amplitudes the authors showed that some portion of the recorded ASSR does contain a physiological response, although it was impossible to know how much of the response was artifact, particularly at high stimulus levels. Overall the study found a reasonable relationship between ASSR threshold and behavioral threshold.

Another approach taken by Hofman and Wouters (2010) was to perform operations to reduce the CI artifact. First, they used the CI itself to generate short-duration biphasic pulses of alternate polarities at the desired modulation rate. A very obvious 100- μ V stimulus artifact was observed. The averaged ASSR (across both polarities) still had a sizable artifact (roughly 20 μ V) suggesting the alternating polarities are not entirely symmetrical. The next step in the artifact reduction process involved “cutting out” the artifact by interpolating the EEG time points between the remaining pulse artifacts. This last process reduced the recorded response to 500 nV (in the range for a 40-Hz ASSR). Correlations of $r > 0.96$ were observed between ASSR thresholds and behavioral thresholds. One drawback of the study was that the stimulus rates used (near 40 Hz) were not close to everyday clinical pulse rates (near 1,000 Hz). Additionally, if there were residual CI artifacts present (after removal) there is the possibility of false ASSR detection. In an effort to address these issues, the authors conducted a follow-up study (2012) in which new stimuli were constructed and new statistical methods employed. The two novel stimuli elicited larger ASSRs with artifacts 10 times larger than the single pulses. The authors employed a novel detection paradigm based on the assumption that ASSR phase, being a neural response, changes as a function of modulation rate whereas an artifact does not. Overall, strong correlations were documented between ASSR and perceptual thresholds. Obtaining ASSRs in response to the electrical stimuli provided by the implant is technically challenging. It remains to be determined if there are any advantages to using electrically evoked ASSRs compared to current techniques of electrically evoked compound nerve action potentials or ABRs, at least for threshold estimation. Because ASSRs provide a method to quantify suprathreshold temporal envelope-encoding ability, a critical feature of speech perception with a CI, there may be some impetus to overcome the technical hurdles. At this time, testing ASSRs in response to CI stimulation using standard, commercially available equipment is not recommended.

Differential Diagnosis of Sensory versus Neural Losses

There is limited information on the effect of neurologic compromise on the 80-Hz ASSR. The conditions for which there are published data are for auditory neuropathy (Rance et al., 1999, 2005), neurologic compromise because of confirmed lesions to the central auditory nervous system (Shinn and Musiek, 2007), and neurologic compromise because of prematurity (Cone-Wesson et al., 2002b). A summary of ASSR findings in 19 children with auditory neuropathy showed that there is no correspondence between behavioral hearing sensitivity and ASSR threshold (Rance et al., 2005). Puretone sensitivity was widely distributed between normal hearing and profound hearing loss, but the average ASSR threshold, regardless of CF, was around 85 to 90 dB HL. Correlations between puretone and ASSR thresholds averaged 0.51 in this group, compared to an average of 0.97 in the group with normal hearing or sensory/neural hearing loss. ASSRs cannot be used to estimate the puretone sensitivity of those with auditory neuropathy or retrocochlear or brainstem lesions. One problem that may occur, however, is in the case of an infant with auditory neuropathy for whom evoked otoacoustic emissions are absent. Unless one specifically tested for the presence of the cochlear microphonic, the absence of acoustic reflexes and an absent ABR might be interpreted as a severe-profound SNHL. Because ASSRs are known to be present in cases of severe-profound SNHL when ABRs are absent (Vander Werff et al., 2002), the presence of ASSR at elevated levels could be mistaken for an SNHL.[‡]

A discrepancy between behavioral thresholds and ASSR thresholds may be used as an indicator of neurologic dysfunction. Shinn and Musiek (2007) obtained 40-Hz ASSR thresholds in a group of patients with well-defined brain lesions. The author showed that the discrepancy between behavioral threshold and ASSR threshold was greater in the patient group, when compared to a control group of adults with normal neurologic status. This is qualitatively similar to the results of Rance et al. (2005), who also show large discrepancies between behavioral and ASSR threshold in the patients with auditory neuropathy.

It is unwise to use ASSR thresholds to estimate perceptual thresholds when the status of the central auditory system is unknown. It should be possible, though, to use ABR in conjunction with ASSRs to help determine the impact of neural hearing loss. ABR Wave I–V interwave intervals and/or abnormal waveform morphology (i.e., missing components, abnormal amplitude and latency of components) are

useful for determining the presence of brainstem dysfunction (see Chapter 13). The combination of a suprathreshold click-evoked ABR along with ASSR threshold may be a rational way to approach an electrophysiologic assessment of the brainstem auditory system.

Other ASSR Applications

Although the vast majority of research efforts have focused on the hearing threshold estimation, applications of ASSRs in other domains are becoming more common. A sample of this work is given here.

Dimitrijevic et al. (2001) developed an innovative stimulus, composed of tones that are independently amplitude- and frequency-modulated (IAFM). They obtained significant correlations between the IAFM ASSRs and word-recognition scores in normal hearing adults. Specifically, they measured word recognition across stimulus level and compared the scores across level to the number of ASSRs present for an IAFM complex stimulus consisting of four CFs, each CF amplitude- and frequency-modulated at different rates. The number of ASSR components detected at each stimulus level was significantly correlated with the word-recognition score at a similar level. In a follow-up study (Dimitrijevic et al., 2004), the IAFM stimulus was refined to better represent the AM and FM components in natural speech. Results in normal hearing and hearing impaired subjects (with and without hearing aids) showed significant correlations between the word-recognition scores and the number of ASSR components present. These investigators suggest that ASSRs for multiple modulated tones correlate with word-recognition scores because both speech and multiple modulated tones contain information that varies rapidly in intensity and frequency. The ASSR “score” (i.e., the number of response components present for the 8-component stimulus) was modeled as an indicator of how much acoustic information was available to the listener. The more information available in the speech-frequency range, and for which the auditory system can process rapidly changing intensity and frequency cues, the better the word-recognition (speech discrimination) capabilities. More recently, Alaerts et al. (2009) found high correlations between ASSRs and phoneme identification and sentence perception in normal hearing and hearing impaired adults. Their ASSR stimulus was a speech-weighted noise carrier with AM at 4, 10, 20, and 38 Hz. These rates were chosen because much of the speech envelope contains information below 40 Hz (Rosen, 1992; Drullman, 1994). A combined measurement of ASSRs at 4, 10, and 20 Hz showed high correlations with phoneme and sentence identification. Interestingly, the higher modulation rate, 38 Hz, did not show a significant relationship with either phoneme or sentence scores.

The principle of using a complex ASSR stimulus for estimating speech perception abilities was applied in a cohort of infants under the age of 1 year by Cone and Garinis (2009).

[‡]It is also possible to evoke a response from the vestibular system when high-level modulated stimuli are used. These may be mistaken for auditory responses unless steps to rule out other sources of artifact are undertaken (Gorga et al., 2004).

They trained infants to perform a speech-feature detection task using an operant-conditioned response. Speech token levels were presented at several different levels to develop a performance-level function. ASSRs for the complex stimulus were also measured as a function of level. There was a strong correspondence between the ASSR and behavioral performance-level functions. As there are no methods for determining speech perception ability in preverbal infants, an electrophysiologic indicator, such as ASSR, could have benefit.

ASSRs in response to suprathreshold modulated noise have been correlated with temporal gap detection and the detection of modulation (Purcell et al., 2004). Young and old adult listeners had ASSRs recorded for modulated noise, in which the frequency of modulation was swept across the range of 20 to 600 Hz. They also underwent psychophysical tests of gap detection and modulation detection. First, the highest modulation frequency at which an ASSR was detected (using a 25% modulation depth) was significantly correlated ($r = 0.72$) with the modulation detection threshold. Second, the amplitude and phase (latency) of the ASSRs in several ranges of modulation were also correlated with modulation detection. Third, several of the ASSR response parameters were also correlated with gap detection. Because temporal processing is crucial for speech understanding, it is appropriate to develop electrophysiological methods by which temporal processing may be assessed. The ASSR may provide a means of doing so.

Related to temporal processing is phonemic awareness and discrimination. These abilities are also thought to be the basis of reading, and an impairment of temporal processing and/or phonemic awareness is believed to be the basis of some reading disabilities, that is, dyslexia (Goswami, 2011). Adults with dyslexia were shown to have lower 40-Hz ASSR amplitudes than typical readers (McAnally and Stein, 1997). More recent work has focused on differences in laterality of ASSRs at modulation rates associated with syllabic (<4 to 7 Hz) versus phonemic (20 to 40 Hz) processing (Vandermosten et al., 2013). Poelmans et al. (2012) measured group (dyslexic vs. controls) differences in response strength and also laterality for ASSRs at 20 Hz, but not for 80 or 4 Hz. They interpreted this as indicative of dysfunction for the “cortical phonemic processing rate” whereas the “cortical syllabic processing rate” responses (at 4 Hz) and the brainstem responses (at 80 Hz) were not different between the two groups. Vandermosten et al. (2013) used diffusion tensor imaging (DTI) of white matter in conjunction with ASSRs for 4- and 20-Hz modulation to test the hypotheses that dyslexics lack appropriate laterality in white matter and that this is related to the processing deficits identified by Poelmans et al. (2012). They found that, as a group, dyslexic adults demonstrated differences in white matter distribution for the superior posterior temporal gyrus, and arcuate fasciculus compared to typical readers. There was

less pronounced left white matter dominance in dyslexics compared to the typical readers. The results from DTI and ASSR were interpreted as indicating both structural and functional differences in the brain that could be the bases for the phonemic processing problems demonstrated by those with dyslexia. The correlations between perceptual, electrophysiologic, and anatomical findings appear to be in support of the hypothesis that basic mechanisms of spectrotemporal processing are atypical or hypofunctional in those who are dyslexic.

Proposed ASSR Threshold Estimation Protocol

There are several ways to optimize ASSR threshold estimation tests. These take into account stimulus, acquisition, and patient factors that would be expected to influence the results.

STIMULUS

For adults, modulation frequencies may be at 40 ± 5 Hz. As the effects of MM stimuli have not been formally evaluated at 40 Hz, SAM tones are recommended for 40-Hz ASSRs. For infants and children, the modulation rates should be at ≥ 80 Hz but ≤ 120 Hz, MM should be used, and the MF should increase with increasing CF. If more than one CF is presented at a time, the MFs for each CF should be separated by at least 3 Hz. The threshold for modulated noise should be determined prior to that for modulated tones. The threshold for modulated noise can be used to determine the level for initiating a threshold search for specific CFs. A 5-dB step size should be used for ASSR threshold searching with puretones, although a 10-dB step size may be useful for initial testing with modulated noise.

ACQUISITION

Filter settings should be at 1 to 300 or 30 to 300 Hz. The analog-to-digital conversion rate should be at 1,000 Hz or higher (but most commercial instruments do not allow choice of an A/D rate). Artifact rejection, if available, should be employed. The electrode montage for infants and young children should be Cz (vertex) to Mi (ipsilateral mastoid) with the common electrode on the opposite mastoid or forehead. For adults, an Fpz (high forehead) to Oz (inion) may be used.

PATIENT

Infants and young children should be in quiet sleep during the estimation of thresholds. A sedative or light anesthesia may be needed, if the infant is not able to maintain quiet

sleep for the duration of a complete test (40 to 60 minutes). Adults may be awake, but should be encouraged to recline in a comfortable chair, relax, and be still.

TEST METHOD

Testing should not be initiated until the patient is sufficiently quiet. This can usually be determined by observing the patient and the ongoing EEG. Threshold is determined by decreasing the stimulus by 10 dB for each level at which the response criterion is met (i.e., the detection algorithm returns a result that meets the $p < 0.05$ level) and increased by 5 dB when no response is detected. How many averages does it take to determine that a response is *not* present? Some decisions must be made a priori, regarding the amplitude of the response that is to be detected. This decision, then, determines the amount of averaging needed, because it is the averaging process that allows the response to be resolved out of the background noise, as noise decreases with increased averaging. For example, detection of a response of 15 nV would require averaged noise levels to be lower than 10 nV. Depending on how “noisy” the recording is, it may take 10 to 12 minutes to obtain such fine resolution. A 10-nV “noise” criterion has been recommended as a stopping rule for terminating a trial averaging (Picton et al., 2003). Averaging should then proceed for as long as it takes to meet this criterion, or until a response is detected, whichever comes first. If the noise criterion is not met, and a response is not detected, this should be reported as a failure to achieve the a priori criterion. In such cases, a “threshold” cannot be determined. Raising the noise criterion will mean that ASSR thresholds are elevated in comparison to published norms for which the noise criterion was met.

There are other rules that may be employed at the discretion of the clinician, however, when application of these rules would be expected to affect threshold. For example, following the custom of “repeating” a trial as for ABR, some would require that a response be present for two independent trials given at the same level. This means that the criterion that a response is present has been made stricter. Using a stricter criterion will result in elevated thresholds in comparison to the more lax criterion. To avoid spurious “false-positive” responses, some require that the ASSR also be present at 10 dB above the lowest level for which a response is detected (to the same stimulus). False positives are sometimes seen when using a multifrequency technique wherein the ASSR thresholds vary as a function of frequency. For example, the threshold for a 500-Hz CF may be at 35 dB HL and for 2,000 Hz at 15 dB HL. In testing the 2,000-Hz response to threshold, a “response” to the 500-Hz CF may be detected at 15 dB HL, but not at 20, 25, or 30 dB HL. Thus, the “response” obtained at 15 dB HL is not considered valid.

INTERPRETATION OF THRESHOLDS

The ASSR thresholds should be interpreted with respect to published data that have established the relationship between ASSR and puretone threshold. This may involve the use of regression formulae (see Table 15.2) or correction factors (see Table 15.3). An important aspect of interpreting ASSR thresholds in this way is to acknowledge the sample characteristics on which they were based, such as the age (infants, children, or adults), the type of hearing losses (conductive, sensory/neural, or mixed), and the range of hearing losses represented.

Case Study

Some of these principles are illustrated in the following case (Figure 15.9). The response spectra are shown in the left panel, with open triangles denoting responses for tones presented to the right ear and filled triangles for the left ear. The audiograms are shown on the right, with open circles denoting behavioral thresholds and filled squares indicating the ASSR thresholds. For the right ear, ASSRs at 500 Hz and 1.0 kHz are present at 40 dB HL; at 2.0 and 4.0 kHz, ASSRs are present at 60 and 70 dB HL, respectively. For the left ear, a response to 500 Hz is seen at 70 and 50 dB HL, but not at 60 dB HL. The response to 1.0 kHz is present at 40 dB HL, and to 2.0 kHz at 50 dB HL. The ASSR threshold at 4.0 kHz is 80 dB HL. Is ASSR threshold at 0.5 kHz at 70 dB HL or 50 dB HL? A steep upward slope to the audiogram between 0.5 and 1.0 kHz is not unheard of, yet not likely, given the overall configuration of the audiogram. Other information, such as tympanometry and acoustic-reflex thresholds, may also be used to interpret ASSR thresholds. Finally, the 0.5-kHz response is absent at 40 and 30 dB HL, suggesting that 50 dB HL is the threshold. Yet, if one adopted a conservative criterion, requiring the response to be present at 10 dB above the lowest level detected, then the threshold would be judged to be 70 dB HL.

Using ASSR–puretone threshold differences determined from a study of adults with sensory/neural hearing loss (Herdman and Stapells, 2003), the right ear puretone thresholds would be estimated to be 26, 32, 50, and 67 dB HL for octave frequencies at 0.5 to 4.0 kHz, respectively, and left ear thresholds would be estimated at 36, 32, 40, and 77 dB for the same frequencies. A mild-to-severe sloping bilateral loss is indicated. Comparing the estimated puretone thresholds to the true puretone thresholds, some discrepancies are obvious, but none exceed 10 dB.

Threshold Rules for ASSR Tests

Consider the threshold test findings in Table 15.5. This case is riddled with many problems. At 500 Hz, significant

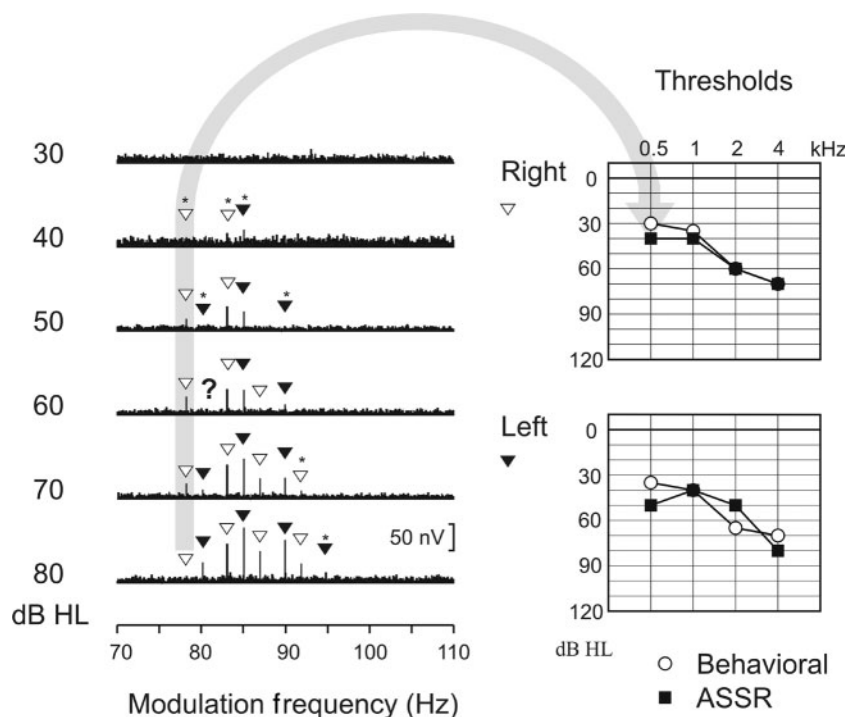

FIGURE 15.9 Response spectra and audiograms for case example. The response spectra are shown in the **left panel**, with *open triangles* denoting responses for tones presented to the right ear and *filled triangles* for the left ear. The audiograms are shown in the **right panel**, with *open circles* denoting behavioral thresholds and *filled squares* indicating the ASSR thresholds.

responses are obtained at 0 and 20 dB HL, but not at 10 dB HL. Is threshold at 0 or 20 dB HL? At 1,000 Hz, responses are present at 0, 20, and 40 dB HL, but not at 10 or 30 dB HL. Where is the threshold? The significant responses at 0 dB may be a false positive (with a statistical criterion of $p > 0.05$, there is a 5% probability of a false positive). On the other hand, the nonsignificant response at 10 dB may be a

false negative. In these types of scenarios, it is essential to establish rules for ASSR threshold determination prior to the interpretation of the results. These rules should be reported in the results.

TABLE 15.5

Test Results as a Function of Level

Level [dB HL]	Carrier Frequency [Hz]			
	500	1,000	2,000	4,000
-10	0	0	X	0
0	X	X	0	0
10	0	0	0	0
20	X	X	0	0
30	X	0	0	0
40	X	X	X	0
50	X	X	X	X
60	X	X	X	0

X refers to a significant response and 0 to a nonsignificant response. See text for a discussion of threshold determination given these patterns of response/no response.

EXAMPLES OF RULES

- i. If there is one nonsignificant response at a stimulus level greater than a significant response, and significant responses are obtained at all higher stimulus levels, then it is assumed that the nonsignificant response is a false negative. In the example given in Table 15.5, threshold for 500 Hz is 0 dB HL because the 10-dB HL result is assumed to be a false negative, as results at 20 dB and higher were all significant. At 1,000 Hz, the threshold is at 20 dB HL because the 30-dB HL response is considered a false negative. The 0-dB HL response is a false positive.
- ii. A significant response must be obtained at 20 dB above the lowest level at which there is a significant response. This is important to rule out any potential false positives. In the example above, threshold for 2,000 Hz would be 40 dB HL, and the 4,000-Hz threshold is unknown because the significant response at 50 dB HL could be a false positive.
- iii. When in doubt, repeat tests at levels for which there are questionable responses.

STOPPING RULES FOR ASSR TESTS

For those who use instrumentation that allows the user to increase the number of sweeps for an average, the decision to stop recording must also be rule bound. The problem is the determination of no response. Specifically, if there is no response, how would we know if sampling for another 5 to 10 minutes might have resulted in a significant response? Usually, a “low-noise” and/or “time” rule can be used. Some potential stopping rules include the following:

- i. Stop after 3 to 5 minutes when responses are significant (i.e., statistical significance must be maintained over a 3- to 5-minute period).
- ii. Stop after 12 to 15 minutes when no responses are significant.
- iii. Stop when averaged residual noise levels are at 10 to 15 nV (for 80-Hz ASSR) or 60 to 90 nV (for 40-Hz ASSRs).
- iv. Stop after 12 minutes, or when averaged residual noise levels are 10 nV, whichever comes first.

As in the case of threshold rules, it is imperative to report the stopping rules used.

SUMMARY AND CONCLUSION

The clinical application of ASSRs, especially for threshold estimation in infants and young children, continues to expand. This is reflected in the steady flow of published studies on humans ($N = 189$) since 2005, the existence of several commercially available systems for recording ASSRs, and the pediatric audiology practice guidelines that acknowledge the role of ASSRs as an electrophysiologic assessment technique.

ASSRs provide an excellent estimate of hearing threshold across the audiometric range (250 to 8,000 Hz), particularly for those with moderate and greater degrees of hearing loss. Threshold tests can be completed in an objective fashion, owing to the detection algorithms indicating statistically significant responses. Results can also be interpreted objectively using regression formulae or correction factors for conversion of ASSR thresholds to (behavioral) puretone threshold estimates. Thresholds can be estimated for both air- and bone-conducted stimuli. Beyond threshold tests, ASSRs have been shown to be correlated with some aspects of supra-threshold hearing, particularly, word-recognition ability and atypical phonologic awareness found in those with dyslexia.

No single audiometric test stands alone as a diagnostic measure and neither does the ASSR. ASSRs should be used in conjunction with tests of middle-ear function (tympanometry and acoustic-reflex tests), cochlear function (evoked otoacoustic emissions), and other evoked potentials (ABR) and, when possible, behavioral hearing tests. Tympanometry and acoustic-reflex tests will aid in the interpretation of elevated ASSR thresholds, especially in the case of young infants with conductive hearing losses. The presence

of otoacoustic emissions when ASSRs indicate significantly elevated thresholds is an indicator of auditory neuropathy. Click-evoked ABR tests provide important information about neural synchrony and brainstem integrity through the absolute and relative latencies of its constituent peaks; this information is not yet available from phase measurements of ASSRs. Although ASSRs are often used to estimate threshold in those too young or disabled to yield reliable behavioral thresholds, there should also be systematic attempts to document the infant’s behavioral response to sound.

The goal is always to obtain the most information possible about the patient’s hearing ability. ASSRs contribute a substantial amount toward that goal.

FOOD FOR THOUGHT

1. If asked, what is the better test of hearing threshold, toneburst ABR or toneburst ASSR, how would you answer? What are your reasons for doing so?
2. What are the major reasons why toneburst ASSR versus toneburst ABR may yield different threshold estimates in a person with normal hearing? In a person with a conductive hearing loss? In a person with a sensory/neural hearing loss?
3. What behavioral tests should we use in conjunction with ASSR to learn more about typical and atypical auditory processing?

Intraoperative Neurophysiological Monitoring

Paul R. Kileny and Bruce M. Edwards

OVERVIEW

Intraoperative neurophysiological monitoring (IOM) is the term we will use in this chapter for this specialized aspect of audiology. Other similar terms include intraoperative neuromonitoring and cranial nerve monitoring. The purpose of IOM is to reduce the incidence of injury to the patient's central and peripheral nervous systems during surgery. This is accomplished by using a variety of electrophysiological methods during surgery. By virtue of their education and additional training, scope of practice, licensure, and/or additional specialty certification, audiologists and/or physicians are permitted to interpret IOM results. Further, audiologists own and supervise IOM programs that are staffed by other audiologists and in some cases they work remotely with trained technicians. This aspect of audiology has grown in sophistication and acceptance in the past 20 to 30 years.

We hope that this chapter will be instructive and illuminating as well as encourage the reader to seek additional information about this interesting, clinically effective field. Although intended primarily for audiology students and practicing audiologists, we believe that the contents of this chapter will be of assistance to other healthcare providers seeking information about intraoperative monitoring.

The earliest form of "intraoperative monitoring" was the brainchild of the renowned neurosurgeon Harvey Cushing who while in medical school contributed to the development of blood pressure monitoring during surgery and developed the prototype of the flow sheet used to monitor patients' vital signs during general anesthesia. With some modifications, this type of data tracking, now computerized, is still used today in countless operating rooms around the world. In the last five to six decades, there has been a remarkable evolution in the efficacy and safety of surgical techniques performed near or directly involving the central and peripheral nervous systems. For instance, as recently as midway through the previous century acoustic neuroma resection was considered to be successful if the tumor was completely resected and the patient survived with minimal or no significant neurological sequelae. Surgery performed to remove an acoustic neuroma was not initially concerned with the preservation of cranial nerve function. However, with advances in the understanding of surgical anatomy and

with developments in instrumentation including the introduction of the operating microscope and associated microsurgical techniques, a burgeoning interest in the preservation of neural function occurred. Acoustic neuroma surgery is an example of a setting in which technologic advances have led to improved functional outcomes. In otology and neurotology in particular, refinements in temporal bone surgery have brought about an increased emphasis on the preservation of auditory and facial function. Similar advances may be found in head and neck surgery for selected primary parotidectomy, revision parotidectomy, and selected thyroid procedures. Now, goals typically include functional maintenance of the extracranial seventh facial nerve and the recurrent laryngeal nerve, a branch of the vagus nerve, during these often complex procedures.

ABOUT INTRAOPERATIVE NEUROPHYSIOLOGICAL MONITORING

The goal of preserving a patient's neural function intraoperatively faces several challenges for a surgical team. For example, an expanding tumor can compress a cranial nerve within a closed space making identification of specific neural structures daunting. Although the surgeon's skill level is crucial to a successful outcome, a limited ability to simply visualize targeted cranial nerves in the setting of an expansive mass lesion makes even more valuable one's ability to continuously monitor and properly interpret electromyography (EMG) and auditory-evoked potentials when a goal of surgery includes maintaining both the structural integrity of the target nerve and its function, too.

Interest in and continued developments in neurodiagnostic techniques by audiology and other disciplines represents an important step in the growth and acceptance of intraoperative monitoring and continued improvement in patients' functional outcomes. A landmark contribution to this field is one that every audiologist should recognize: the description and introduction into clinical practice of the auditory brainstem response (ABR), described by Jewett et al. (1970). The advent of this robust and replicable evoked potential, present even in a state of deep anesthesia, generated an explosion of clinical investigations involving the ABR. It became one

of numerous neurophysiological auditory diagnostic techniques used clinically and was joined by several forms of facial muscle EMG, too. The diagnostic applications of auditory-evoked potential and electromyographic techniques led to an improved understanding of pathological changes involving affected anatomic structures and the responses associated with those neural structures. Retrospectively, these discoveries were necessary and important precursors to current uses of neurophysiological measures in the operating room.

In the late 1970s, to the early 1980s interest was focused on preserving neural function and structures, improving microsurgical techniques, and the broadening of intraoperative use as well as the variety of neuropsychological techniques that led to improved surgical outcomes. These intraoperative methods were modifications of methods used in outpatient diagnostics and were redeveloped with a goal of being capable of providing feedback about the status of neural structures during surgery. Neurophysiological intraoperative monitoring has developed over time and now contributes to improved preservation of facial and auditory function, as well as preservation of various cranial nerves and associated function in otolaryngology-head and neck surgery such as acoustic neuroma resection, retrolabyrinthine vestibular nerve section, repair of semicircular canal dehiscence, microvascular decompression of cranial nerves V, VII, or VIII, as well as preserved cranial nerve function when operating on patients with congenital temporal bone anomalies and cancer of the salivary and endocrine glands.

At this point, it is important to state that IOM should be considered an adjunct to the surgically trained and skilled physicians who operate on or in the vicinity of neural structures. It is also important to note that despite improved technology, it is the authors' opinion that certain "automated," nonattended monitoring devices and techniques based on acoustic alarms are no substitute for the skill, experience, and interactive ability of a skilled clinician who actively interprets monitored activity and provides continuous feedback about one or more neural structures.

The individual responsible for monitoring must have extensive experience in clinical neurophysiology, must understand the pathological effects of the lesion to be treated surgically, and must be familiar with surgical anatomy and technique. In addition, the individual providing intraoperative monitoring should appreciate the pace and flow of the surgical procedure in which they participate. The training needed to become proficient in IOM is determined by an individual's background, motivation, clinical skill, and talents. Solid footing in the principles of neural stimulation and recording, electrophysiology, and surgical anatomy should be fundamental components of a training program in this specialty area. Precept or apprentice-type teaching may provide a valuable method of obtaining practical experience in the operative room. Although these educational activities cannot guarantee quality, they can serve as guidelines in developing a training program.

WHY IS THIS CLINICAL SUBSPECIALTY NEEDED?

Complex primary and revision surgery that risks neural structures, important anatomical components, and blood supply requires that a variety of intraoperative procedures be conducted to monitor, interpret, and continuously report on the integrity of those structures. Thus, the single most important role for the audiologist who performs intraoperative monitoring is to ensure the integrity of neural pathways and associated structures. This is accomplished by identifying and attempting to prevent unintended complications during the surgical procedures. Continuous monitoring with real-time interpretation and prompt intervention can result in improved outcomes for patients, assuming that the audiologist is able to differentiate between changes in baseline activity associated with, for example, anesthetic intervention versus significant surgical events (Edwards and Kileny, 2000). Properly conducted intraoperative monitoring can identify impending neurological insult in settings such as the dissection of a vestibular schwannoma that has wrapped itself around the seventh, fifth, or lower cranial nerves or with manipulation of an offending intracranial structure during microvascular decompression of cranial nerves V, VII, or IX. Properly trained individuals with appropriate knowledge and experience can assist the surgical team to quickly carry out their work.

The necessity for IOM was underscored by the now-expired National Institutes of Health (NIH) Consensus Statement regarding the management of acoustic neuromas and the role of facial nerve monitoring in those procedures (NIH, Acoustic Neuroma Consensus Statement, December, 1991). The conclusions and recommendations of the statement reported that ". . . the benefits of routine intraoperative monitoring of the facial nerve have been clearly established. This technique should be included in surgical therapy for vestibular schwannoma. Routine monitoring of other cranial nerves should be considered." The authors continue to agree with this now historically significant document and suggest that intraoperative monitoring has further expanded in its scope and importance to the profession of audiology. Numerous key purposes exist for continuous intraoperative monitoring in surgeries that involve the brain and brainstem, the spinal cord, and the peripheral nervous system including:

- a. enabling changes in the course of surgical procedures to avoid postoperative complications,
- b. prediction of patients' postoperative outcomes, and
- c. retrospective review of monitoring data to enhance future surgical procedures (Sala et al., 2002).

We advocate that properly utilized instrumentation allows for the collection of data that could be valuable in certain medicolegal situations and also as components in an educational program for trainees. The training and education of

audiology students and resident surgeons is an added value for providers of IOM.

SAFEGUARDING PATIENT OUTCOMES BY STANDARDIZING IOM

Standardizing an intraoperative monitoring service is essential to avoid the many hazards and pitfalls present in all operating rooms and to ensure a consistent approach to providing the service. Edwards and Kileny (2000) have identified key components useful for creating and conducting a systematic, thoughtful IOM service. Attending to these items prior to the surgical procedure enables the audiologist to safeguard against unplanned or unfortunate incidents. Table 16.4 lists selected components useful in planning and establishing an intraoperative neurophysiological monitoring program that can serve multiple surgical services.

Before carrying out any form of intraoperative monitoring, important questions to answer should include the following:

- “Why is the patient having surgery?”
- “What type of equipment will be most useful for this case?”
- “What motor and/or sensory cranial nerves could come into play during this procedure?”

- “What are key portions of this surgical procedure that involve IOM?”
- “What are the anticipated outcomes of IOM and surgery?”

The specific monitoring setup for each operative procedure should be well thought out before one’s entry into the operating room and should be formed in part by the patient’s medical and surgical history. Further, the comprehensive plan for monitoring should be discussed with stakeholders including the patient, the attending surgeon, anesthesiology, and nursing. In this way, everyone is aware of the planned monitoring setup for the patient, the anesthetics that may best support nerve monitoring, the benefits and limitations that IOM has to offer, and the cost-carrying supplies that will be needed by the monitoring team.

Table 16.1 provides a simple planning scheme for intraoperative cranial nerve monitoring in selected surgical procedures. This could be used to standardize initial, presurgical preparation for a variety of operative procedures that involve cranial nerves. In the table, it can be seen that some operative cases involve monitoring just one cranial nerve (see revision mastoidectomy or parotidectomy), whereas other surgical interventions benefit either from multimotor nerve monitoring (see plans for surgical approaches to masses in the parapharyngeal space) or multimodality cranial nerve

monitoring (see vestibular schwannoma or microvascular decompression for suggestions about motor and sensory nerve monitoring). With due consideration paid to at-risk cranial nerves during otologic, head and neck, as well as skull-based procedures, certain pitfalls may be avoided, leading to fewer technical interruptions, improved surgical outcomes, and continued confidence in monitoring services.

PATIENT PREPARATION

Careful patient preparation and an understanding of the electrical environment in the operating room are key components for obtaining replicable recordings in the operating room. However, electrical artifacts that may obscure, distort, or mask the intended responses are not completely avoidable. In terms of their temporal characteristics, such artifacts may be thought of as continuous or transient in nature.

A constant electrical artifact or interference is a major problem in the operating room because it may result in an inability to monitor electrophysiological function by obscuring the intended signals. Such artifacts may originate from equipment that is poorly grounded or inadequately shielded and may originate in the host operating room or even in an adjacent room that shares electrical wiring. One of the reasons this type of artifact is extremely troublesome is because of its constant nature and because its source is not easily identifiable. The most common artifact is the 60-cycle interference that may take the form of a 60-cycle sign wave that masks all electrophysiological recordings or it may be a sign wave or a more complex wave composed of 60-cycle harmonics. Poor grounding of the patient or the neurodiagnostic equipment used for monitoring may cause such interference. Sixty-cycle interference is more likely when monitoring equipment shares an outlet with other electronic equipment used in the operating room such as patient warmers, sequential compression devices, electrocautery, operating microscopes, and ultrasonic dissecting devices. Therefore, it is desirable to make every attempt to identify and use a properly grounded outlet that is not shared with other equipment.

Constant or continuous interference may also take the form of very high frequency signal that may originate from monitor screens. Monitor screens are in abundance in many operating rooms associated with the anesthesia equipment, video equipment including monitors linked to an operating microscope mounted camera, monitors used to view imaging studies, or monitors linked to frameless, stereotactic neuronavigation instrumentation.

Proximity of neurophysiological monitoring leads to electrocardiography (EKG) leads may result in a continuous artifact. Given the relatively short time base used for neuro-monitoring, this type of artifact may not look like typical EKG. However, if one is able to capture this activity in an extended epoch, the various peaks of the EKG waveform are recognizable.

These continuous artifacts may be resolved in a systematic manner. The monitoring team should be familiar with the characteristics of various types of artifacts unique to specific operating rooms. Often, these artifacts can be resolved by repositioning recording electrode leads, patient interface connectors, or preamplifiers. If the artifact causes an evoked potential such as the ABR to be unidentifiable, slight changes in the stimulation rate (even by one or two decimals) may improve the ability to record a response. Other times recording parameters may need to be changed, especially the cutoff settings of the high-pass or low-pass filters; this may apply to both the ABR and to free-running and triggered EMG modalities. A cautious approach to stimulating and recording parameter alterations is recommended: One must be mindful of parametric changes on monitored activity as they may impact the continuous interpretation of responses or the comparison of ongoing activity with previously recorded “baseline” activity.

Transient artifacts are common during surgical procedures but are generally less disruptive and easier to resolve. Such artifacts may be associated with the temporary use of specific powered surgical instrumentation such as electrocoagulation, a powered scalpel, or an ultrasonic dissecting device. However, it is important that everyone in the room understands that electrophysiological responses are obscured while such instrumentation is used, owing to the massive interference artifact created. If it is necessary to use these instruments for lengthy periods of time, it is useful to have an agreement with the surgical team to provide periodic breaks to allow effective neurophysiological monitoring.

Patient preparation also includes the setup, or the arrangement of monitoring electrodes, transducers, extensions, stimulators, headboxes, and amplifiers on or about the patient and the operating table. Table 16.2 provides suggested recording sites for selected types of surgical procedures in which the authors routinely participate. Using the placement sites in this table, and with the suggestions offered in this section of the chapter, the audiologist will have a significantly increased opportunity to standardize the IOM setup within and across cases. This will help to improve the likelihood that a patient’s outcome will be acceptable for all members of the care team, providing that the audiologist brings to the operating room the requisite training, skill, and experience required to perform IOM.

ANESTHESIA

One of the fundamental components of a standardized, well-conceived approach to offering neurophysiological monitoring to a variety of surgical departments includes the ability to work in a collaborative manner with anesthesiology colleagues. Careful selection and delivery of anesthetic agents coupled with information shared between anesthesiologists and audiologists about the effects of anesthesia on neurophysiological modalities impacts the success of monitoring

TABLE 16.2

Suggested Recording Sites for Properly Conducted IOM

Cranial Nerve[s]	Recording Muscle Site[s]	Comments
Oculomotor (III)	Extraocular muscles: Medial, superior, inferior recti	Useful in surgery involving the cavernous sinus
Trochlear (IV)	Superior oblique	Access challenging
Trigeminal (V)	Masseter or temporalis	Helpful as adjunct to facial nerve monitoring in cases of large vestibular schwannomas; possibly useful in trigeminal nerve microvascular decompression surgery
Abducens (VI)	Lateral rectus	Useful in surgery involving the cavernous sinus
Facial (VII)	1. Upper division and lower division montage [frontalis, orbicularis oculi in pairs and orbicularis oris, mentalis in pairs, respectively] for otologic and neurotologic surgery 2. Temporal, zygomatic, buccal, marginal mandibular branches of extracranial distribution of facial nerve [frontalis, orbicularis oculi, orbicularis oris, mentalis muscles, respectively]	Arguably the most frequent monitored motor cranial nerve in otologic, head and neck, posterior skull base, pediatric, and neurosurgical operative procedures
Cochleovestibular (VIII)	Electrode montage: Vertex or nape of neck [active], shoulder or forehead [ground], ipsilateral ear anterior to tragus for auditory brainstem responses; tympanic membrane surface for electrocochleography; cranial nerve for direct nerve recording [various reference sites selected for individual or combined auditory-evoked potentials]	Useful in planned hearing preservation surgery as well as during microvascular decompressions, vestibular neurectomy, endolymphatic sac procedures
Glossopharyngeal (IX)	Soft palate, pharyngeal wall	Effective for neurosurgical procedures including mass lesions involving the lower cranial nerves
Vagus (X)	Vocal cords, posterior cricoarytenoid, vocalis muscles [recurrent laryngeal nerve branch]	Hookwire or surface electrodes on endotracheal tube; used during thyroid surgery or cases involving brainstem or lower cranial nerves
Spinal accessory (XI)	Trapezius or sternomastoid muscles	May be used during radical neck dissection, anterior approaches to cervical spine
Hypoglossal (XII)	Ipsilateral tongue, laterally	Used with IX/X setup in posterolateral skull base surgery

and patient outcomes. Primary goals for an anesthesiology service in the operating room include keeping the patient properly immobile and pain-free (Banoub et al., 2003). There are a host of anesthetic agents available to achieve those goals and many of these medications have the power to mildly or profoundly affect cranial nerve monitoring in either the motor or the sensory modalities. Thus, it is crucial for the monitoring team to have pre- or perioperative discussions with members of the anesthesiology team. It is impor-

tant to avoid surprises during the operative procedure that could result in a reduced ability to provide neurophysiological monitoring or that may interfere with nerve monitoring for the entire case. Long-lasting neuromuscular blockades, such as doxacurium, pipecurium, and tubocurarine, are contraindicated when monitoring schemes include the provision of free-running and triggered EMG. Intermediate effects resulting from the use of atracurium, cisatracurium, pancuronium, and vecuronium could be a problem if

TABLE 16.3

Pharmacologic and Physiologic Effects on IOM

Pharmacologic Agents	Effects
Modality: Electrocochleography Modality: Auditory brainstem response Inhalational agents (enflurane, halothane, isoflurane, etc.)	Resistant to anesthesia effects ≥0.5–1.0 ms latency shift in wave V; inhibition on averaged responses varies among agents but can prolong wave I–V interpeak latencies with end-tidal concentrations >1.5%; children more resistant than adults
Injectable agents (lidocaine, thiopental, pentobarbital, propofol)	Depending on dosages, amplitude reductions, and increases in absolute latencies, particularly wave V are noted
Modality: Electromyography Neuromuscular blockade: Doxacurium, pipecuronium, tubocurarine have long-lasting effect; atracurium, cisatracurium, pancuronium, vecuronium have intermediate effects; mivacurium, rocuronium, succinylcholine are short-acting agents Local anesthetics (lidocaine, tetracaine, bupivacaine, etc.)	Free-running (motor unit recruitment) and triggered activity (compound muscle action potentials) abolished for minutes to hours depending on the agent selected; each has dose-dependent effects which may be chemically reversed with anticholinesterase inhibitors Amplitude reduction and delay in electrically evoked responses because of altered axonal propagation
Physiologic Events Local and/or systemic decreases in temperature	Effects noted in absolute as well as interpeak latencies of averaged auditory-evoked potentials, triggered electromyography
Compression of tissue from retraction, crush, etc.	Degraded or abolished waveform activity depending on structural tolerance of instrument pressure
Insufficient ventilation, hemodilution, systemic hypotension, regional ischemia	Decrease in oxygen supply to hearing end organ leads to reduced endocochlear potentials, impaired cochlear output, loss of averaged responses

After Edwards BM, Kileny PR. [2000] Intraoperative monitoring of cranial nerves. In: Canalis RF, Lambert PR, eds. *The Ear: Comprehensive Otolology*. Philadelphia, PA: Lippincott Williams & Wilkins.

the surgical procedure quickly involves a monitored cranial motor nerve, as in the case of a pediatric revision mastoidectomy. Importantly, an anesthesiologist may be able to select or alter anesthetic techniques to facilitate monitoring while affording maximal patient safety (Nuwer, 2002).

In the majority of cases that the authors have monitored over three decades, surgical, anesthesia, nursing, and monitoring teams have worked in full cooperation to achieve good patient outcomes. Nonetheless, pharmacologic, physiological, and mechanical factors under the control of the surgeon and the anesthesiologist must be continuously scrutinized by the audiologist. Any changes in IOM related to the previously mentioned factors should be reported to the room so that interventions can be made in time to avert suboptimal results. For an excellent review of the topic of anesthetic effects on sensory and motor nerve activity, the reader is referred to the comprehensive paper by Banoub et al. (2003).

Table 16.3 offers a selected list of routinely employed pharmacologic agents available to anesthesiology members of the operating room team. These therapeutic drugs are commonly found in operating rooms, and their effects must

be well known to the monitoring audiologist to avoid a scenario wherein monitoring is rendered useless.

ELECTROMYOGRAPHY APPLIED TO IOM

To understand the principles and clinical applications that can be provided by clinical EMG, one must be familiar with the anatomy and physiology of the nerve–muscle complex. Striate or voluntary muscle fibers have contractile properties and consist of myofibrils made up of numerous myofilaments composed of actin and myosin which are the building blocks of muscle tissue. A motor unit (Figure 16.1) is an entity consisting of a neuron and its axon divided into several synaptic terminals, each innervating muscle fibers at the myoneural junction. On activation, each synaptic terminal/muscle fiber generates an electric signal, the motor potential. The sum of motor potentials from numerous muscle fibers innervated by the same axon results in a larger motor unit action potential (MUAP). Thus, the MUAP represents the electrical activity of several muscle fibers innervated by the same motor unit.

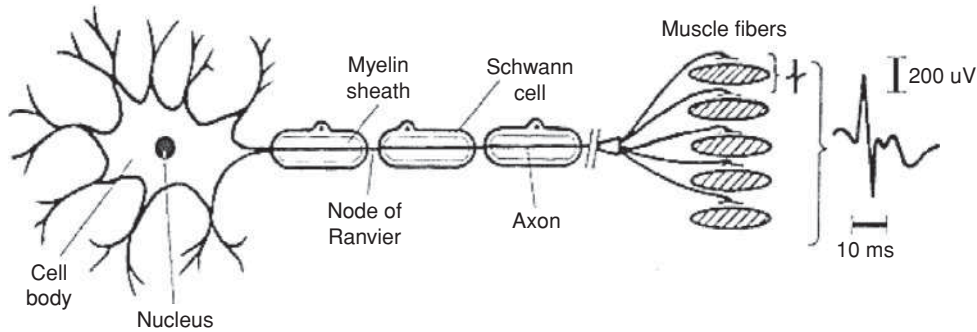

FIGURE 16.1 The motor unit.

How is one able to observe so-called “free-running” EMG during surgical procedures? For these electrical potentials to be generated, the axon innervating these muscle fibers must first be activated, or depolarized. This happens when a motor movement is initiated in the brain’s motor cortex; muscle fibers innervated by the same axon generate single fiber potentials, and the sum of these single fiber potentials originating from the same axon results in a larger, single fiber potential we know as the MUAP. This response is recorded from the appropriate muscle using an intramuscularly placed needle electrode. The triphasic MUAP amplitude is determined by first, the number of single fiber potentials that constitute the motor unit potential and second, the proximity of the recording electrode to the source of this potential. The frequency or density of these MUAPs in a specific epoch depends on the magnitude of the muscular effort. Healthy, normally innervated muscle at rest generates no spontaneous activity; however, with increasing effort, motor units are recruited ultimately resulting in a high-frequency signal. As the magnitude of the voluntary effort diminishes, the recruitment pattern becomes less dense until at complete rest no motor units are seen. Figure 16.2 illustrates motor unit potential recruitment recorded from the orbicularis oculi muscle demonstrating initial muscle rest or inactivation, followed by an increase in effort of eye closure resulting in recruitment of motor unit activity, followed by relaxation

of the orbicularis oculi muscle as motor units disappear. This figure illustrates the absence of motor unit potentials at rest and the recruitment of motor units present with effort. For neurodiagnostic purposes one can isolate a single motor unit potential and evaluate and examine its configuration. During intraoperative monitoring applications, one observes spontaneous or free-running EMG observing some of the applications and techniques just described.

Another component of neuromuscular function used intraoperatively is the compound muscle action potential (CMAP), a triggered response that is similar to an averaged evoked potential in that it requires a stimulus with the ability to stimulate or activate in a synchronized manner a relatively large number of MUAP. Unlike free-running EMG that depends on voluntary effort, so-called “triggered EMG” responses require that electrical pulses be delivered somewhere along or in proximity to a motor cranial nerve. This results in the contraction of muscle fibers innervated by this particular cranial nerve or a branch of the nerve. Here, one stimulates not individual axons but an entire nerve trunk. This CMAP response may be recorded using either intramuscular needle electrodes or surface electrodes; the stability of the latter option makes it impractical in the operating room where procedures can last for hours. The CMAP’s configuration is a biphasic sine wave which is the result of the synchronized depolarization of a large number of axons

FIGURE 16.2 Recruitment of motor unit potentials.

resulting in the simultaneous activation of numerous MUAP. To measure this response for diagnostic purposes, the electrical pulse is delivered superficially along the facial nerve as it exits the stylomastoid foramen. The intraoperative application involves the use of a handheld surgical stimulator and direct electrical stimulation of the exposed motor cranial nerve (or tissue that may be in continuity with the target nerve). This specific component of EMG used in the operating room will be addressed in more detail in this chapter.

ANATOMY OF THE FACIAL NERVE

The facial nerve is physiologically and functionally complex as it courses through the posterior cranial fossa and the temporal bone before innervating peripheral facial muscles (Figure 16.3). Intracranially, the facial nerve emerges from

the brainstem at the pontomedullary junction after receiving fibers from the facial motor and superior salivatory nuclei. After crossing the subarachnoid space of the cerebellopontine angle (CPA), the facial nerve passes into the internal auditory canal (IAC) joining the vestibulocochlear nerve. The intracranial segment of the facial nerve lacks an epineurial sheath which is the fibrous sheath protecting the more peripheral segments of the facial nerve trunk. Consequently, even a healthy facial nerve which is not compressed and attenuated because of the presence of a tumor is at a relatively high risk for surgical injury because of this inherent weakness when compared to its more peripheral segments. The facial nerve traverses the IAC and then enters the fallopian canal of the temporal bone at the point where the fallopian canal has the smallest diameter—the meatal foramen. The facial nerve then makes several turns to form

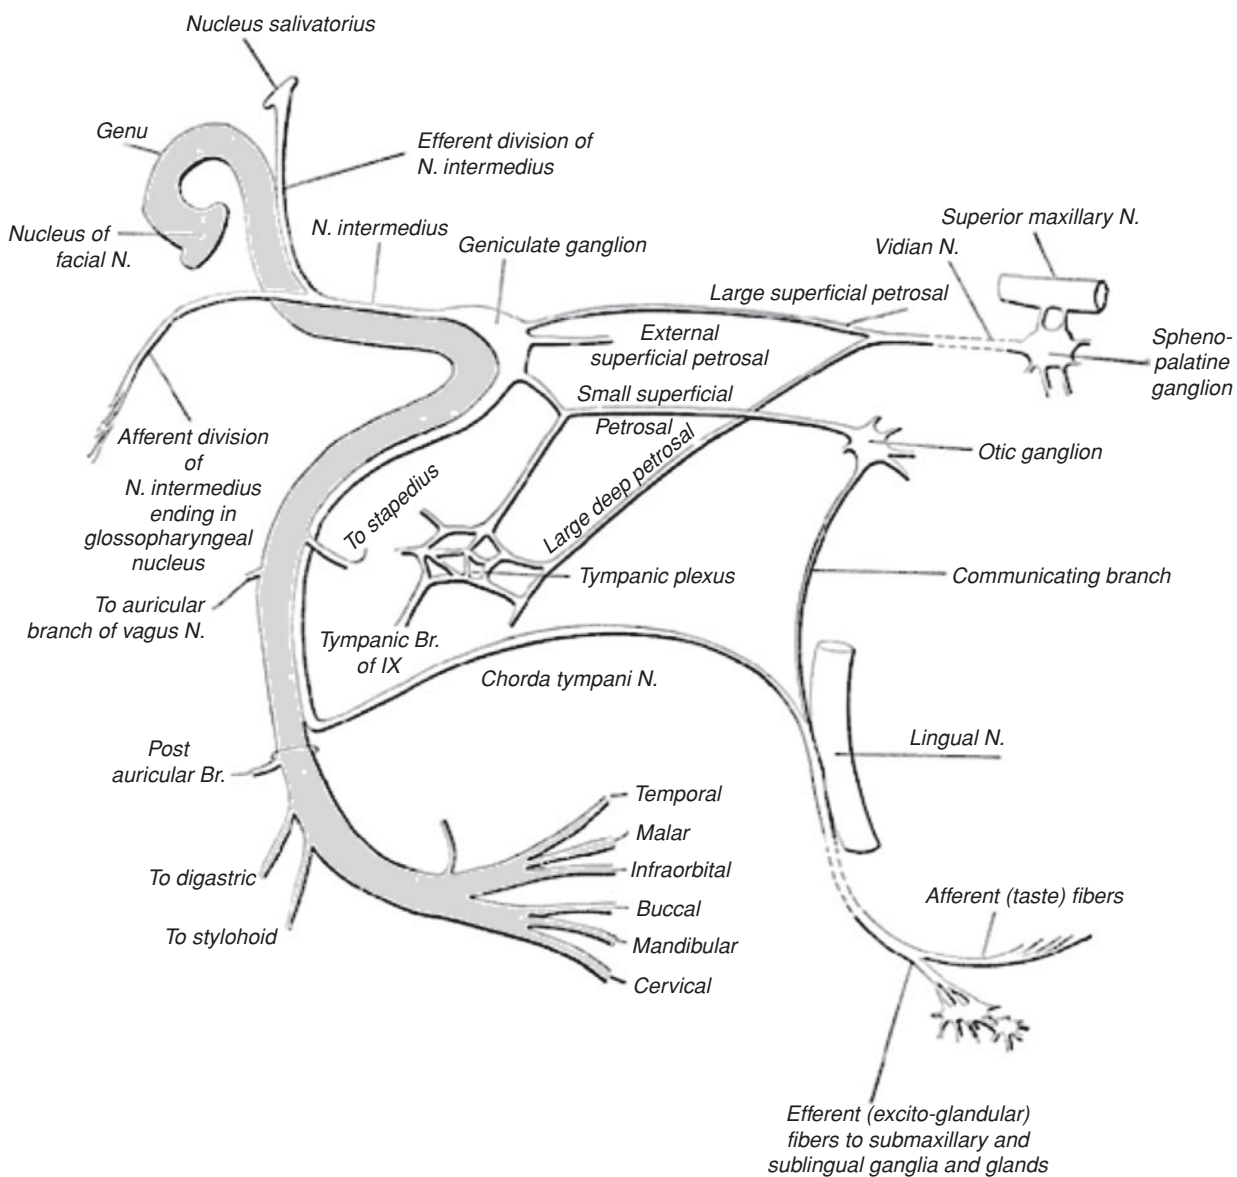

FIGURE 16.3 Course of the facial nerve from the pons to its distribution in the face.

the (1) labyrinthine, (2) geniculate, (3) tympanic, and (4) mastoid portions of the fallopian canal to exit from the skull base via the stylomastoid foramen. Following its exit through the stylomastoid foramen, the extratemporal segment of the facial nerve enters the parotid gland where it is contained in between the superficial and deep lobe of the parotid, and this is where it branches into several peripheral branches before it finally terminates on the motor end plates of the 16 muscles of facial expression on each side. The facial nerve also supplies the posterior belly of the digastric muscle, the stylohyoid muscle, and the stapedial muscle. As audiologists know, the acoustic stapedial reflex depends on an intact and functioning facial nerve. The facial nerve also provides parasympathetic innervation to the lacrimal, submandibular, and sublingual glands as well as to the mucous membrane of the nasopharynx and the hard and soft palate. Taste sensation for the anterior two-thirds of the tongue is also provided by the facial nerve as well as taste sensation to the hard and soft palates. The facial nerve also has a general sensory component providing general sensation for the skin of the concha of the auricle and a small area posterior to the auricle. Whereas the motor fibers of the facial nerve constitute the largest portion of the nerve, the remaining three components (the parasympathetic, the special sensory (taste), and general sensory components) are bound in a distinct fascial sheath and the branch of the facial nerve containing these components is referred to as the *nervus intermedius*.

Depending on the specific surgical procedure, facial or other motor nerve monitoring is directed to accomplish one or more of the following goals (Niparko et al., 1989):

1. early recognition and identification of impending surgical trauma to the nerve with timely feedback made available to the surgical team;
2. distinguishing the targeted cranial nerve from the adjacent soft tissue, tumor, or other cranial nerves;
3. facilitation of tumor excision by electrically mapping and confirming that the regions of the tumors are remote from the facial nerve;
4. confirmation of nerve stimulability following tumor removal; and
5. identification of the site and degree of neural degeneration in selected patients undergoing nerve exploration for suspected facial nerve neoplasm or decompression of acute facial palsy.

Events associated with intraoperative monitoring of cranial motor nerves are influenced by the preoperative status of the nerve and the anatomy and morphology of the nerve affected by a compressive tumor. Clearly, neurophysiological monitoring may have a limited role in cases with complete preoperative facial paralysis as determined by clinical exam and electrophysiological diagnostic measures (Kileny et al., 1999). In the presence of partial neurodegeneration, nerve-related monitored neural activity varies

with the degree of ischemia and compression of the nerve. With compression, local irritation of the nerve results in increased sensitivity to mechanical stimulation that may be associated with surgical dissection, and thus the more likely appearance of spontaneous EMG activity. Demyelinating neuropathies are also associated with increases in spontaneous firing and mechanosensitivity of peripheral nerves attributable to the increased sodium channels present in the remaining myelinated nerve fibers (Bergmans, 1983). Increased spontaneous electromyographic activity associated with the mechanical stimulation of the facial nerve has been demonstrated in cases where the facial nerve was extensively involved with tumor (Prass and Luders, 1986).

COMMENTS REGARDING TRIGGERED ELECTRICAL STIMULATION OF CRANIAL MOTOR NERVES

Intracranial surgery in the vicinity of cranial nerves entails dissection through a complex array of tissues often surrounded by a fluid media that has the propensity to shunt the electrical current used for stimulation (Moller and Jannetta, 1984). Stimulus delivery to the nerve may be attenuated by that fluid, increasing the chance of false-negative stimulation. To counteract this problem, a constant voltage approach could be used in which voltage is unvarying but current changes according to the degree of stimulus shunting as determined by impedance encountered at the stimulator tip. However, because nerve depolarization is a function of electric current, most applications use constant current stimulation that varies voltage as a function of impedance to maintain a constant current at the tip of the stimulator (Prass and Luders, 1985). Additionally, the use of a probe that incorporates insulation to the end of the probe helps to provide controlled stimulus delivery across most conditions.

A concern when directly stimulating an exposed cranial nerve particularly in its intracranial course is whether direct delivery of electrical current to the nerve is in fact safe. Few recent studies have critically evaluated the safety of electrical stimulation of surgically exposed cranial nerves. Love and Marchbanks (1978) described the case of facial paralysis after acoustic neuroma resection possibly related to the use of a disposable, handheld nerve stimulator. In their paper, the site of nerve stimulator application was characterized as “blanched,” suggesting that a cautery-like effect may have been exerted by the nerve stimulator. Further experimental studies carried out by these investigators in the rabbit model suggested that direct-current nerve stimulation produced neural damage by inducing thermal injury. Hughes et al. (1980) demonstrated that repetitive, prolonged direct-current stimulation produced significant myelin and axonal degeneration in the rodent model. In a follow-up investigation, Chase et al. (1984) demonstrated that the damaging

effects of direct-current stimulation were avoidable if the nerve and stimulator were in contact for brief periods.

PRINCIPLES OF MOTOR CRANIAL NERVE MONITORING

The audiologist needs to clearly identify the specific muscles innervated by cranial motor nerves that will undergo monitoring. For example, when monitoring the function of peripheral branches of the facial nerve, recording electrodes must be placed in each muscle of interest associated with these peripheral branches, that is, frontalis, orbicularis oculi, nasolabial, and mentalis muscles. Choices in electrode design allow one to select the most appropriate type of electrode for the operative case. For example, paired sets of intramuscular monopolar needle electrodes could be positioned at interelectrode distances best suited to the size and bulk of the target muscle. Or for very specific recording from a small volume muscle (such as intrinsic laryngeal muscles), one may utilize a concentric needle electrode or paired hooked wire electrodes.

When multiple muscle monitoring is required (the muscles innervated by the same or by various cranial motor nerves), one needs to ascertain that the instrumentation selected for IOM has sufficient numbers of channels for free-run and triggered EMG as each monitored muscle requires a separate channel to allow the clinician carrying out the monitoring to distinguish between individual muscles/innervating nerve branches. Another important prerequisite is for the provider of IOM to have a working knowledge of the pharmacologic agents available to be administered to the patient either as premedication or during surgery. As mentioned elsewhere in this chapter, long-acting neuromuscular blocking agents should be avoided unless contraindicated by the patient's medical condition. Although a short-acting paralytic agent used for patient intubation is acceptable, close communication with the anesthesiologist is very important to avoid an anesthetic course that includes

neuromuscular blockade throughout the operation. This is an extremely important aspect of intraoperative monitoring. In many surgical situations, patients are paralyzed throughout the procedure to modulate the overall concentration of anesthetics provided. Therefore, one should not assume that an anesthesiology team will refrain from using neuromuscular blockade. Even a subparalytic dose used throughout surgery has the potential to decrease the sensitivity of intraoperative monitoring.

As stated previously, one of the goals of IOM of motor cranial nerve function is to assist in the avoidance of unintended injury to a particular cranial nerve that may be at risk because of its specific anatomic location, relative to the lesion operated on. When surgery is performed by a skilled and experienced surgeon, IOM can significantly assist in nerve function preservation. Nerve preservation depends on the following variables. Identification is extremely important if the surgeon is to successfully dissect tumor away from nerve. Often, significant anatomical distortions are caused by expansive intracranial masses and as a result, cranial nerves may not be located in their normal anatomical position or condition. Nerve identification can be accomplished by discrete intracranial electrical stimulation of soft tissue structures near the cranial nerve of interest. This is especially important if the nerve has been compressed and attenuated by the expanding tumor. Electrical stimulation of the targeted cranial nerve(s) will produce a CMAP recorded by the intramuscular electrode(s) associated with a given cranial nerve. Stimulation of other structures should not result in the production of a CMAP. Figure 16.4A is a schematic representation of a situation involving a tumor (a), an attenuated nerve running along the tumor capsule (b), and the peripheral portion of the nerve trunk (c), within an innervated muscle (d). In the figure, paired intramuscular electrodes in muscle (d) display intramuscular activity on the neurodiagnostic monitor (e). When a nerve stimulator is used to deliver low-level electrical current pulses to the tumor capsule near the nerve but not quite touching the

FIGURE 16.4 **A:** Schematic depicting no response to electrical stimulation. Note only the stimulus artifact on the monitor. **B:** Schematic depicting a response to electrical stimulation in the form of a compound muscle action potential that follows the stimulus artifact on the monitor.

nerve (f), the screen of the neurodiagnostic equipment continues to show baseline activity with the exception of the spike near the onset of the trace representing the stimulus artifact. No response to stimulation is present, and that specific interpretation made by the audiologist would be reported to the surgical team immediately. In Figure 16.4B, nerve stimulation via the probe (f) is applied directly to the nerve and elicits the CMAP as displayed on the screen of the neurodiagnostic equipment. The biphasic CMAP waveform occurs after the stimulus artifact spike and represents a positive response to stimulation which would be reported to the surgeon.

This simple example illustrates the principle of utilizing intraoperative monitoring to identify cranial motor nerves as distinguished from surrounding tissue. It is of note that with monopolar stimulation, in the setting of an operative field which contains fluid, especially with higher levels of current stimulation, the electrical current could spread to adjacent tissues away from the tip of the stimulus probe. A “false positive” could occur, that is, a surgeon could apply the stimulator to soft tissue that does not contain targeted nerve but is fairly close to the nerve and at higher intensity one could conceivably obtain a CMAP that would suggest that the stimulated site was in fact a cranial nerve. Therefore, caution is advised relative to current levels used for intracranial stimulation in particular if the stimulated site is anatomically closed to the presumed anatomical site of the target cranial nerve. With appropriate attention paid to stimulus delivery, excellent reliability can be accomplished. Specificity and reliability are important in IOM because an absent response to electrical stimulation is as significant as the presence of a response. An absent response indicates to the surgeon that this could be a safe area to dissect without risking the continuity or the function of the motor cranial nerve. Therefore, providing accurate, timely information to the surgical team is extremely important and will help to optimize patient outcomes.

Another important aspect of motor cranial nerve monitoring is providing feedback to the surgical team regarding

inadvertent “mechanical” stimulation of the targeted cranial nerve that may result in temporary or permanent damage to the nerve and dysfunction for the patient. This can occur in situations where a cranial nerve has been identified and is within plain view in the surgical field or in a situation where the cranial nerve is not visible within the surgical field. As mentioned earlier, healthy muscle at rest is quiescent and both voluntary contraction and mechanical manipulation of the motor cranial nerve will give rise to motor unit potentials in a variety of patterns. Notably, a motor cranial nerve that has been compressed and/or attenuated can be more sensitive to mechanical manipulation than a cranial nerve in its normal condition. It is of note that completely harmless intraoperative events, such as cold irrigation in the vicinity of a cranial nerve, can also trigger a salvo of motor unit potentials. These motor unit “trains” are recorded on free-running EMG channels of the monitoring equipment. Thus, baseline or free-running EMG activity must be monitored continuously throughout the surgical procedure. This is different than triggered EMG stimulation used to identify or track the course of neural tissue in the operative field. In the latter case, one activates the stimulator when the surgeon requests to stimulate the nerve or adjacent tissue.

During continuous monitoring of free-running EMG, when a pattern of motor units appear in the course of surgery, this event needs to be communicated quickly to the surgical team. It may indicate possible proximity to the nerve of interest and/or potential damage to the monitored nerve. It is important to note that the appearance of these motor unit potentials do not necessarily indicate that the nerve has been injured but simply that it has been stretched or compressed mechanically in the course of dissection; continued surgical manipulation of this nature may result in temporary or permanent injury. This is particularly important in a situation in which the target cranial nerve has not yet been visually identified. Figure 16.5A,B schematically illustrates surgical dissection of a tumor while employing continuous IOM methods. In Figure 16.5A, the screen of the neuromonitoring equipment exhibits a quiet,

FIGURE 16.5 **A:** Baseline electromyography that illustrates a quiet free-running recording. **B:** Twelve motor units are observed in this depiction of an electromyographic change from the quiet baseline.

unchanged EMG baseline as tumor is manipulated without disturbing the cranial nerve with which the tumor may be in contact. Figure 16.5B demonstrates traction in the vicinity of the cranial nerve that results in the appearance of many motor units.

Importantly, after the audiologist observes and reports this acute change in activity, the surgeon may choose to reverse the maneuver that led to the decrement. For example, cessation of traction may produce a complete or an incomplete return to the previously observed quiet “motor-unit-free” baseline. Mechanically induced motor units may persist after cessation of the initiating maneuver and may even progress to a recurring train activity, consistent with muscle spasm. This may suggest that unintended injury has occurred or has the potential to occur. A brief pause in the surgical procedure may be recommended until a reduction in the spasm activity is observed.

Ideally, one should have the ability for direct electrophysiological recordings of facial nerve activation and responses to be used as indicators of direct or indirect mechanical manipulation of the nerve, to detect conditions that may lead to nerve injury, and finally to assist in the localization, identification, and mapping of the facial nerve. However, direct recording from cranial nerves during surgery is impractical presently and therefore, electromyographic recording of innervated muscle activity is the electrophysiological method used for intraoperative monitoring. Free-running facial muscle activity is recorded by means of intramuscular needle electrodes and multiple channels of electromyographic activity may typically be sampled. Depending on the desired sensitivity and specificity, one may record EMG differentially from a muscle using paired monopolar electrodes. Smaller interelectrode gaps (electrodes placed closer to one another) produce higher specificity of recorded activity from the target muscle. If the distance between the recording electrodes is relatively wide, the specificity may diminish but sensitivity may increase due the ability to detect activity within a broader muscle mass.

Importantly, a healthy, resting muscle is electrically quiet, that is, there is no spontaneous baseline activity present. Muscle contractions manifest in the appearance of motor unit potentials signaling mechanical manipulation of the target cranial nerve. Thus, nerve manipulation that is associated with certain mechanical forces such as blunt dissection, compression, or stretching may result in a burst of motor unit potentials. These surgeon-induced mechanical forces do not have to be exerted directly on the nerve. Indirect application of force such as with dissection of a tumor capsule adherent to a facial nerve may result in a pattern of activation similar to when a cranial motor nerve is directly manipulated.

Triggered electrical stimulation may also be used to map the course of a motor nerve or to determine the functional status of a nerve intraoperatively. Direct nerve stimulation produces a single CMAP that is synchronized with

electrical stimulus pulses delivered by the surgeon using a handheld probe. The configuration of this response is typically biphasic and does not require signal averaging. For example, direct electrical stimulation of the facial nerve is often used to identify and map the course of the nerve and can provide information regarding the functional status of the nerve before, during, and after the dissection. Repeated measures obtained during surgery may reveal alterations in the amplitude of the CMAP, or the stimulus level required to elicit a response, and may be useful in determining the maintenance of the targeted motor nerve.

INTRAOPERATIVE MONITORING OF AUDITORY FUNCTION

The IOM plan developed for each patient begins well before surgery. For example, in the setting of neurotological surgery to treat mass lesions in the IAC and/or the CPA members of the surgical and intraoperative monitoring teams develop a surgical plan based on the size and appearance of the mass lesion and the patient’s hearing and facial function. Puretone air and bone conduction thresholds, word recognition scores, immittance measures including stapedial reflexes, otoacoustic emissions, and ABR should be components of the preoperative study. For patients suspected to have facial nerve involvement, assessment of facial function may help to form the IOM plan. A clinical assessment using a measure such as the House–Brackmann Facial Nerve Grading Scale (House and Brackmann, 1985) coupled with electrophysiological measures such as ENOG and/or facial EMG is a useful measure to complete before formulating an IOM plan.

The compressive effects of mass lesions in the IAC or the CPA on neural or vascular components that supply sensory cranial nerves can include diminution or loss of function of the involved sensory system. For example, in the IAC an expanding lesion may compress the vestibulocochlear nerve, labyrinthine artery, and/or the facial nerve. The effect of compression of the eighth cranial nerve or cochlear blood supply may be evident in higher frequency hearing thresholds, word recognition scores, the strength or presence of otoacoustic emissions (Kim et al., 2006), and prolongation or diminution of ABR wave III or wave V components that have neural generators medial to the IAC. Those effects can be related to the source of the lesion, that is, inferior or superior vestibular nerve, facial nerve, meninges, and so on (Hirsch and Anderson, 1980). Because neither hearing function nor auditory-evoked responses are easily predicted by the size of a vestibular schwannoma (Badie et al., 2001; Sunderland, 1945) preoperative baseline studies of hearing and auditory-evoked potentials obtained just days prior to surgery help to identify the practicality of planned hearing preservation surgery and also help to modify the plan to perform intraoperative monitoring of eighth cranial nerve (Schwartz and Morris, 1991).

If the plan includes hearing preservation, AEPs obtained in the operating room before the opening incision take on a different role. In this case, the goal is to obtain and store a “baseline measure” against which subsequent measures are compared. To obtain this baseline measure recording and stimulating parameters should be manipulated to achieve the best recording possible prior to incision. For this reason, knowledge of the software associated with the equipment used to perform neurophysiological monitoring and ability to manipulate recording and stimulating parameters are critical skills of the monitoring audiologist.

Auditory nerve monitoring performed during surgery may include electrocochleography (ECOG), ABR, or direct nerve recordings. Each modality can be affected by either pharmacologic agents or physiological changes experienced by patients during operative procedures. Table 16.3 describes pharmacologic and physiological effects on IOM with which the audiologist should be familiar to be able to properly interpret IOM activity obtained over many hours of IOM. Properties such as temperature, hypoxia, hypotension, and hemodilution can impact evoked potential measures obtained in the operating room. For example, mild hypothermia, known to hamper synaptic transmission and nerve conduction as a result of reduced enzymatic reactions along the nerve pathway, may be demonstrated by variable response amplitudes and delays in conduction (Blair, 1965; Kileny et al., 1983). Conduction latency is less evident if the neural pathway has relatively fewer multiple synapses. This may explain why ABR peaks I, III, and V are delayed in the presence of relatively mild systemic cooling. Notably, effects of cooling can be cumulative; later components are delayed to a greater extent than the earlier ones. When extreme low core temperatures are encountered, averaged responses disappear (Banoub et al., 2003).

As mentioned previously, regional hypothermia may occur with prolonged exposure to a cold operating room or with use of cold irrigation fluids. Temperature management of room air and irrigation fluids can be effective in controlling their effects on auditory-evoked potentials. It is recommended that the monitoring audiologist periodically check with anesthesiology regarding a patient’s vital signs including core temperature (Schwartz et al., 1988).

Mild hypoxemia, or a reduction of oxygen supply to tissue below physiological levels, is typically less apparent in the ABR. However, sudden, severe hypoxic or ischemic events can manifest in the loss of the ABR as a result of failure of the cochlear blood supply (Sohmer et al., 1982, 1986). This can occur because of encroachment of tumor on the auditory nerve or during surgery when cochlear blood supply is compromised during tumor removal.

Another common problem in IOM is masking of the auditory stimuli by the operating drill (Legatt, 2002). This predictable event is minimized or eliminated when the drilling stops or with reduced drilling periods. It is important to share this information with the surgeon to decrease the

opportunity for unacknowledged injury. Although the auditory brainstem response is relatively resistant to anesthetic and anesthetic pharmacologic agents, it is not completely unaffected by these agents. Therefore, during intraoperative ABR monitoring, one must recognize the pharmacologic agents administered to a patient to sort out surgical versus nonsurgical changes in latency and amplitude. Brief, direct, and regular communication is key to avoiding unintended, potentially permanent change in monitored activity and associated hearing loss.

Intraoperative monitoring of auditory function examines the status of the cochlea, eighth cranial nerve, and at least several of the brainstem nuclei defining the auditory pathway and is typically used in otologic, neurotologic, and neurosurgical procedures when hearing preservation is a goal by detecting acute changes in auditory function and discussing such events with the surgical team before these changes become permanent. Typically, the surgical team takes some corrective action to avoid adverse effects.

As previously discussed, it is crucial to know the results of a patient’s preoperative audiologic examination. To lessen the chance that a patient’s auditory function will change significantly before surgery, these measures should be performed shortly before the surgical date. Results of the electrophysiological measures should be used both to determine the feasibility of monitoring the auditory pathway and to plan for the most effective way of carrying out eighth nerve monitoring. Notably, auditory electrophysiological activity can represent peripheral and central auditory function depending on the type of auditory-evoked potential that will be monitored. For instance, ABR combined with ECOG provides information about the cochlea, cochlear nerve function (peaks I and II), and brainstem activity via waveform peak III (cochlear nuclei), waveform peak IV (superior olivary complex), and wave V (nucleus of the lateral colliculus) if one can record each of those component parts during surgery.

The ABR is unquestionably the most frequently used method for monitoring eighth nerve function. The advantage of ABR monitoring is that it is more representative of activity generated from the auditory pathway than other methods, at least to the level of the midbrain. A disadvantage is that signal averaging required to record the ABR imposes a time delay between a potentially adverse intraoperative event and its detection. However, with the patient under general anesthesia, use of a faster stimulus rate (31 to 40 sweeps/second) produces an averaged response in less than 30 seconds. We routinely observe that during surgical manipulations in the vicinity of the eighth cranial nerve, response desynchronization or deterioration of the averaged response may occur with little notice, underscoring the importance of rapid averaging.

Auditory nerve function may also be monitored in actual time by directly measuring the compound action potential (CAP) utilizing a sterile electrode in the form of a saline-soaked, cotton wick attached to a thin wire electrode

placed on the proximal cochlear nerve by the surgeon and retained via careful positioning of the metallic portion of the electrode. Direct nerve monitoring requires access to an exposed cochlear nerve and successful recording of the CAP may be related to the size of the mass lesion. In cases of larger tumors, the electrode can be placed only after the mass in the CPA has been resected, exposing the cochlear nerve. In cases of smaller tumors, with less involvement of the cochlear nerve, access is simpler. Advantages of direct nerve monitoring include immediate averaging owing to the amplitude of the response related to the proximity of the electrode to the neural generator.

Further, real-time activity recorded from the cochlear nerve provides information regarding the distal auditory nerve and cochlear function. This is valuable in the setting of intracanalicular acoustic neuromas which are located further from the recording site. For instance, if blood flow to the cochlea decreases because of the intraoperative compression of the labyrinthine artery, a change in the directly recorded CAP could be seen and immediate feedback to the surgeon might lead to rapid corrective action prior to an irreversible ischemic change to the cochlea. A shortcoming of direct nerve recordings is that if not used in conjunction with ABR, changes in auditory pathway function beyond the cochlear

nerve may not be detected. Another option open to the audiologist in the operating room is to record electrocochleographic activity using either a transtympanic needle electrode or a tympanic membrane surface electrode. This method provides an enhancement of the nerve action potential after brief periods of signal averaging. Fewer sweeps are required to obtain this response when compared to the ABR owing to its closer proximity to its neural generator and the associated improvement in signal-to-noise ratio. However, it too should be provided in combination with the ABR to observe the distal and the more proximal auditory nerve intraoperatively. Figure 16.6A,B displays portions of IOM results obtained during similar surgical procedures performed on two different patients with an aim in each case to preserve hearing function during resections of acoustic neuromas that measured approximately 1 centime in size. Each IOM setup included ECOG and ABR to monitor distal as well as proximal eighth nerve activity, respectively. In Figure 16.6A, observe the presence of responses throughout the monitoring period represented in the curve stack for both ECOG and ABR. The epoch includes the last portion of activity recorded during the hearing preservation for this case; the ABR and the ECOG were maintained throughout tumor removal, and hearing was successfully preserved. In contrast, Figure 16.6B demonstrates

FIGURE 16.6 A: A stack panel of auditory-evoked potentials including the auditory brainstem response and electrocochleography. Individual waveform components are present at the conclusion of the case (bottom of the panel), suggesting preserved hearing function was achieved for this patient.

FIGURE 16.6 (Continued) **B:** A stack panel of auditory-evoked potentials includes the auditory brainstem response and electrocochleography. Individual waveform components are absent at the conclusion of the case (bottom of the panel), suggesting preserved hearing function was not realized in this case.

consecutive recordings of ECOG and ABR responses during a similar hearing preservation procedure that did not result in preserved hearing function postoperatively. Note in the left-hand column changes in the ABR wave I amplitude beginning at 13:32; in the right-hand column, changes in the ECOG's AP amplitude are observed as well. By the end of the surgical dissection, ABR responses are essentially absent whereas the ECOG AP response was absent as well. Unfortunately, the patient had no measurable hearing postoperatively, presumably related to an acute interruption of cochlear blood supply during the very last portions of the surgical intervention.

THE DEVELOPMENT AND MANAGEMENT OF AN INTRAOPERATIVE MONITORING PROGRAM

Intraoperative monitoring requires a team approach with the surgeon, anesthesiologist, operating room nurse or technician, and audiologist contributing their respective skills while working toward a goal of excellent patient out-

comes. Although members of this team have different roles and training, each must understand the others' set of skill and role. For instance, the audiologist who may be responsible for performing the necessary preoperative audiological evaluations, planning and arranging neurophysiological monitoring, and recording, monitoring and interpreting the pertinent events must also have a thorough understanding of the surgical procedure. The audiologist must know the surgical anatomy and surgical indications for taking corrective action when trauma is imminent. The audiologist must be inquisitive and have a good working knowledge of the effects of pharmacologic agents on the electrophysiological events to be monitored in the operating room and must collaborate closely with the anesthesiologist or nurse anesthetists to properly decode response changes associated with alterations in anesthetic regimen. It is crucial to have adequate knowledge and preparation to be able to differentiate between changes in intraoperative monitoring events related to anesthetic intervention and those related to surgical events.

Differences exist across institutions regarding the specific models of intraoperative monitoring that the institution will

support financially and administratively. Therefore, before initiating such a program there should be a clear understanding among all stakeholders as to what the program will require, what will it consist of, financial implications, staffing, and staff preparation. All members of the operating room team need to be well informed about plans for this program and be aware that introducing IOM into the operating room may change the routine of a number of people to some degree. The unannounced appearance of an IOM work station in an already-crowded operating room may create problems. Similarly, a last-minute request to the anesthesia team about avoiding the use of neuromuscular blockade might also be a problem if, for example, a patient's medical condition imposes limitations in terms of the type and dosage of anesthetic agents used. Thus, the value of an intraoperative monitoring program lies in the preparation of all of the individuals involved in or affected by this practice. This also requires an understanding of the needs of the particular patient and the limitations of other professionals involved. Therefore, specific protocols for specific types of surgical procedures requiring intraoperative monitoring are necessary for a given institution. The standards and criteria associated with each protocol will assist the clinician carrying out intraoperative monitoring to provide a level of service that will maximize surgical outcomes.

Clearly, program differences in the IOM model exist across institutions. The "continuously attended" model involves someone other than the surgeon to prepare the patient, record pertinent neurophysiological activity and interpret activity within the context of the surgical procedure, and, importantly, provide specific feedback regarding changes in the monitored activity that might result in specific changes in surgical technique or approach. The intraoperative neuromonitoring clinician needs to have the ability to observe the surgical procedure (typically on a monitor connected to a microscope mounted camera in most microsurgical procedures) and correlate that activity with neurophysiological events. For instance, in the case of motor cranial nerve monitoring, continuous observation of spontaneous EMG and the immediate interpretation of any changes associated with mechanical manipulation of the motor component of the cranial nerve are important, because those events may be relevant to the prevention of postoperative paralysis or paresis. Additionally, one should follow established criteria that quantitatively assess the electrically activated CMAP as a predictor of postoperative functional status. Similar principles apply to sensory-evoked potential monitoring that may utilize ABR, ECOG, or direct cochlear nerve measurements.

Another model of intraoperative monitoring, arguably the most frequently used method, is the so-called "black box" or "remote" technology. This approach is utilized exclusively for monitoring the function of motor cranial nerves and also involves the recording of EMG events by means of intramuscular electrodes. The EMG activity is routed to an instrument that is intended to provide acoustic alarms upon mechanical manipulation of the target nerve.

A similar acoustic alert signals the presence of a CMAP response associated with electrical nerve stimulation. In this model, no audiologist observes or interprets the various events occurring during surgery. Instead, the surgeon is required to attend to the alerting sounds and must learn to discriminate between acoustic alarms that signal either a baseline change in the free-running EMG associated with surgical events or spurious noise emanating from contact between noninsulated instruments touching in the operative field. The surgeon also needs to distinguish between acoustic signals that represent just stimuli being delivered about three times per second and the sound of effective nerve stimulation resulting in a CMAP. In this paradigm, the onus for proper and immediate interpretation of monitoring events belongs to the surgeon. The recognition of a particularly adverse situation is typically based solely on the perception of a change in acoustic output from the monitoring equipment's speaker. Some devices provide a screen that displays monitored activity or responses to stimulation in various ways. However, with attention properly focused on the operative field, the visual representation of activity on a screen is typically disregarded.

In addition to a decision regarding the type of monitoring employed, that is, continuously attended versus remote or nonattended, another decision that needs to be made beforehand concerns the type of procedures that will be monitored. In other words, what surgical service(s) will be supported by the IOM program? Among other things, this decision will impact the size of the monitoring staff, the type and level of training of that staff, and the type of neuromonitoring equipment purchased to support the service. For instance, if major skull base cases will be monitored requiring multiple channels available for cranial nerve monitoring, devices that allow for that level of activity must be sought out, purchased, and importantly supported for the life of the equipment. Decisions about surgical monitoring also impact the type of disposable supplies used including acoustic transducers, types of electrodes, and special EMG endotracheal tubes. There are multiple types of surgeries within the broader specialty of otolaryngology-head and neck surgery that benefit from monitoring. They include pediatric, otologic, and head and neck procedures involving the parotid gland or thyroid gland, and/or neck dissections.

Importantly, in 1992 and again in 2004, the National Institutes of Health published consensus statements based on expert testimony summarizing management options including facial nerve monitoring during surgical treatments for vestibular schwannoma (Edwards and Kileny, 2005). The American Academy of Otolaryngology-Head and Neck Surgery (1998) concurred with the value of facial nerve monitoring and noted that competently performed IOM of the facial nerve is effective and minimizes the risk of injury. Greenberg et al. (2002) sampled 500 members of the American Academy of Otolaryngology-Head and Neck Surgery regarding the value of facial nerve monitoring. Two

TABLE 16.4

Selected Elements of a Standardized Intraoperative Cranial Nerve Monitoring Service

- I. Intended procedure
 - A. Surgical service
 - 1. Otology
 - 2. Head and neck
 - 3. Skull base
 - 4. Pediatric otolaryngology
 - 5. Neurosurgery
 - 6. Thoracic/endocrine/general
 - B. Estimated procedure duration
 - C. Operating room characteristics
 - 1. Physical dimensions
 - 2. Access to single-use supplies
 - 3. Location of monitoring and surgical teams
 - a. Sight lines
 - b. Communication obstacles
- II. Recording Issues
 - A. Electrodes
 - 1. Surface, subdermal, tympanic membrane surface, promontory needle, EMG endotracheal, hookwire
 - 2. Matched impedances
 - 3. Patient ground
 - B. Monitoring system components and parameters
 - 1. Amplifiers
 - 2. Filters
 - 3. Averaging mode
 - C. Artifact issues
 - 1. Isolating source
 - 2. Comprehending presence/magnitude in ongoing activity
- III. Stimulation issues
 - A. Trigger source
 - 1. Internal versus
 - 2. External
 - a. Synchronization with sweep cycle
 - B. Electrodes
 - 1. Exposed tip, flush tip
 - 2. Lead extensions
 - C. Electrical stimulation
 - 1. Monopolar versus bipolar
 - 2. Constant current versus constant voltage

 - 3. Tests of structure [computerized tomography, magnetic resonance imaging, radioisotope injection, etc.]

hundred and twenty-three of these respondents were private practitioners. Within that group, 82% of self-described otolaryngologists use facial nerve monitoring as compared with 50% of self-reported general otolaryngologists. Seventy-six percent of all respondents reported that they had access to facial nerve monitoring when desired. The more frequent users of facial nerve monitoring were employed in academic medical centers and were more recently trained or were subspecialized otolaryngologists. Most did not advocate mandatory monitoring for chronic ear surgery. Wilson et al. (2003) examined the cost-effectiveness of facial nerve monitoring in middle ear and mastoid surgery. The primary outcome measure selected by these authors was the increased cost per incremental quality adjusted life year (QALY) saved. The decision matrix examined cost-effectiveness of facial nerve monitoring in three cohorts of patients: Those who receive facial nerve monitoring for all middle ear mastoid surgery, patients who had selective facial nerve monitoring, and patients who received no monitoring at all during their surgery. QALYs were obtained by multiplying life expectancy with estimated utility of patients living with a facial paralysis. Calculations were made using a self-evaluation tool for patients with facial paralysis (Kahn et al., 2001). Results strongly favored facial nerve monitoring for any patients undergoing middle ear and mastoid surgery. A cost range of approximately \$223 to \$528 associated with the provision of IOM was reported. Rank-ordering of QALY supported a strategy to monitor primary and revision surgery versus either revision only or no monitoring scenarios. Associated costs of facial paralysis increased with decreasing use of monitoring, that is, higher costs were associated with no provision for monitoring.

Importantly, audiology membership groups support IOM in their various policy documents and scopes of practice. For example, the American Speech Language-Hearing Association recognized audiologists' growing interest and involvement in IOM. In 1991, the Legislative Council approved an official policy document entitled "Neurophysiologic Intraoperative Monitoring." The intent of the document was to provide audiologists with guidelines that considered primarily the quality of care offered to patients for whom IOM was an option (American Speech Language-Hearing Association, 1992). Their scope of practice was revised in 1996 to include IOM while promoting the continued development of professional and technical standards (American Speech Language-Hearing Association, 1996). Similarly, the American Academy of Audiology included in its scope of practice the provision of IOM by audiologists (1996), strengthening that statement several years later (American Academy of Audiology, 2004).

FOOD FOR THOUGHT

1. Please discuss the difference between automated, non-attended intraoperative monitoring versus monitoring provided by a qualified clinician. Please consider

the surgeon's point of view, as well as the audiologist's/neurophysiologist's point of view. Who takes responsibility? Who is liable if something goes wrong? Who is responsible for setting up the automated, non-attended device, and does that person have any responsibility?

2. How do you interact with the surgical and anesthesia team members in the operating room; what information do you share with either or both specialties in the course of a surgical procedure? What do you do when you identify a significant change in the neural function of one or more of the structures you are monitoring for a given surgical procedure?
3. Consider the electrically hostile OR environment and discuss ways and means to combat those issues. Is there one solution for all; would the same solution work every time?

DEDICATION TO A FRIEND AND COLLEAGUE

The authors recognize the contributions of the late Dr. Roger Ruth in the development of IOM in the field of audiology and for his contributions to the material in this chapter. He is greatly missed by his family, friends, colleagues, and students.

Middle-Latency Auditory-Evoked Potentials

Anthony T. Cacace and Dennis J. McFarland

INTRODUCTION

Middle-latency auditory-evoked potentials (MLAEPs) occur from approximately 15 to 70 ms and may be of value in estimating auditory thresholds as a function of frequency and in assessing higher-order auditory processes. This chapter focuses on anatomy and generator sites, theoretical and practical considerations including recording parameters and state and subject variables, and other topics relevant to clinical concerns. Some applications, such as those related to sensory gating and depth of anesthesia, have emerged with increased frequency in recent years. Thus, this chapter provides a comprehensive overview of MLAEPs that would be valuable to students and informative to seasoned professionals.

ANATOMIC FRAME OF REFERENCE

Knowledge of thalamic and cortical anatomy is necessary to understand MLAEPs. The auditory thalamus (medial geniculate nucleus, MGN) is an integral component of the subcortical afferent auditory pathways; descending reciprocal pathways from cortex to thalamus and other areas are also noteworthy (Winer and Lee, 2007). Ascending thalamocortical fibers on route to the cerebral cortex course through the sublenticular portion of the internal capsule (Truex and Carpenter, 1964). The ventral division of MGN projects to the core areas of the auditory cortex (AC) located on the superior aspect of the temporal lobe; the dorsal division of MGN projects more diffusely (Rauschecker et al., 1997). The ventral MGN sends direct projections in parallel to primary and rostral areas of the AC, which are highly responsive to puretone stimuli. The dorsal-medial and other aspects of the MGN send direct inputs to caudal-medial aspects of AC. These caudal-medial areas respond preferentially to more complex broadband stimuli. Auditory cortical regions also project back to the medial geniculate regions from which they receive projections (Pandya et al., 1994). Thus, both feedforward and feedback neural projections coexist. These reciprocal relationships allow thalamocortical circuits to be

interactive with the environment, thus allowing spectral and temporal transformations of stimulus representations to dynamically modify perception and behavior. In this regard, the classical view of the thalamus as being merely a “passive relay area” requires modification and updating (Winer et al., 2005).

The AC consists of a core area on the superior temporal plane (including Heschl’s gyrus) (Figure 17.1A). The core contains three cochleotopically organized fields (Kaas et al., 1999), surrounded by a belt of association areas, which in turn are surrounded by parabelt association areas, extending to the lateral surface of the superior temporal gyrus. The belt also receives afferent input from the core area and dorsal divisions of the medial geniculate complex, with minor projections from ventral and medial geniculate areas. The parabelt has strong connections with the belt area, has minimal connections with the core, and receives thalamic inputs in parallel with belt inputs across its subdivisions. Additionally, the belt and parabelt zones consist of several regions that are distinct in terms of cyto-architecture and connections (Hackett et al., 1999). A block diagram from Kaas et al. (1999) summarizes known neuroanatomical relationships relevant to higher level thalamocortical processing (Figure 17.1B) described above. There is support for the view that these various auditory association areas may be specialized for processing two distinct classes of auditory features (i.e., sound identity information and temporal and spatial information) (Rauschecker et al., 1997) in a manner analogous to what has been described in visual cortical areas (Mishkin et al., 1983). Polysensory regions of the temporal, parietal, and frontal cortices also receive input from AC (Pandya, 1995). Thus, there are both feedforward and feedback connections within and between subregions, including connections with multimodal insula, the superior temporal sulcus, and long association connections with amygdala and prefrontal cortex. Contemporary neuroanatomical staining methods and various imaging-related activation studies suggest that human AC can be subdivided into at least eight different putative regions (Rivier and Clarke, 1997). Human investigations continue to be elaborated on by the increased use of functional neuroimaging methodology (e.g., Saenz and Langer, 2014).

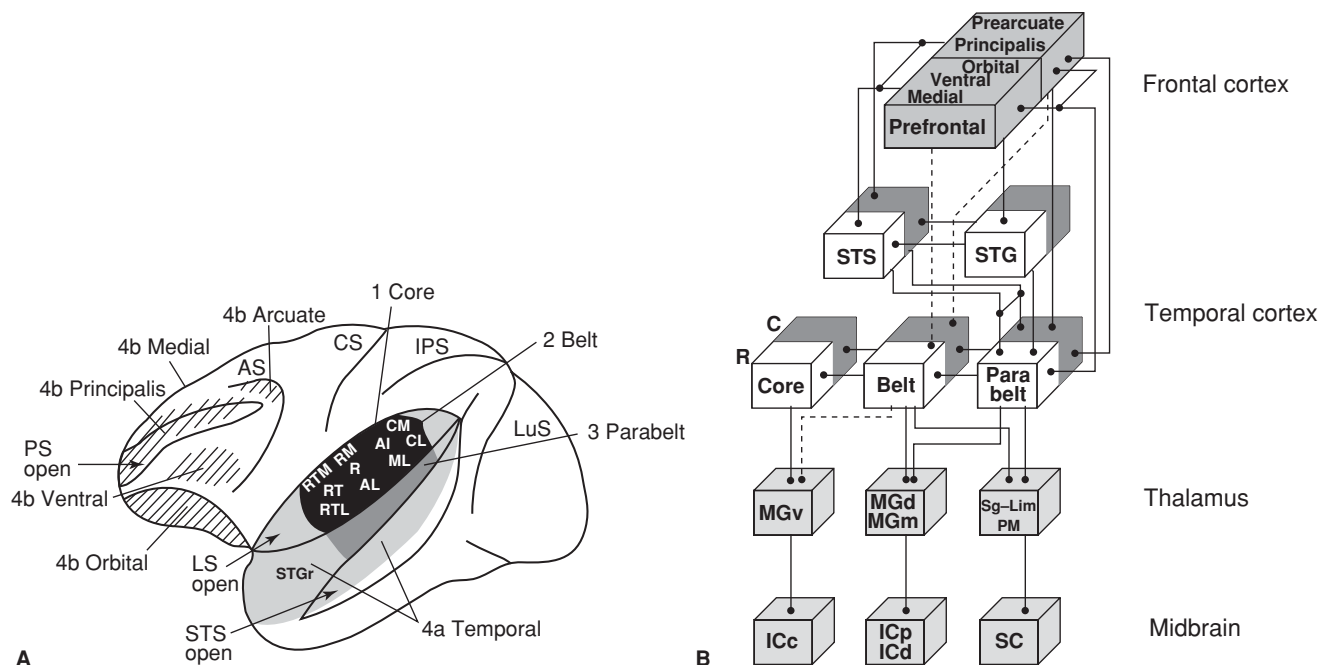

FIGURE 17.1 **A:** Schemata of contemporary auditory cortical neuroanatomy based on levels and regions of processing. In this representation, the lateral sulcus (LS) is opened to show auditory areas of the lower bank and the superior temporal sulcus (STS) has been opened to show the extension of auditory-related cortex in this sulcus. *Level 1* represents the core [darkest shading]; *level 2* represents the belt [moderate shading]; *level 3* represents the parabelt [light shading]; *level 4a* represents the temporal region [dense hatching]; and *level 4b* represents the frontal region [sparse hatching]. In this diagram, the following abbreviations are used: AL, anterolateral; AS, arcuate sulcus; CL, caudolateral; CS, central sulcus; IPS, intraparietal sulcus; LuS, lunate sulcus; ML, middle lateral; PS, principle sulcus; RM, rostromedial; RTL, lateral rostrotemporal; RTM, medial rostromedial, STGr, rostral superior temporal gyrus. **B:** Block diagram providing details of known connections and levels of processing to the primate auditory cortex. The *solid lines* represent major connections and the *dashed lines* represent minor connections. According to this framework, the main stream of processing involves the central nucleus of the inferior colliculus (ICc), the ventral nucleus of the medial geniculate complex (MGv), and the core areas of the auditory cortex. A parallel stream involves the dorsal (ICd) and pericentral (Icp) divisions of the inferior colliculus, the dorsal (MGd) and medial (MGm) divisions of the medial geniculate complex, and the belt cortex. The superior colliculus (SC) projects to parts of the medial pulvinar (PM), supragenicolate (Sg), and limitans (Lim) nuclei, as a possible third source of input to the parabelt cortex. Additional levels of processing include cortex of the superior temporal gyrus (STG), adjoining belt and parabelt regions, STS, and prefrontal cortex. The preferential connections of rostral (R) and caudal (C) sectors of cortex are indicated. [Both the anatomical representation and block diagram are taken from Kaas JH, Hackett TA, Tramo MJ. (1999) Auditory processing in primate cerebral cortex. *Curr Opin Neurosci.* 9, 164–170, with permission].

GENERAL CONCEPTUAL FRAMEWORK OF AUDITORY-EVOKED POTENTIALS

Electrical activity measured from scalp electrodes in response to sensory stimulation represents the sum (superposition) of the electrical fields projected by all active sites at any given point in time. These include thalamic nuclei, the ascending thalamocortical fibers, primary auditory and auditory association areas, polysensory association areas, and inter- and intracortical fiber tracts. The polarity, spatial distribution, and whether or not electrical potentials generated from brain-

stem or from within the brain can even be detected by surface electrodes on the scalp depend in large part on the underlying geometry of active cell populations. Idealized and highly schematic examples of the spatial organization of different populations of cells and their resultant electric field distributions are shown in Figure 17.2A to D. The work of Lorente de Nó (1947), updated by Buzsáki et al. (2012), forms the basis for understanding the transformation of electric activity from near-field (intracranial) to far-field potentials detectable at the scalp. Populations of neurons can be regarded as sources of electrical current with a positive charge at one location and negative charge at another (so-called stationary dipoles). The electric field distributions of different populations of neurons

FIGURE 17.2 Examples of closed [A, B], open [C], and open-closed fields [D], for different populations of neurons in the CNS. The *left column* represents different populations of neurons; the *right column* represents activated neuronal populations together with *arrows* representing the lines of current flow at the instant when the impulse has invaded the cell bodies. The zero (0) indicates the isopotential line. In [A], the schematic depicts the oculomotor nucleus with dendrites oriented radially outward. The isopotential lines are circles with current flowing entirely within the nucleus. This results in a closed field with all points outside the nucleus remaining at zero potential. In [B], the schematic depicts the neurons of the superior olive having dendrites oriented radially inward. Here also, the currents result in a closed field. In [C], the accessory olive is represented by single neurons and associated long dendritic processes. In this arrangement, the sources and sinks permit the spread of current in the volume of the brain and result in an open-field configuration. In [D], two structures mixed together generate an open-closed field. [Adapted from Lopes da Silva F, Van Rotterdam A. [1999] Biophysical aspects of EEG and magnetoencephalogram generation. In: Niedermeyer E, Lopes da Silva F, eds. *Electroencephalography: Basic Principles, Clinical Applications and Related Fields*. 4th ed. Baltimore, MD: Williams & Wilkins; pp 93-109, based on the work of de No [1947], with permission].

have been classified as closed (Figure 17.2A and B), open (Figure 17.2C), and open-closed fields (Figure 17.2D). In an open-field configuration, if dendrites from these populations of cells are all orientated in the same general direction, then in theory, the far-field potentials will be large and easily detectable at the scalp. Indeed, the morphologic polarization of pyramidal cells

with long and vertically directed apical dendrites that terminate in the most superficial layers of cortex (gyral crests) can be characterized in this manner. These cell populations, which line the walls of sulci, can generate strong electric and extracranial magnetic fields (Lewine and Orrison, 1999). In neocortical tissue, which is composed of characteristic cell layers, the polarity of the sources and resultant fields are thought to be at a right angle to the plane of the surface and are consistent with this notion of cell distribution (Nunez, 1995). However, in populations of neurons in which the cell bodies are positioned in the center with dendrites projecting in all directions (so-called closed-field or open-closed-field configurations (Figure 17.2A, B, and D), the amplitudes of the resultant far-field electric potentials will be much smaller and may not be detectable at the scalp at all. This observation results from the fact that various components of these electric fields can cancel each other over time. Further complications arise for surface recordings from human AC based on the convoluted nature and complex three-dimensional geometry of the superior temporal plane. Galaburda and Sanides (1980) report that the superior temporal plane is “one of the most highly folded in the human brain” (p 603). Furthermore, individual differences complicate matters further by introducing additional variability between hemispheres and brains.

Given the spatial geometry of active cell populations in both the thalamus and on the superior temporal plane, the resultant electric fields in response to acoustic stimulation should project toward the top of the head and be largest at medial central and/or anterior-central locations. Moreover, these potentials, which are localized at central scalp locations, should be diffuse, since in theory their sources are at a distance. In these circumstances, electric field projections should be broader with greater distance from the generator source. This is in contrast to the projections from auditory association or belt regions on the lateral surface of the temporal lobe, which in theory should produce more focal and lateralized scalp distributions, since the generators are closer to the surface of the scalp. Recent evidence and other supporting data show that there is considerable divergence in the auditory thalamocortical pathway (Winer et al., 2005) and, consequently, results in more complex *radial* and *tangential* cell orientations (Cetas et al., 1999).

Yvert et al. (2005) examined intracranial responses to tone-evoked potentials in subjects being evaluated for epilepsy surgery and found a sequential spread of evoked activity from Heschl’s gyrus to surrounding auditory association areas. They modeled the spread of this activity on the scalp and concluded that potentials at the surface represent the activation of multiple sources that are simultaneously active. Furthermore, Boutros et al. (2013) observed activity in the P50 time frame evoked by the first of a pair of tones in temporal, parietal, and cingulate areas. These studies show that there are multiple diverse sources of the P50. Moreover, in a modeling study, Ahlfors et al. (2010) showed that even a small number of simultaneously active dipoles could

produce cancellation of activity at the scalp. Thus, based on empirical evidence and results from modeling experiments, it is evident that multiple sources are simultaneously active in the middle (~15 to 70 ms) and longer (>70 to <256 ms) latency ranges and that there is considerable overlap in both temporal and spatial distributions on the scalp. Thus, adequate spatial sampling with electrodes is necessary.

RECORDING CONSIDERATIONS

The most common type of AEP study is accomplished via surface electrodes. Electrode placement on the surface of the scalp is based on specific conventions, allowing for comparisons between different laboratories and countries (see Jasper, 1958). Depending on the specific context, recordings in the middle-latency range have been derived from single-channel recordings (Thornton et al., 1977), from two channels (Schochat et al., 2010), from linear arrays (Scherg and von Cramon, 1986a), or from more comprehensive matrix designs where data are sampled from a wide range of locations over the entire scalp (Cacace et al., 1990).

A restrictive set of MLAEPs may be recorded from a single channel, with electrodes placed, for example, at the vertex (noninverting electrode), a known reference site (inverting electrode), and ground (common). Evoked potentials recorded from one channel (i.e., two electrodes; active and reference) can be compared to sampling the waveform with only two points in time (Lopes da Silva, 1999). Whereas auditory brainstem responses (ABRs) are far-field electric potentials that reflect broadly distributed responses from fiber tracts and nuclei in peripheral and brainstem auditory pathways (Møller, 1988), MLAEPs originate from sources closer to the surface of the scalp. As a result, MLAEPs show more variation with electrode position and consequently some degree of spatial sampling appears necessary. The electrical potential recorded at any particular electrode, at any point in time, can be regarded as the signal of interest corrupted with unwanted noise. If the noise is random and uncorrelated with the signal, then averaging of multiple samples can improve the signal-to-noise ratio proportional to the square root of “ N ”, where N is the number of samples in the average (Lopes da Silva, 1999). In theory, by averaging many poststimulus epochs of EEG, the noise component decreases toward zero and the AEP waveform can be extracted from the noise. This approach is the most common analytical strategy for capturing the neural reactivity of “synchronized” EEG to a sensory stimulus (Dawson, 1951). This “additive model” assumes that data contained within individual trials are composed of a linear combination of stimulus (or time-locked activity) plus background noise. However, a fundamental shortcoming of the additive model concerns the way in which nonstimulus locked activity is handled. For example, nonstimulus locked activity is also known as induced, emergent, or “unlocked activity” (see Ba ar and Bullock, 1992; McFarland and Cacace, 2004). The

distinction between “stimulus locked” and “unlocked” activity requires consideration because it recognizes that in addition to synchronized activity reflected in the time-domain average, two additional types of signals are embedded within ongoing background EEG. These signals include (1) EEG that is *reactive* to the stimulus but *not* time-locked to the event and (2) unwanted noise. Unlocked activity is largely rhythmic or oscillatory in nature and therefore, it does not have a fixed waveform. In this context, the unlocked component represents those frequency-dependent changes in EEG rhythmicities that are modulated by sensory stimulation. The key point here is that these oscillatory dynamics thought to underlie EEG reactivity *cannot* be captured by typical signal averaging techniques in the time domain and therefore alternative methodologies such as frequency-domain analysis are needed (see Cacace and McFarland, 2006). Accumulating research shows that unlocked oscillatory activity is a rich source of information about brain function which can provide a unique perspective when incorporated within perceptual, cognitive, and motor paradigms (Başar and Bullock, 1992). With more complex tasks used to elicit longer latency AEPs (i.e., oddball or other cognitive-related paradigms), research has shown that unlocked EEG spectral power is associated with attended targets during a frequency discrimination task (McFarland and Cacace, 2004). Precisely how important the spectral dynamics of oscillatory EEG is for MLAEPs is just beginning to be explored; however, recent work has shed light on the fact that assessment of EEG oscillations has implications for P50 in the context of sensory gating endeavors used in psychiatry (Smucny et al., 2013). Additionally, Kruglikov and Schiff (2003) have shown that MLAEPs vary with the phase of the background EEG and suggest that a new conceptualization is required to account for such findings. Phase resetting may also have important implications related to perception, but a more cohesive account of these types of data will be needed for this body of research to advance (Ross et al., 2005).

Ultimately, the more effective the clinician/researcher is in isolating and removing sources of noise contamination during data acquisition, the better the recordings will be. Noise sources which electrodes can pick up by induction include extracranial electrical fields such as the 60-Hz noise from nearby power lines (50 Hz in Europe) and electrical potentials resulting from the movement of the wires connecting the electrodes to the amplifying system. Other intracranial nonauditory noise sources include low-frequency potentials induced by lateral eye movements, higher frequency fields resulting from vertical eye movements (blinks), and broadband signals resulting from electromyographic (EMG) activity. As noted in a previous review on this topic (Cacace and McFarland, 2002), distinguishing true “neurogenic” from “myogenic” activity had complicated the interpretation of MLAEPs for some time. Sources of EMG contamination are provided in Table 17.1. Moreover, if the underlying noise (lateral eye movements, eye blinks, EMG) is in-phase

TABLE 17.1

Time-averaged Electromyographic Potentials from Post-auricular, Temporalis, and Neck Muscles that Can Be Recorded from the Scalp in the Middle-latency Time Frame

Reflex	Description
Post-auricular muscle	Variable from subject to subject and even with subjects. Large negative peak at 11.8 ± 0.8 ms and positive at 16.4 ± 0.7 ms
Temporalis muscle	Very easily recordable from subjects with clenched teeth. Large negative peak at 17.2 ± 1.9 ms and positive peak at 22.8 ± 2.8 ms
Neck muscles	Recordable from theinion. Begins as early as 7.4 ms. Has multiple components: Negative waves at 11.3 ± 0.2 and 24.6 ± 1.5 ms and positive waves at 16.8 ± 2.4 and 33.8 ± 0.5 ms
Frontalis muscle	Highly variable response. There is usually a distinct positive component at approximately 30 ms

Adapted from Picton TW, Hillyard SA, Krausz HI, Galambos R. (1974) Human auditory evoked potentials: I. Evaluation of components. *Electroencephalogr Clin Neurophysiol.* 36, 179-190.

(i.e., time-locked) with stimulus presentation rate (e.g., 50 to 60 Hz or a harmonic thereof), then the signal averaging strategy discussed above will be unsuccessful. In summary, to improve the quality of the recorded potentials, it is advisable to minimize and/or control exogenous and endogenous artifacts and sources of contamination as best as possible.

Bandwidth is another important consideration in recording MLAEPs. Scherg (1982) has reported that MLAEPs are readily detectable with averaging over a relatively wide bandwidth (1.0 to 5,000 Hz). Campbell and Leandri (1984) have demonstrated that filtering can introduce temporal and amplitude distortions that may not be distinguishable from true potentials. Based on the work of Chang et al. (2012), it can be seen how a narrow recording bandwidth could negatively influence waveform morphology in the middle-latency range; four passbands were compared (0.23 to 75, 10 to 50, 10 to 75, 10 to 200 Hz). To illustrate temporal and amplitude distortions, we present a simulated waveform under three filtering conditions: (1) unfiltered, (2) filtered between 2 and 400 Hz, and (3) filtered between 10 and 50 Hz (Figure 17.3). As can be seen, comparing the unfiltered and 2 to 400 Hz filter (Figure 17.3A and B) shows that the waveform is relatively unchanged. However, when too narrow a filter setting is used (Figure 17.3C; 10 to 50 Hz filter),

FIGURE 17.3 A simulated waveform is shown under three filtering conditions: [1] Unfiltered, [2] filtered between 2 and 400 Hz, and [3] filtered between 10 and 50 Hz. The first two conditions compare the unfiltered and 2 to 400 Hz filtered condition [A, B]. They show that the simulated waveform is relatively unchanged [dropped dashed line] with respect to latency and amplitude. However, when too narrow a filter setting is used [C; 10 to 50 Hz], the waveform is significantly altered; latencies of peak x and y are prolonged, amplitude is clearly diminished, and an additional component [peak z], not seen in the unfiltered or filtered waveform between 2 and 400 Hz [A, B] was added. This simulation illustrates that too narrow a filter setting can induce significant artifacts in the recordings including the addition of new peaks that were not part of the original unfiltered AEP.

the waveform is significantly altered; latency of peak x and y is prolonged and amplitude is diminished. Most significant, however, is the observation that an additional component (peak z) was added to the waveform complex. This filter setting was used by Chang et al. (2012) to record the P50 during sensory gating and demonstrates that too narrow of a filter setting can induce significant artifacts in the recordings including the addition of new peaks that were not part of the unfiltered evoked potential. Litvan et al. (2002) used a finite impulse response (FIR) 170th order band-pass filter (25 to 65 Hz) to record MLAEPs in the operating room to identify depth of propofol anesthesia along with a rapid signal averaging method. Limited waveforms are provided and

their technique shows that the amplitudes are significantly blunted. In sum, too broad a filter may retain too much noise in the recording and too narrow a filter can introduce unwanted artifacts that should be avoided. Nevertheless, with available technology, it is possible to design an optimal filter for detecting middle-latency components.

Alternative signal-processing methods, such as correcting for latency jitter (Lopes da Silva, 1999), may also prove useful for improving signal-to-noise ratio. In the audiologic literature, technical considerations related to temporal and amplitude distortions have been discussed (Kraus et al., 1994). The issue of filter bandwidth is also related to the context in which MLAEPs are recorded. For example, it has been suggested that combining ABR and MLAEP recording can enhance threshold estimation for frequencies <1,000 Hz (Scherg, 1982). In this context, the filter's passband needs to be relatively broad to accommodate both ABR and MLAEP spectra. The digital signal-processing strategy of Scherg (1982), including dual artifact rejection algorithms and broad bandwidth (1.0 to 5,000 Hz), appears optimal for these types of recordings. However, the variability of MLAEP detection during different stages of sleep complicates broad bandwidth recordings, particularly when estimating frequency-specific thresholds in infants and young children. In contrast to combining ABR and MLR responses, others have focused on the simultaneous recording of middle and longer latency AEPs (Cacace et al., 1990; Wood and Wolpaw, 1982). In this context, the low-pass cutoff frequency can be more restrictive and the passband of 1.0 to 300 Hz is adequate.

The middle-latency waveform has been characterized by the amplitude and latency of individual components, by means of area under the curve, or by spectral analysis. Various authors describe different numbers of middle-latency potentials. Musiek et al. (1984) identify four positive and three negative waves at the vertex, which they label as Po, Na, Pa, Nb, Pb, Nc, and Pc, similar to the nomenclature used by Thornton et al. (1977). Ceszia and Brigell (1999) describe three negative and two positive middle-latency waves, whereas Scherg (1982) identified a single negative and positive peak. Pynchon et al. (1998) describe a procedure involving baseline correction, rectification, and integration of the vertex waveform across an interval determined by the latency of Na and Nb. The rationale for this method is based on the premise that it "is believed to represent the total amount of neural energy contributing to the evoked response" (Pynchon et al., 1998, p 1). As noted earlier, because the potential recorded at the scalp evoked by acoustic stimulation is the superposition of electrical fields projected by all active underlying neural sources, and since sources may cancel, the net projection will vary with the point on the scalp being considered. Thus, it is unlikely that an integration of the scalp waveform at a single point on the scalp represents the total amount of neural energy contributing to the evoked potential.

Reference Electrode

An electrical potential on the scalp, or any other place for that matter, is always recorded between two points. Although some recording montages are referred to as monopolar, they are in fact recordings between two electrodes: An electrode of interest and a shared reference. The potential waveform recorded at any noninverting electrode varies with the reference electrode site used (Gencer et al., 1996). If sources are modeled as dipoles, then a given component will be larger when it is close to the electrode in question and parallel in orientation to a line drawn between the electrode and the reference.

One current view holds that the optimal site for a reference electrode is the placement on the head or body where the potential field is most stable (Wolpaw and Wood, 1982). This consideration ensures that changes in the evoked potential field over time reflect changes in the vicinity of the recording electrode(s) and not a complex combination (sum) of changes at both reference and recording electrode locations. Based on available empirical information, the balanced noncephalic sternovertebral reference of Stephenson and Gibbs (1951) is an optimal choice for use in recording auditory-evoked potentials. Chen et al. (1997) have shown that MLAEPs are larger with a balanced noncephalic reference versus linked earlobes. It is also important to realize that if hemispheric asymmetries exist, as is the case in longer latency AEPs (Cacace et al., 1988; Wolpaw and Penry, 1975), then the balanced noncephalic reference is preferred over other sites.

If clinicians are sampling from many electrode sites on the scalp, then so-called "reference-free derivations" can be used. The common average reference assumes that if one samples the time/voltage waveform at electrode locations all around the skull, the average voltage value of all points would sum to zero. In theory, this approach would provide a reference that would not favor any one electrode over another and presumably would not distort the *true* response. However, this assumption depends on the number of sites sampled. Rarely could one sample all locations around the skull, and as a result, significant biases can occur with this method. The Laplacian method (McFarland et al., 1997) may be applicable to enhance the topographic distinctiveness of the various evoked potential components. This relatively underused but powerful methodology has utility to help delineate evoked potentials in the middle- and long-latency time domains (Hjorth and Rodin, 1988; Law et al., 1993).

Defining AEP Components: Analysis Strategy

Electrode placements for clinical studies need to be based on detailed topographic studies in the time frame of interest. Figure 17.4 provides the waveforms at several recording sites (central, Cz, and temporal, T3 and T4) and detailed topographic maps in the middle-latency range for two individual subjects, which are representative of average data (Cacace et al., 1990).

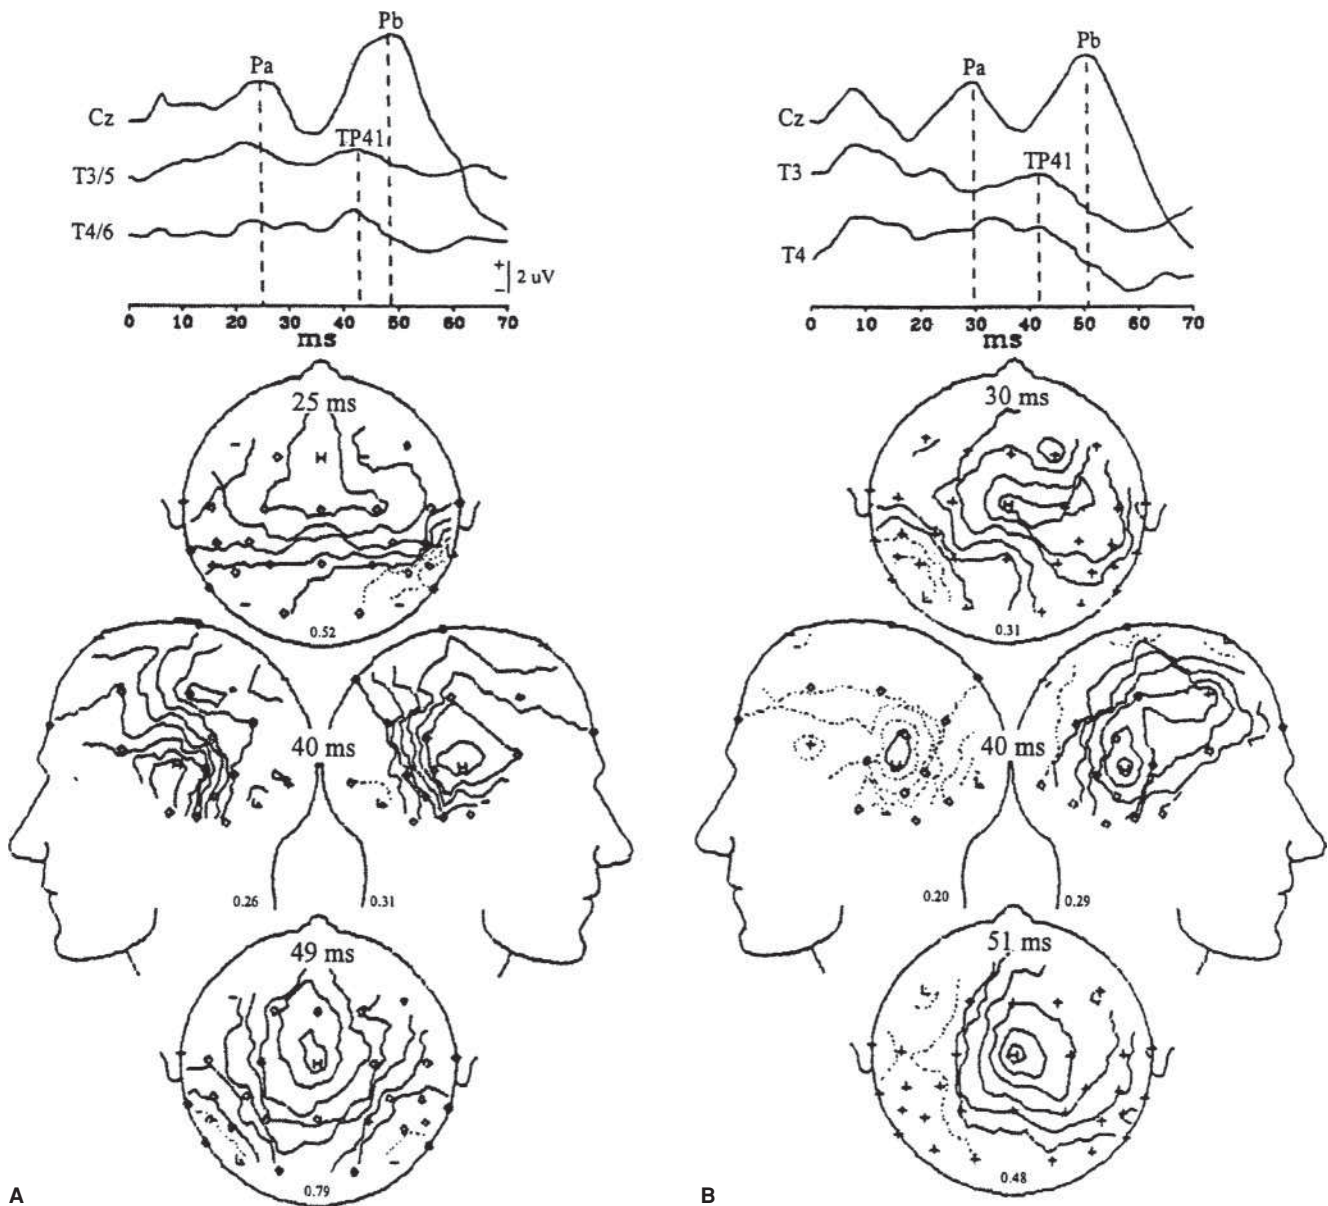

FIGURE 17.4 Middle-latency waveforms and corresponding topographies for two individuals (**A, B**) at central scalp locations [Cz] and over auditory cortex on the lateral surfaces of the temporal lobes [T3/5 or T3 and T4/6 or T4]. Data represented are in response to binaural clicks. Middle-latency components Pa and Pb are seen in the vertex waveforms and TP41 is seen in the temporal waveforms. The central and lateral view topographies are designated at times when components Pa, Pb, and TP41 are maximum. *Solid lines* represent positive voltages, *dashed lines* represent negative voltages; H, high point; L, low point. [Reprinted from Cacace AT, Satya-Murti S, Wolpaw JR. [1990]. Middle latency auditory evoked potentials: vertex and temporal components. *Electroencephalogr Clin Neurophysiol.* 77, 6–18, with permission].

In the middle-latency range (~15 to 70 ms), three components were dominant: Two centered at or near the vertex (Pa, P30; Pb, P50 or P1) and one centered over posterior lateral surface of each temporal areas (TP41). Data provided by Law et al. (1993) show convincingly that the Laplacian derivation, in contrast to the standard potential recordings, enhances the temporal components in the middle- and long-latency domains (Figure 17.5). The spatiotemporal dipole model of Scherg and

von Cramon (1986a) also identifies a radial source potential in the middle-latency range that is consistent with TP41. The lateral scalp topography is TP41 is shown convincingly in Figure 17.6. This montage is contrasted with C3 and C4 recording sites used by Schochat et al. (2010), where the rationale for these particular scalp locations is not justified, given available topographic data and known information derived from theoretical models.

FIGURE 17.5 Middle- and long-latency AEP waveforms are compared in the standard (*top*) potential versus Laplacian derivation (*bottom*), at central [Cz] and right and left temporal lobe sites [T4, T3]. Data are in response to mid-frequency tone pips presented at 50-dB sensation level [SL]. The electrodes were based on 19 recording sites, referenced to a balanced sternovertebral lead. The top waveform designated as potential shows at Cz well-known middle- and long-latency AEP components [Pa, Pb, N1, P2]. The temporal MLAEP component TP41 is not well observed and T-complex components [Ta and Tb] are obscured. However, with the Laplacian derivation (*bottom*), the MLAEP temporal component TP41 and T-complex are clearly enhanced by this transformation. [Adapted from Law SK, Rohrbaugh JW, Adams CM, Eckardt M]. [1993] Improving spatial and temporal resolution in evoked EEG responses using surface Laplacians. *Electroencephalogr Clin Neurophysiol.* 88, 309–322, with permission].

As noted by Møller (1994), coincidence in latencies does not necessarily constitute proof that near-field potentials are the sources of far-field potentials recorded at the scalp. For example, early cortical potentials in the middle-latency range (approximating 13 ms) are small and can only be recorded from a limited area localized to the posterior aspect of Heschl's gyrus. Subsequent potentials recorded at 30 ms are much larger. Liegeois-Chauvel et al. (1994) note that the response of the planum temporale is more diffuse than that observed in Heschl's gyrus and as such is physically more capable of being propagated to the surface. Hashimoto (1982) used intraventricular electrodes and found that the No–Po–Na complex appeared largest in the vicinity of the inferior colliculus. In addition, it was argued that thalamic contributions to surface recordings are minimal because of the closed-field structure of these cell populations. Thus, the

initial response of the primary auditory area is not clearly associated with a reliable scalp potential, a view that has been noted by others (Goff et al., 1977).

Middle-Latency Component Pa: Evidence for Neural Origin

Human pial surface recordings demonstrate a positive peak of Pa latency over temporal and parietal lobes (Chatrian et al., 1960; Lee et al., 1984). Human neuromagnetic recordings show a positive peak at approximately 30 ms (Pelizzone et al., 1987). A positive peak of approximately 30 ms was reported from within the brain (Goff et al., 1977). Furthermore, neuromuscular blockers do not eliminate Pa (Kileny et al., 1983). Multielectrode probe measures at depths above and below Heschl's gyrus failed to show a Pa phase reversal (Goff et al.,

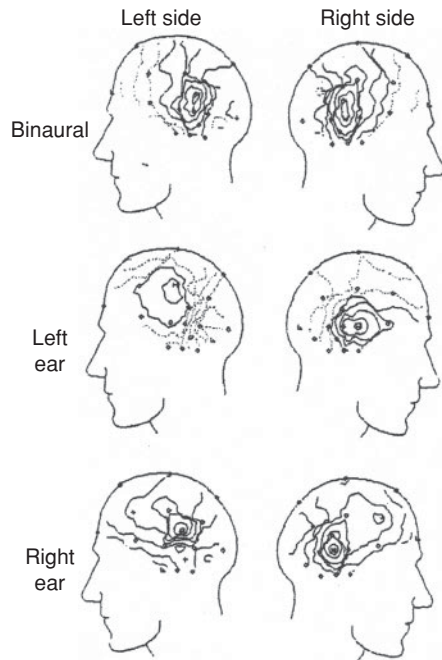

FIGURE 17.6 Middle-latency TP41 is represented by distinct topographic distributions over posterior temporal regions [lateral scalp views; left and right hemispheres] in responses to left, right, and binaural click stimuli. [Reprinted from Cacace AT, Satya-Murti S, Wolpaw JR. [1990]. Middle latency auditory evoked potentials: vertex and temporal components. *Electroencephalogr Clin Neurophysiol.* 77, 6–18, with permission].

1977) (Figure 17.7), as would occur if Pa were generated at this site. Neuromagnetic recordings show that the supratemporal AC is active during Pa and a change in waveform morphology occurs in the anterior–posterior plane (Pelizzone, 1987). Pial surface recordings show a similarly oriented change (Lee et al., 1984). However, lesion studies do not provide unambiguous evidence of Pa's origin.

Furthermore, Pa is unaffected by sleep apnea (Mosko et al., 1984) (i.e., ancillary evidence of a noncortical origin). Whereas recent modeling studies suggest Pa is produced by tangentially oriented dipole sources in AC (Scherg and von Cramon, 1986a), data are also consistent with similarly oriented subcortical sources.

Middle-Latency Component Pb: Evidence for a Neural Origin

Recordings from the pial surface in humans demonstrate a positive peak at Pb latency over temporal and parietal lobes (Chatrian et al., 1960). Human neuromagnetic recordings show a positive peak at approximately 50 ms (Pelizzone et al., 1987). A positive peak at approximately 50 ms was reported from within the brain, but less prominent than Pa (Goff et al., 1977). Pb is altered by stage of sleep (Erwin and

FIGURE 17.7 Middle-latency AEPs recorded from bilateral fronto-temporal probes from within the human brain. Arrows indicate the approximate location of the probe. Each probe has 18 contact points (electrodes), with electrode 1 at the most superficial location and electrode 18 at the deepest location. Individual waveforms are grand averages, shown at the right side of the figure. Waveforms represented by *solid lines* are from the right-sided probe; *dashed lines* are from the left-sided probe. Middle-latency component Pa is clearly seen at a latency approximating 25 ms. As shown in the graph [*lower left panel*], Pa amplitude remains relatively constant across recording locations. No phase reversal for Pa is noted at depths above and below Heschl's gyrus. [Adapted from Goff WR, Allison T, Lyons W, Fisher TC, Conte R. [1977] Origins of short latency auditory evoked potentials in man. In: Desmedt JE, ed. *Auditory Evoked Potentials in Man. Psychopharmacology Correlates of Evoked Potentials.* Prog Clin Neurophysiol. Vol 2. Basel: Karger; pp 30–44, with permission].

Buchwald, 1986) and in patients with Alzheimer's disease (AD) (Buchwald et al., 1989).

MLAEP Pb SOURCE

Multielectrode probe measures from within the human brain at depths above and below Heschl's gyrus failed to show a Pb phase reversal (Goff, 1978; Goff et al., 1977). Neuromagnetic recordings show that the supratemporal AC is also active

during Pb and that a change in waveform morphology occurs in the anterior–posterior plane (Pellizzone et al., 1987). Reite et al. (1988) suggests that the source is the planum temporale. Goff (1978) reports a positive peak comparable in latency at a depth and location corresponding to the hippocampus and it has been shown that Pb disappears with large lesions to the hippocampus (Woods et al., 1987). Because depth recordings do not show a phase reversal across Heschl's gyrus and since Pb depends on stage of sleep, Pb may not originate in AC but in subcortical structures.

Recent mapping and more invasive studies on the pial surface with grid electrodes in epilepsy patients have been performed based on continuing interest in the area of sensory gating of the P50 paired-stimulus paradigm (Boutros et al., 2013; Korzyukov et al., 2007). Based on this methodology and stimulus paradigm, including source reconstruction and mapping data, the general consensus holds that P50 has prominent generator sites localized in the temporal, parietal, and cingulate regions of the brain. This analysis also suggested that neuronal activity contributing to the amplitude reduction in the P50 time range was localized to the frontal and parietal lobes and the cingulate area.

MLAEP TP41: A New Component

Because early studies have used relatively few electrodes and concentrated on central and not temporal scalp areas, the temporal middle-latency component was not identified. In addition, most studies used ear or mastoid reference electrodes which do not obscure Pa and Pb but markedly obscure and even eliminate TP41. However, it is noteworthy that the appearance of TP41 may require long interstimulus intervals (ISIs) (e.g., 1 second: Knight et al., 1988; 3.3 seconds: Cacace et al., 1990) or pseudo-random ISIs (Scherg and von Cramon, 1986a, 1986b). Furthermore, TP41 may habituate to large numbers of stimuli. Nevertheless, detailed topographic analysis shows that TP41 is highly localized over lateral temporal scalp locations of each hemisphere in response to left, right, and binaural click stimulation.

TP41: EVIDENCE FOR A NEURAL ORIGIN

TP41 is undoubtedly neural in origin. In our experience, subjects were relaxed and online monitoring of temporal channels did not show overt EMG activity. The post-auricular muscle reflex is seen more anteriorly with induced muscle tension and this component has a much shorter latency (Picton et al., 1974). A positive peak of comparable latency has been seen in human pial surface recordings over lateral temporal and perisylvian regions (Celesia, 1976). Also, TP41 matches the P39 radial dipole source potentials in the left and right hemispheres of the spatiotemporal dipole model proposed by Scherg and von Cramon (1986a, 1986b).

SUBJECT AND STATE VARIABLES

Age and Gender Effects

McGee and Kraus (1996) have reviewed many relevant issues, which are important toward understanding the complexity of maturational changes in infants and young children that continue through the first decade of life. In adults, Kelly-Ballweber and Dobie (1984) and Woods and Clayworth (1986) found that Pa latency and amplitude increased with age throughout the life span. Gender effects were not found in the Woods and Clayworth (1986) study and Kelly-Ballweber and Dobie (1984) only studied males. In a study limited to females, Chambers and Griffiths (1991) showed that Pa amplitude grows linearly with age, although interpretation can be complicated by changes in hearing sensitivity. In partial contrast, Erwin and Buchwald (1986) found a significant increase in Pa amplitude but not latency with age. Data of Newman and Moushegian (1989) also report larger MLAEP amplitudes in older subjects at higher stimulation rates. Amenedo and Diaz (1998) showed a positive relationship between Na–Pa amplitude and age for individuals between 20 and 86 years.

Pfeifferbaum et al. (1979) reported that Pb (P1 or P50) amplitudes increased with age in women. However, their data are difficult to compare with other studies because they combined Pa and Pb in their data analysis. Chambers (1992) also found larger Pb amplitudes in older individuals (51 to 71 years vs. 20 to 24 years). Using a paired-stimulus paradigm and binaural stimulation, Papanicolaou et al. (1984) showed differential recovery cycle effects on P1–N1 amplitude, characterized by a more rapid recovery in young versus older individuals. Recovery cycle effects for P1 latency, however, were not significant and gender effects were not evaluated. With binaural stimulation, Erwin and Buchwald (1986) found longer Pb latencies in older women. They speculated that menopausal-related hormonal instability might have contributed to this finding. Spink et al. (1979) also failed to find age-related changes in Pb latency, although their sample size was small. Amenedo and Diaz (1998) showed a positive relationship between Nb–Pb amplitude and age for individuals between 20 and 86 years.

Prior use of MLAEPs in certain types of neurologic disease or their early states (minimal cognitive impairment [MCI], AD, Parkinson's disease, Rett syndrome) has been reported but research is limited to a small number of studies with mixed results. Additional details regarding these issues are reviewed in the web version of this chapter.

Extremely large amplitude MLAEP components have been reported in individuals with chronic tinnitus (Gerken et al., 2001), an effect that maybe related to alterations in inhibitory mechanisms (Gerken, 1996). Enhancement of steady-state magnetic fields has also been reported in patients with problem tinnitus (Diesch et al., 2004). In

their study, variations in component amplitude were not observed in the normal-hearing and hearing loss groups. Whereas MLAEP amplitudes reportedly increase with age, very large amplitudes were less common in the elderly group than in the younger group with problem tinnitus. Because increased amplitude MLAEPs have been associated with elderly individuals with MCI, and in individuals with problem tinnitus, larger MLAEPs may not be pathognomonic of any particular dysfunction and may result from different underlying mechanisms.

Handedness

Hood et al. (1990) found that Pb varies with handedness, being 4 ms longer in left-handed adults. Stewart et al. (1993) also found an increase in the latency of the MLAEP components in left-handed individuals, with the greatest effect being on Pb.

State Variables

Whereas MLAEPs are generally unaffected by attention (Picton and Hillyard, 1974), attention-related effects have been shown for amplitude-modulated steady-state responses (Ross et al., 2004). Short latency AEPs (i.e., electrocochleography and ABRs) have been used in the operating room for purposes of monitoring auditory function during otologic or otoneurologic surgery (Møller, 1988). Middle-latency AEPs have also been applied successfully to issues of importance to anesthesiologists or emergency room physicians (i.e., Thornton and Sharpe, 1998), such as monitoring depth of anesthesia (Litvan et al., 2002), in the development of adaptive controllers to deliver anesthesia (Nayak and Roy, 1999), and in the assessment of different hypnotic states in infants and young children (Weber et al., 2004). Interestingly, a device is being marketed to ascertain the degree of consciousness in comatose patients using the MLAEPs, most notably in emergency departments of hospitals (Tsurukiri et al., 2013), but there is little data on this topic. Lastly, knowledge of anesthesia-related issues is important when assessing electrically evoked potentials during cochlear-implant surgery. Kileny et al. (1983) showed that MLAEPs are not affected by nitrous oxide and narcotic analgesics.

MLAEPS AND THE SPEECH-EVOKED ABR: A CHALLENGING TOPIC WITH AN UNCERTAIN INTERPRETATION

First described by Kraus and colleagues (Song et al., 2006) and recently reviewed by Banai and Kraus (2009), the speech-evoked ABR (sABR) is pertinent to MLAEPs because this response is measured over a time interval which

captures middle-latency responses (i.e., 70 to 80 ms). It is typically recorded in response to a repetitive synthesized speech stimulus (typically /da/; ~40 ms in duration) that reflects the onset, offset, and periodicity of the stimulus. Some studies have recorded over a longer time frame (–40 to 190 ms) (Anderson et al., 2012). Nevertheless, the presumed transient component elicited by the stimulus includes ABR Waves I, III, and V (with the most prominent Wave V positive peak and negative trough A) and is thought to represent speech encoding in the brainstem. The so-called “sustained” portion of the response, which follows the ABR, is much less clear and somewhat ambiguous in terms of where and how the speech signal is being processed. In some reports where repetitive waves are observed, investigators invoke the so-called “frequency-following response” (FFR) (Galbraith and Arroyo, 1993). However, Kraus and colleagues never provide a clear explanation why conventional MLAEP components (Pa and Pb) are not observed in this time frame. Furthermore, it is also important to understand whether the response obtained from the speech token is reliable (Hornickel et al., 2011; Song et al., 2011). There is reason to believe that it is not; it is also reasonable to suggest that statistics used to evaluate reliability were not appropriate (see McFarland and Cacace, 2011, 2012). Thus, a wide range of metrics has been proposed (Song et al., 2011) and it is unclear which of these components produces consistent results in a clinical setting.

Perhaps most important is a consideration of the evidence for the proposed brainstem origin of these potentials (Chandrasekaran and Kraus, 2010). It is well known that early components of the auditory-evoked potential can be associated with brainstem sources (Møller and Jannetta, 1983). However, potentials recorded at these later intervals could have contributions from sources located more rostrally. This issue is glossed over in discussions of the significance of these potentials, but as illustrated by our earlier discussion of conventional middle-latency components, source identification can be a complex issue. Song et al. (2008) invoke the “corticofugal system” as influencing the sABR. However, they only provide speculative scenarios and no direct evidence to support their position.

STIMULUS CONSIDERATIONS IN MIDDLE-LATENCY RESPONSES

Middle-latency responses can be affected by changes in various stimulus parameters, including frequency, level, duration, rise/fall time, monaural versus binaural presentation, spectral complexity, and recency (e.g., McPherson and Starr, 1993; Thornton et al., 1977). For example, increases in stimulus rise time have the general effect of significantly increasing latency and decreasing peak amplitudes of Na, Pa, and P1 or Pb (Kodera et al., 1979). Vivion et al. (1980) similarly found that the latencies of five middle-latency components (Pa, Nb, Pb, Nc, Pc) increased and their amplitudes

decreased as rise time increased from 3 to 10 ms, or as the equivalent duration increased from 10 to 30 ms. Thornton et al. (1977) performed parametric studies on MLAEPs in normal-hearing adults using linearly gated tone bursts varying in frequency (250, 1,000, and 4,000 Hz) and stimulus level (no stimulus, 10 to 80 dB HL, in 10-dB steps) and evaluated amplitude and latency components Na, Pa, Nb, and Nc. An inverse relationship was found between latency and frequency but latency was only slightly affected by changes in stimulus level. Input/output functions varied with frequency and depended on the specific MLAEP studied. Audiogram reconstruction is an ambitious goal using evoked potentials, because the degree of frequency specificity is influenced by temporal constraints. Therefore, the type of windowing function used (Harris, 1978) is thought to be important, because it influences how energy is distributed in the frequency domain. When stimuli are presented in isolation, one accepts the same limitations inherent in the behavioral puretone audiogram; depending on stimulus level, and based on basilar membrane traveling-wave characteristics, low-frequency stimuli have poorer frequency selectivity and poorer synchrony. Therefore, one is less confident in the precision of frequency-dependent thresholds, particularly if hearing loss exists. Alternatively, stimuli can be presented in the presence of various types of masking noise, with the intent of restricting spread of excitation in the cochlea and improving the place specificity of the response. The first option is relatively straightforward and simple to apply with current computer technology. The second option is much more complex and more difficult to implement, particularly in the clinical setting, and in some instances, results can have more complicated rather than simpler interpretations (Margolis et al., 1981).

Several recent investigations have addressed these issues and their findings can help clinicians to select the appropriate stimuli for AEP studies. In normal-hearing subjects, the degree of frequency and place specificity was studied by comparing brainstem and MLAEPs in response to short-duration, linear rise/fall, and Blackman-windowed 500- and 3,000-Hz stimuli presented at a moderate level, ~52 to 53 dB nHL (Oates and Stapells, 1997a, 1997b). In these investigations, stimuli with linear rise/fall times were constructed based on a 2–1–2 design (two cycles of rise time, two cycles of fall time, and one cycle of plateau). The Blackman-windowed stimuli were five cycles in total duration, with no plateau (50% rise/50% fall times). Stimuli were either presented alone or in the presence of high-pass noise at various high-pass cutoff frequencies (Oates and Stapells, 1997a). Subtracting the response obtained at one high-pass masker cutoff frequency from the response obtained at a higher frequency high-pass cutoff, Oates and Stapells (1997b) evaluated the place specificity of these derived responses. The results from both studies showed that at moderate input levels, few or no differences exist in the place specificity under these various stimulus conditions and that either linear- or

Blackman-windowed stimuli presented in isolation were appropriate.

We also emphasize that the above-mentioned findings must be tempered in patients with steeply sloping high-frequency hearing loss in whom higher stimulus levels are needed to elicit a response. Here, side-lobe energy contamination to lower frequencies becomes more of an issue and the windowing function takes on greater importance, particularly if masking is not used. Consequently, the result of such side-band energy contamination would be to underestimate the magnitude of high-frequency hearing loss. However, in the case of low-frequency hearing loss, spread of excitation to higher stimulus frequencies, as stimulus level is increased, is potentially a much greater concern. In this instance, stimulus shaping alone may be insufficient to guarantee frequency and place specificity. Based on thresholds derived from psychoacoustic studies, special masking procedures in conjunction with click or tone-burst stimuli may be needed to ensure that more accurate thresholds are ascertained (Halpin et al., 1994; Turner et al., 1983).

Erwin and Buchwald (1986) studied recovery cycle effects for middle-latency components Pa and Pb (P1), in part to assess if these components may arise from different generator systems. They showed that increasing stimulus presentation rate (0.5, 1, 5, 8, and 10/second) differentially affected peak-to-peak amplitudes of Pb, but not Pa. They suggest that this evidence supports the existence of separate neural generators for Pa and Pb. Using a noncephalic reference, Nelson et al. (1997) reported a rate effect for Pb, showing that this component is largest at slower rates and for lower frequencies (500 vs. 4,000 Hz). Using MEG, Onitsuka et al. (2003) also found a rate effect for P50m but not for P30m. These findings are in partial contrast to those of McFarland et al. (1975), in which rates as high as 8/second had little effect on the middle-latency waveform or its identifiability.

Although mismatch responses are usually associated with later potentials, MLAEPs have been found to be enhanced to the oddball in a mismatch paradigm (Boutros et al., 1995). Althen et al. (2013) provide evidence that acoustic regularities are encoded at different levels of the auditory system as MLAEPs are sensitive to simpler stimulus features as compared to later potentials which respond to a wider range of mismatch features. Their results suggest that auditory change detection involves a distributed system that is not confined to later time periods.

There has been considerable recent interest in stimulus-evoked and induced oscillatory activity, particularly in the gamma (40-Hz) range (Tallon-Baudry and Bertrand, 1999). This response may be related to the 40-Hz steady-state potential identified by Galambos et al. (1981), as discussed below. Evoked oscillatory activity is phase-locked to the stimulus and can be seen in the averaged waveforms. Induced activity is not phase-locked and requires spectral analysis or some related technique. There has been

speculation that gamma rhythms are neural correlates of various perceptual processes (e.g., Tallon-Baudry and Bertrand, 1999).

CLINICAL USE OF MIDDLE-LATENCY POTENTIALS

Threshold Estimation

EFFECTS OF HEARING LOSS ON MLAEPs

Initially, it was felt that MLAEPs could serve as a means of threshold estimation in the lower frequency range for audiometric purposes. This view came about because MLAEPs are less dependent on temporal synchrony than ABRs and because frequency-specific ABRs are less reliable below 1,000 Hz than above this frequency (Gorga et al., 1988). Clearly, this type of application is important in the assessment of hearing sensitivity in infants and young children. Xu et al. (1995) used the cross-correlation function of two MLAEP waveforms to ensure response identification and found good agreement between evoked potential and behavioral thresholds in individuals with moderate hearing loss. Hausler et al. (1991) also reported good agreement between MLAEPs and behavioral responses in infants and developmentally delayed children. However, others have expressed caution in estimating low-frequency (500 Hz) thresholds with MLAEPs, particularly in children (Barajas et al., 1988a, 1988b).

Galambos et al. (1981) described a steady-state auditory potential elicited by a continuous 40-Hz stream of acoustic stimuli. Initial studies in normal-hearing and hearing-impaired adults showed promise at threshold estimation in both the low- and high-frequency range with this technique (Dauman et al., 1984; Galambos et al., 1981; Stapells et al., 1988). Presently, there is a resurgence of human steady-state responses, and this area is reviewed by Dimitrijevic and Cone (Chapter 15 of this book). However, interest in steady-state or transient MLAEPs waned when they were found to be absent in infants and were affected by sleep, sedation, and anesthesia (Kraus et al., 1989; Plourde and Picton, 1990; Small and Stapells, 2004; Stapells et al., 1988).

Because MLAEPs are less dependent on neural synchrony than ABRs, suggested applications include threshold assessment in the low-frequency range (<1,000 Hz), particularly in those instances where neurologic damage may affect neural synchrony, making threshold detection with ABRs difficult or impossible (McGee and Kraus, 1996). However, those clinical instances in which use of AEPs are most important, such as early identification of peripheral hearing loss in infants and young children, are also those settings in which MLAEP variability is highest. As noted above, sleep and anesthesia affect MLAEPs and as a result, they may not be useful in patients who cannot or will not cooperate with the examiner. Based on a series of experiments (Oates and

Stapells, 1997a, 1997b), the frequency specificity of MLAEPs and ABRs at low (500 Hz) and high frequencies (2,000 Hz) were found to be relatively similar. Therefore, because of the general robustness of the ABR response and its independence from state variables, the need to use MLAEPs for low-frequency threshold detection on a routine basis, at least at 500 Hz, is questionable.

Site-of-Lesion Testing

An analysis of the effects of cerebral lesions on MLAEPs can provide information about underlying neural generators. In addition, correlation of evoked potential results with perceptual disturbances provides a means of establishing the validity of various components as indices of central auditory processing. Woods et al. (1984) examined a case of bitemporal lesions associated with cortical deafness, in which they observed a positive wave at 57 ms and a negative wave at 98 ms with normal topographies, latencies, and amplitudes. They suggested that one possible explanation of these results is that middle-latency vertex potentials are produced by polysensory cortex in the vicinity of auditory areas. In a subsequent study, Knight et al. (1988) reported reduced amplitudes of temporal and vertex middle-latency peaks in a group of patients with lesions of the superior temporal gyrus. In contrast, lesions of the inferior parietal lobe produced minimal effects. They concluded that the superior temporal gyrus played a critical role in the generation of these potentials. Scherg and von Cramon (1986b, 1990) suggest that there are three types of AEP alterations resulting from unilateral lesions to central auditory pathways: (1) An “acoustic radiation” type, with unilateral reduction in middle-latency dipole source potentials and preserved tangential and radial dipole source potentials; (2) a “primary AC” type with unilateral reduction of both middle- and long-latency radial and tangential dipole source potentials; and (3) an “auditory association” type, showing normal MLAEPs with a localized reduction of long-latency radial N150 and preserved tangential long-latency dipole source potentials.

As we noted above, the issue of number of electrodes (i.e., spatial sampling) becomes crucial in attempting to determine the effects of CNS lesions on these potentials. Initial studies have limited electrode placements to central scalp locations, and therefore are limited in scope. Many studies evaluating the effect of brain lesions in the middle-latency range have not even placed recording electrodes over temporal lobe sites or have used reference electrode sites that make such obtained data uninterpretable. Parving et al. (1980) recorded MLAEPs in a patient with auditory agnosia and found a normal Pa response. Although they conclude that Pa was neurogenic in origin (an important issue at that time), they also argued that MLAEPs cannot be regarded as being generated exclusively, if at all, in primary AC. Özdamar et al. (1982) report a case of cortical deafness

with preserved BAEPs but absent middle-latency peak Pa. Based on CT studies, Özdamar and colleagues concluded that the absence of the MLAEP component Pa was due to hematomas and infarcts of the left and right temporal lobes. However, this interpretation has been challenged, suggesting that secondary changes because of retrograde degeneration of subcortical structures were not ruled out as a cause for this abnormality. In 19 patients with temporal lobe lesions studied by Kraus et al. (1982), Na–Pa was reduced over the involved hemisphere. According to Kraus and colleagues, normal intersubject variability of conventional amplitude measures and occasional myogenic contamination set limits in establishing reliable criteria that could be applied clinically for the diagnosis of patients with temporal lobe lesions. In two patients with central deafness resulting from bilateral localized vascular lesions at the level of the putamen, Tanaka et al. (1991) reported auditory thresholds in the moderately severe-to-profound range, intact ABRs (Waves I to VI), and complete absence of middle-latency component Pa bilaterally. Interesting, the long-latency AEP (LLAEP) (N1P2 complex) was preserved in both cases. In a review of other cases with bitemporal lesions of the AC, which did not produce cortical deafness, Woods et al. (1984) were unable to support the view that the primary generator sources of MLAEPs and LLAEPs reside exclusively in AC. They suggest that abnormalities found in MLAEPs are associated with subcortical lesions or cortical lesions extensive enough to denervate thalamic projection nuclei. Woods et al. (1987) reported a case of cortical deafness in an 82-year-old woman, resulting from successive strokes of the right and left temporal lobes secondary to bilateral occlusion of the posterior temporal branch of the middle cerebral arteries. MLAEPs and LLAEPs (P1, N1, P2) were preserved, despite the fact that puretone behavioral thresholds were in the moderate-to-profound range and no auditory discriminations could be made. According to the authors, this case is an example of dissociated perception from MLAEPs and LLAEPs. Based on a three- or four-electrode array in the coronal plane (Cz, C6, C5, T3, T4), Kileny et al. (1987) showed that Pa was reduced over the involved hemisphere, but remained intact over the contralateral hemisphere, in individuals with unilateral lesions of the temporal lobe. In this study, the ABRs, particularly Wave V latency, were normal regardless of the site of lesion. No mention was made of whether TP41 was recorded. Comparing conventional MLAEPs with those obtained using maximum-length-sequence technique in controls and individuals with CNS lesions, no advantage was observed using the more sophisticated technique (Musiek and Lee, 1997). In a study that used both magnetic and electric AEPs, Leinonen and Joutsiniemi (1989) examined four patients with temporal lobe infarcts and recorded AEPs in the 40- to 200-ms range. Responses were abnormal in all four patients, and missing in two. In one individual, responses were of abnormally high amplitude, and in another, parts of the response sequence were

missing. Electric AEPs were in accordance with the magnetic field measures, although magnetic recordings are *insensitive* in evaluating radially oriented dipoles (Lewine and Orri-son, 1999), and therefore cannot delineate the TP41 or later T-complex waveforms. In 12 patients with intractable seizures, Jacobson et al. (1990) found that Pa was unaffected by anterior temporal lobectomy, whereas Na latency and Na/Pa amplitude showed significant increases after surgery. They suggest that changes in Na and Na/Pa amplitude reflect a loss of the modulating influence of the cortex on the subcortical generators of Na. In 24 patients with cortical lesions affecting primarily the temporal lobes (i.e., by CT documentation), Na and Pa obtained over vertex were normal, whereas MLAEPs over the coronal plane showed Pa amplitude to be attenuated or absent over the damaged temporal lobe, relative to the vertex or intact hemisphere (Shehata-Dieler et al., 1991). Again, no mention was made of abnormalities to the temporal component, TP41. Vizioli et al. (1993) suggested that Na and Pa have different generator sites, based on findings from three individuals with brain tumors. Toyoda et al. (1998) suggest that large vessel vascular disease, including those with Moyamoya-like vasculopathy, significantly affects auditory-evoked MEG fields and dipoles in the middle-latency range. Toyoda and colleagues also correlated MEG abnormalities with changes in blood flow using positron emission tomography (PET) and showed that reduced perfusion in areas encompassing both the auditory radiations and AC correlated with the deficits in auditory-evoked magnetic fields. Setzen et al. (1999) found absent MLAEPs and LLAEPs but normal transient-evoked and distortion product otoacoustic emissions and ABRs in a child with Moyamoya disease with central deafness. In this case, digital subtraction angiography showed that the middle cerebral artery was absent on the right side and almost completely occluded on the left side, except for a prominent angular/parietal branch. However, the lesions in this case were more diffuse, including subcortical and cortical ischemic damage and focal lesions in frontal, parietal, and temporal lobes. The absence and occlusion of the vessels noted above is significant, because they supply blood to the lateral two-thirds of each hemisphere (motor, tactile and auditory areas) as well as to adjacent subcortical sites (Taveras, 1996). Additionally, unilateral lesions of the superior temporal gyrus abolish TP41 over the lesioned hemisphere. No change in either latency or amplitude of TP41 is observed with inferior parietal lobe lesions (Knight et al., 1988).

Cochlear Implants

The use of MLAEPs has been suggested for the evaluation of cochlear-implant candidates (Kileny and Kemink, 1987). These authors have generally found that MLAEPs evoked by electrical pulses are similar to those evoked by acoustic stimulation. In adults, electrically evoked MLAEP

thresholds correlated positively with acoustic thresholds obtained using the implanted device. Furthermore, in post-lingually deafened adults, MLAEP variations in amplitude and latency were related to specific speech-perception abilities. In contrast to electrically evoked ABRs, studies using MLAEPs have additional advantages: They are not influenced by electrically induced stimulus artifacts, longer stimulus pulse trains can be used, which results in lower levels of stimulation, and a greater proportion of the auditory pathway is activated, which may correlate better with outcome. When P1 (P50 or Pb) is used as a marker of auditory system maturation, its latency becomes adult-like by 15 years of age (Eggermont et al., 1997). The P1 peak latency was found to mature at the same rate in normal-hearing and implanted children, and it was found that the time to maturity in implanted subjects is delayed by an amount approximately equal to the duration of deafness. Kelly et al. (2005) studied MLAEPs and LLAEPs in experienced adult cochlear-implant users and compared them to speech-perception measures. Electrode sites were limited to central scalp locations. For middle-latency component Pa, similar latencies and amplitudes were found in normal-hearing and cochlear-implant groups. The authors noted considerable intersubject variability and found no relation between MLAEPs and CI performance for sentences and word lists. Gordon et al. (2005) evaluated the electrically evoked MLAEPs in children receiving cochlear implants. Except for testing that was performed at the time of surgery, recordings were made when individuals were awake using a standard central recording location and recording (epoch 80 ms). Middle-latency AEP detection increased dramatically over a 5-year period (from poor detection at the time of surgery in the operating room to near 100% detection after 5 years of use). These results suggest that electrically evoked MLAEPs are not useful clinically for predicting optimum stimulation levels or assessing CI function at early stages of device use. Whereas MLAEPs were not found to be particularly useful during early stages of CI usage, they may be a valuable tool to track activity in thalamocortical pathways in CI use over time.

SENSORY GATING AND THE DUAL-STIMULUS PARADIGM USED IN PSYCHIATRIC RESEARCH

Other applications of MLAEPs related to sensory processing have been in the area of psychiatric research concerned specifically with the neurobiology and theoretical underpinnings of schizophrenia, focusing specifically on P50 or Pb. Available data suggest that when comparing the responses of normal healthy subjects to paired identical acoustic stimuli (with an ISI approximating 500 ms), the second stimulus in the pair usually elicits a much smaller P50 amplitude (Dolu et al., 2001). The decrement in response has been inter-

preted to mean that when a continuous stream of incoming (repetitive) auditory information is presented, this stream is gated or screened, preventing an overload of higher-order stages of auditory information processing. It has been hypothesized that individuals with schizophrenia have a disturbance in this gating phenomenon that results in the “inability” to filter out extraneous noise stimuli from meaningful sensory inputs (Boutros and Belger, 1999; Freedman et al., 1987). Individuals with schizophrenia do not show the normal attenuation of the P50 response to the second stimulus in a pair of acoustic stimuli. This has been interpreted as an inability of the schizophrenic brain to inhibit or gate its response to specific stimuli. In fact, the P50 response to the second stimulus is often larger than normal and this has been interpreted as a deficit in P50-response suppression. As a potential marker for sensory gating, a considerable literature now exists linking a disturbance in this phenomenon to brain neurobiochemical abnormalities and other developmental and genetic influences (Adler et al., 1998; Freedman et al., 1995; Light, 1999). Impaired suppression of P50 to the second stimulus in a pair has also been found in individuals with post-traumatic stress disorder (Karl et al., 2006), antisocial personality disorder (Lijffijt et al., 2009a), bipolar disorder (Lijffijt et al., 2009b), post-traumatic stress disorder with a history of torture (Gjini et al., 2013), psychosis proneness and cocaine dependence (Gooding et al., 2013); the use of P50 as an outcome measure for drug treatment in schizophrenia has also been explored (Oranje and Glenthøj, 2013). Other areas which fall under the heading of learning disabilities have shown mixed results; abnormal MLAEPs have been reported in selected groups (Arehole et al., 1995) and where others have failed to find abnormalities in children with a wide range of cognitive, neurologic, speech, and language disorders (Kraus et al., 1985; Mason and Mellor, 1984).

The novel application of correlating P50 latency with the diffusion tensor imaging (DTI)¹ metric fractional anisotropy (FA) was explored in a neurodevelopmental study comparing groups of typically developing normal children with children along the autistic spectrum (Roberts et al., 2013). FA was measured using a region-of-interest analysis that was localized to the thalamocortical radiations; P50 was measured using

¹Diffusion tensor imaging measures the displacement of water molecules (diffusion) within white matter tracts, providing information on the microstructure of cerebral white matter of the brain, thus serving as a biomarker of tissue integrity. For each voxel, DTI estimates diffusion in three orthogonal axes (eigenvectors) of an ellipsoid, defining the principal (major), intermediate, and minor axes. The most commonly used metric to quantify the relationship between eigenvalues is FA, a normalized scalar that represents the fraction of the diffusion tensor which is anisotropic. The FA metric ranges between 0 and 1, where 0 represents perfectly “isotropic” diffusion, such as is found in the cerebrospinal fluid where diffusion is equivalent in all directions, and where 1 is the extrema for “anisotropic” diffusion, indicating maximum difference between directional components, such as is found in coherent white matter tracts which consist of long tubes.

magnetoencephalography. The authors found that FA values increased with age in the typically developing group but not in the autistic spectrum group. In typically developing children, P50 latency decreased as FA increased with age. In the autistic spectrum group, no such relationship was observed. These correlations underscore the importance of white-matter development in auditory thalamocortical electrophysiological measures in normal development whereas the lack of association between P50 and FA observed in the autistic spectrum group implies an “uncoupling” between structure and function in the thalamocortical radiations. Clearly, the introduction and utilization of clinically based electrophysiology and magnetic resonance imaging should result in further advancements in this area as more researchers apply these power methods in future investigations.

Are MLAEPs Modality Specific?

It has been suggested that MLAEPs may be valuable indices of central auditory processing disorders (e.g., Musiek and Baran, 1987; Pasman et al., 1997). As noted in our discussion of the literature, several authors have suggested that polysensory areas contribute to the generation of AEPs. Of primary concern here is the extent to which alterations in auditory-evoked potentials are influenced by pathology in polysensory or supramodal brain areas. This topic has been the concern of investigations using other AEP components, such as the mismatch negativity. For example, Alho et al. (1994) report that lesions to the frontal cortex can impair the generation of this response.

CONCLUSIONS

Based on this overview, it is evident that MLAEPs have been applied to virtually all areas of auditory research and one cannot escape the conclusion that these potentials seem to have more theoretical than practical value; however, as we have shown, there are areas where this may change, such as in the P50 gating literature and in the context of MRI and electrophysiological correlations. As an audiometric tool for threshold determination in infants, MLAEPs have not been particularly reliable. Nevertheless, although routine clinical applications are limited, sophisticated research studies continue to add to the literature on this topic (Rupp et al., 2004) which is encouraging for future developments.

FOOD FOR THOUGHT

1. How can one determine whether or not an evoked potential component is modality specific?
2. Would it be a good idea to use an adaptive filter that adaptively varies the bandpass in order to enhance EEG signals?

3. Why are the well known MLAEP components (e.g., Pa and Pb) not observed in speech-evoked ABRs given the typical time epoch being recorded?

Cortical Auditory-Evoked Potentials

Kelly Tremblay and Christopher Clinard

INTRODUCTION, INSTRUMENTATION, AND IMPLEMENTATION

Over the past few decades, there has been a great deal of research aimed at identifying the neural mechanisms of central sound processing using various approaches including single-cell recordings in nonhuman primates, functional magnetic resonance imaging, and scalp recording of neuroelectric or neuromagnetic brain activity. We provide a review of the literature that is relevant to students, audiologists, and clinician scientists by focusing on cortical auditory-evoked potentials (CAEPs) and how they are used to (1) characterize the neural detection and/or discrimination of sound(s) and (2) assist with the assessment and rehabilitation of people with auditory-based communication disorders.

These potentials are sometimes called event-related potentials (ERPs, AERPs) or long-latency responses (LLRs) by psychologists. Time-locked evoked cortical activity provides information regarding the timing (through latency measurement) and salience (through amplitude measurement) of sound processing. To some extent, information regarding the location of processing may be determined by means of scalp topography, brain source modeling, and statistical inferences (Hillyard and Picton, 1987). Many ERPs are not sensory, specific, meaning they can be evoked by more than one type of stimulus modality and therefore can be used to study multisensory processing (e.g., auditory visual integration). Because they are used to measure sensory, cognitive, and motor events, neurologists and psychologists also use CAEPs to study brain and behavior relationships underlying human communication as well as related disorders.

In the sequence of auditory-evoked potentials (AEPs), LLRs occur 50 ms or later after the stimulus; each deflection is identified according to its polarity, order of occurrence, and latency. For example, the P1-N1-P2 cortical response consists of a small positive wave (P1), a large negative component (N1), followed by a positive peak (P2). The N1 peak, also referred to as the N100, is a negative peak that occurs approximately 100 ms following sound onset (Figure 18.1). Neuroscientists sometimes display polarities in the reverse

direction, with positive polarities down and negative peaks up. The reason for this difference has more to do with historical and cultural differences between hearing and cognitive scientists and less to do with the science. Therefore, the interpretation of the CAEPs remains the same, regardless of how polarity is displayed.

What Do the Latencies and Amplitudes of an AEP Imply?

CAEPs are said to result from stimulus-locked postsynaptic potentials within apical dendrites of pyramidal neurons in the cerebral cortex. As described by Eggermont (2001), and shown in Figure 18.2, extracellular electric currents spread through the conductive brain tissue, the cerebrospinal fluid, the skull, and the skin, resulting in voltage differences at the scalp surface, which are recorded using electrodes placed on the scalp. The number of activated neurons, extent of neuronal activation, and synchrony of the neural response all contribute to the resulting CAEP pattern. The amplitude of each CAEP component quantifies the strength of the response and is measured in microvolts (μV). Latency

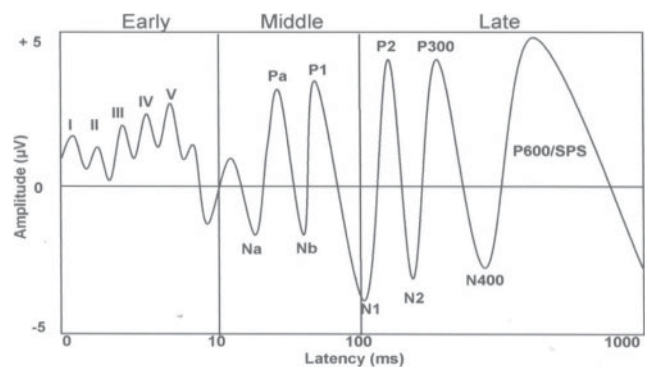

FIGURE 18.1 A hypothetical illustration of auditory-evoked potentials, from early responses occurring at the level of the auditory nerve and brainstem to the later cortical responses. [Reprinted with permission from Friesen L, Tremblay K. (2003) Electrophysiologic measures of speech, language and hearing. *Perspect Neurophysiol Neurogenic Speech Lang Disord*. 13 [1], 3-10.]

FIGURE 18.2 An illustration of a neural dipole, representing the neural activity that scalp electrodes are able to detect. [Reprinted with permission from Bear M, Connors B, Paradiso M. [2007] *Neuroscience: Exploring the Brain*. 3rd ed. Philadelphia, PA: Lippincott Williams and Wilkins.]

refers to the amount of time, in milliseconds (ms), that it takes to generate the bioelectrical response following stimulus onset. Latency is therefore related to neural conduction time and the location of the neural generator: The time it takes for the sound to travel through the peripheral auditory system to the place of excitation in the central auditory system. Even though they are not routinely utilized in clinical settings, long-latency ERPs are regularly used in research to determine how physical acoustic energy translates into patterns of brain activity and contributes to perception in normal and hearing-impaired listeners (see Burkard et al., 2007, Chapter 11 for more about recording and analysis of auditory CAEPs).

Whereas the auditory brainstem response (ABR) has been used to examine synaptic events related to more peripheral sensory function (bottom up—afferent), longer latency cortical CAEPs have been used to examine more central processes related to how the brain makes use of the sound (top down—efferent). The boundaries between bottom-up and top-down cortical contributions are becoming increasingly blurred as increasing numbers of integrated neural networks, involving afferent and efferent processes, are defined.

Exogenous and Endogenous Contributions

CAEPs can be described as being sensitive to exogenous (acoustic representation) or endogenous (attention and

learning) aspects of sound processing. Exogenous can be defined as brain activity that is influenced by external sources, like the decibel level of a signal. Endogenous refers to brain activity modulated by internal events like motivation and alertness. In this respect, earlier latency responses like the ABR are described as exogenous because they are sensitive to the intensity level and other acoustic characteristics (e.g., rise time) of the incoming signal and are relatively insensitive to subject state of the individual. For example, the ABR can be used to estimate hearing sensitivity thresholds in infants during sleep. Despite these exogenous aspects of the ABR, and the recording parameters used to capitalize on these strengths for the purpose of estimating hearing sensitivity, there is also evidence to show that efferent contributions (descending cortical to brainstem neural networks) modulate brainstem activity. When studying brainstem activity contributing to the frequency-following response (FFR), sometimes referred to as the complex auditory brainstem response (cABR), there is evidence that short- (over days/weeks) and long-term (over years) listening experience influences activity of the auditory brainstem (for a review, see Chandrasekaran and Kraus, 2010). So, it can be said that evoked potentials have endogenous and exogenous aspects, but the resultant AEPs that are recorded depend on the methods used to acquire them.

If the purpose is to use CAEPs to estimate perceptual abilities in difficult-to-test clinical populations that cannot provide a reliable behavioral response, then recording CAEPs in a “passive” paradigm is typically used. Here, the term “passive” refers to the collection of brain activity without an active response of the subject. Passive recordings are used for many different reasons, especially when behavioral measures might not be possible (e.g., coma and dementia) or when there is suspicion of malingering. An ABR protocol for estimating hearing sensitivity in infants is one example of a passive paradigm because the infant is not expected to respond in any way. Even if perception was possible to measure, it would be difficult to determine if impaired behavioral responses were the result of cognitive deficits, fatigue, malingering, or other potential contributing factors. Therefore, “passive” electroencephalography (EEG) recordings can be seen as an opportunity to measure the physiological capacity of the auditory system, independent of a perceptual task, to determine if there is biologic evidence of abnormal physiological processing that might be contributing to impaired perception. If there is evidence of abnormal physiological encoding of sound, then rehabilitation efforts could center on improving the neural detection and discrimination of sound. However, if the neural detection/discrimination of sound appears normal, then rehabilitation efforts can focus on making better use of this physiological capacity.

When there is no active participation on the part of the test subject, these “passively” recorded CAEPs are often called “preattentive”; however, the use of this term is not entirely accurate because one cannot control or quantify all attentive

FIGURE 18.3 **A:** Illustration showing radial and tangential components. **B:** The 10–20 electrode placement system. [Reprinted with permission from Malmivuo J, Suihko V, Eskola H. (1997) Sensitivity distributions of EEG and MEG measurements. *IEEE Trans Biomed Eng.* 44 [3], 196–208.]

processes. For example, the mismatch negativity (MMN), described later in this chapter, involves a “passive” paradigm where oddball (deviant) stimuli are presented within a series of similar (standard) stimuli (e.g., da, da, da, da, ga, da, da, da, ...). The deviant sound can differ from the standards in one or more perceptual features such as pitch, duration, loudness, or phonemic content. The purpose of the MMN is to determine if a person’s auditory system is able to detect the change in stimuli, evoked by the oddball /ga/ stimulus in this example. The presence of an MMN, signaling the neural detection of the deviant stimuli, is described as a noninvasive, preattentive, task-independent, physiological correlate of stimulus discrimination and auditory sensory memory. Because its acquisition does not require an active task, the MMN has been used to study “preattentive” auditory processing in clinical populations (e.g., children with specific language impairment (SLI) suspected of abnormal auditory physiological discrimination capabilities (Naatanen et al., 1978, 2007). The same oddball paradigm can evoke what is called a P300 if the participant is asked to signal the presence of the deviant stimulus, either through a motor task or by counting, during “active” EEG recording. An argument in favor of using “active”, rather than “passive”, EEG recordings is that one should record neural mechanisms that are activated during the perceptual task to truly understand how the brain is contributing to perception. Therefore, the type of recording paradigm and CAEP that is measured depend on the user’s intended purpose.

EEG versus MEG

When reviewing the literature, readers will note that the CAEPs described in this chapter can be recorded using EEG

or magnetoencephalography (MEG). When the N1 CAEP is recorded using MEG, for example, scientists sometimes report it as the N1m. In many ways, the interpretation and functional significance of the EEG and MEG CAEP waveforms are similar; but the methods used to obtain them as well as the neural mechanisms that contribute to them differ (Malmivuo et al., 1997). Whereas scalp EEG is sensitive to both tangential and radial components of a current source (Figure 18.3), MEG detects only its tangential components. This means scalp EEG is sensitive to activity in the sulci and cortical gyri, but MEG is most sensitive to activity originating in sulci. EEG is therefore described as being sensitive to activity in more brain areas, but activity that is visible in MEG can be localized with more accuracy. Because magnetic fields are less distorted than electric fields by the skull and scalp, MEG is said to provide better spatial resolution than EEG. The typical needs of the audiologist involve EEG because it is far more feasible and cost-effective than MEG. Thus, the remaining focus of this chapter will be on acquisition of CAEPs involving EEG.

Electrode Configurations and Acquisition Parameters

Clinical EEG systems are more limited in functionality than research EEG systems. Clinic devices feature ease of use, but flexibility is often sacrificed. For example, some clinical systems only have a small number of channels, do not provide the opportunity to present sounds in oddball paradigms, and do not permit data analysis offline. Clinical EEG systems often do not permit the use of customized sounds and so the user is limited to the type of stimuli they can use.

Research systems, although more expensive, have greater flexibility and permit the ability to present all types of stimuli and allow offline processing so data can be analyzed in a multitude of ways.

CAEPs are typically recorded using the 10–20 system or International 10–20 system. It is an internationally recognized method that is used to describe the placement of electrodes on the scalp. A standardized application method assures reproducibility across multiple test sessions as well as across different clinics and laboratories. Each electrode site has a letter to identify the brain region over which it is placed, as well as a number to identify the hemisphere location (odd numbers = left hemisphere). The letters F, T, C, P, and O represent frontal, temporal, central, parietal, and occipital regions, and the “10” and “20” refer to the distances between adjacent electrodes (10% or 20% of the total front–back or right–left distance of the skull). Although these electrode location labels provide location information pertaining to the scalp, this should not be confused with internal neural generator sources. CAEPs recorded from electrode F3, for example, reflect postsynaptic activity generated from sources outside of the left frontal lobe. “Z” (zero) refers to an electrode placed on the midline.

Audiologists generally use a small number of electrodes for ABR use, but many other clinical professions will use 20 or more for various types of neurologic evaluations. It is advantageous to use a smaller number of electrodes as it requires less preparation and cleaning time, and fewer channels can mean that a less expensive piece of EEG equipment is necessary. However, research should begin with high-density recording arrays (typically, via cap or net containing up to 256 electrodes), otherwise, relevant information will be missed. As an example, the N1 vertex potential has historically been described as a reliable and stable CAEP that does not change from test session to test session. This is true when recorded from electrode site Fz and other frontal-central midline locations; however, when viewed from temporal electrodes (e.g., T3 and T5), amplitude increases from session to session are evident (Tremblay et al., 2010). Changes in waveform morphology across different areas of the scalp are not necessarily viewed as a confound; with regard to the study of auditory exposure and auditory learning, the P1-N1-P2 is proving to be a relevant CAEP. So whereas it is important to design recording montages that are efficient and feasible for clinical application, the development of clinical CAEP protocols should start with high-density recordings (e.g., 64 channels). These protocols should then be further refined to a set of optimized recording parameters (e.g., fewer channels) that are more clinically feasible.

Electrical and myogenic noise can interfere with CAEP recordings. In addition to 60-Hz electrical line noise, eyeblink artifact is a major source of noise in CAEPs and should be monitored. Electrical activity related to eyeblinks may be recorded by using electro-oculograms (EOG) with verti-

cal (VEOG) and/or horizontal (HEOG) electrodes placed in the vertical or horizontal planes of the eye, respectively. These electrodes may be placed close to the inner and outer canthi, as well as above the eyebrow and below the eye. EOG electrodes can help to adjust artifact rejection so that any sweeps with eyeblinks can be rejected. Eyeblink artifact is large; it is seen most clearly in frontal electrodes, although it can be picked up by electrodes across a wide area of the scalp.

Similar to ABR, each electrode is connected to one input of a differential amplifier (one channel per pair of electrodes); a common system reference electrode is connected to the other input of each differential amplifier. The voltage between the active, inverting electrode and the reference, noninverting electrode is amplified typically 1,000 to 100,000 times, or 60 to 100 dB of voltage gain. Analog-to-digital sampling typically occurs at 256 to 512 Hz in clinical scalp EEG for cortical AEPs; sampling rates of up to 20 kHz are used in some AEP research applications.

TYPES OF CAEPS

What follows is a brief overview of the auditory CAEPs including a description of each component and information that each AEP component provides to audiologists regarding speech-processing capabilities of their patients. Table 18.1 provides a cursory comparison to highlight how CAEP components can be distinguished from each other. Tables 18.2 and 18.3 provide the reader with recording protocols to guide data collection. The reader is also directed to publications that describe recommended methods for acquiring CAEPs as they pertain to central disorders, including psychiatric and neurologic disorders. Published guidelines are intended to assist investigators who use ERPs in clinical research, in an effort to standardize methodology and facilitate the comparability of data across laboratories. Duncan et al. (2009), for example, describe recording techniques to elicit, record, and quantify three major cognitive components MMN, P300, and N400. Picton et al. (2000) provide recording standards and publication criteria when using human ERPs to study human perception and cognition.

P1-N1-P2

Of all of the CAEPs, the P1-N1-P2 complex has received a great deal of attention by audiologists and clinician scientists because it is similar to the ABR in that it reflects exogenous properties of the incoming signal, making it relevant to the estimation of hearing threshold levels. It is an excellent tool to assess suspected functional hearing loss, as well as the neural detection of sound and its acoustic phonetic components at more central levels than the ABR (Hyde, 1997). As described by Picton (1994), much of today's AEP history began with the P1-N1-P2 complex. It was Hallowell and Pauline Davis who made the first recordings of the

TABLE 18.1

A Comparison of the P1-N1-P2 Onset Response and the ACC, MMN, and P300

Issue	P1-N1-P2 Onset	ACC	MMN	P3
What it indexes	Encoding (detection)	Encoding (detection) of acoustic change–discrimination capacity	Preattentive discrimination requires a sensory memory of the standard	Further processing of consciously discriminated sounds
Minimum number of electrodes	At least three: Cz, ground, reference (nose or one mastoid)	At least three: Cz, ground, reference (nose or one mastoid)	At least five: Fz, ground, reference, vertical eye channel. Mastoids (to examine response inversion) and additional electrodes (to examine scalp distribution) helpful for response identification	At least five: Pz, ground, reference, vertical eye channel. More channels permit examination of scalp distribution and are helpful for response identification
Elicited by	Sound onset	Acoustic change[s]	Stimulus or pattern deviance	Task-relevant deviance
Present when	Sound is detectable	Acoustic change is detectable	Stimulus deviance is detectable (some exceptions)	Stimulus deviance attended, detectable, and task relevant
Absent when	Sound not detectable or neurologic disorder	Acoustic change not detectable, presumably in some neurologic disorders	Stimulus deviance not detectable (some exceptions)	Stimulus deviance not attended and/or not task relevant in some psychiatric and neurologic disorders
Good at individual subject level?	Yes	Yes	No	Usually
Appropriate for young children?	Yes—may not obtain typical P1-N1-P2 pattern	Preliminary data indicate yes	Yes for groups, no at the individual subject level	No
Oddball paradigm required?	No	No	Yes	Yes
No. sweeps needed?	~100+ sweeps	~100+ sweeps	~200+ deviants	~100+ deviants
Test–retest reliability	Good	Good	Fair (better for adults than children)	Fair to good
Test time	Fast	Fast	Long	Medium
Ready to use in the clinic?	Yes to estimate threshold: yes to index pathway integrity; no for fine-grained diagnosis	No, but it is likely within 3–5 yrs	No for individuals; yes for groups	No for individuals; yes for groups
Biggest problem for clinical use	Lack of norms maturation effects	Lack of norms	Reliability at individual subject level particularly in children	Lack of norms

TABLE 18.2

Recommended Recording Parameters for P1-N1-P2

Subjects	State	Awake and alert
	Eyes	Open during recording
	Attention	Ignore stimuli
Stimuli	Interonset interval	0.05–0.20 ms
	Stimulus duration	100–1,000 ms
	Intensity	50–300 ms 60–80 dB peSPL
Recordings	Channels	Minimum of four channels (Fz, Cz, mastoid, and vertical EOG) or electrode cap
	Reference electrode	Electrically neutral (tip of nose or average reference)
	Eye artifact	Record vertical EOG for eyeblink artifact, also horizontal EOG if possible
	Filters	0.1–100 Hz [online], 1–30 Hz [offline]
	Amplifier gain	10,000–30,000
Response detection	Time window	–50 to at least 400 ms, depending on stimuli
	Visual detection	Recordings replicate well Scalp topography should be appropriate Response should be two to three times larger than the prestimulus baseline
	Statistical detection	Statistical detection is preferred over visual detection
Measurements	Many options (see Duncan et al., 2009; Picton et al., 2000)	N1 latency and baseline-to-peak amplitude, integrated MMN, area under MMN, MMN duration, MMN peak latency, and amplitude For group data, use a grand mean MMN waveform to establish the latency of the MMN

human AEPs, beginning with the N1 CAEP (also called the vertex potential). In 1939, they published the founding papers for evoked potential audiometry but it was not until the 1960s when averaging computers made their recordings sufficiently objective for clinical use. In the 1960s and early 1970s, while studying the effects of attention on this response, Hallowell Davis also recorded some of the first recordings of the P300 wave, a wave that is related to human information processing. So why then, as pointed out by Hyde (1997), is not the P1-N1-P2 used more often in clinic? Probably because clinicians are usually not trained in the use of them in their audiology programs.

The P1 component of the P1-N1-P2 complex typically starts at about 50 ms following stimulus onset in adults with normal hearing. Ross and Tremblay (2009) showed different source locations for auditory-evoked N1 and P2 sources using MEG with the auditory P2 being generated at least in part in the auditory cortex, the temporal region, and the reticular activating system. P1-N1-P2 response analysis includes the measurement of latency and amplitude of each individual peak component; however, there are also objective detection algorithms that can be used.

One example is a wavelet-based Rayleigh test on phase coefficients (Ross et al., 2007). When high-density EEG or MEG recordings are used, analyses such as source localization and dipole modeling may be carried out (e.g., BESA or LORETA).

When high-density recordings and modeling are used, multiple subcomponents contributing to the P1-N1-P2 can be defined (Woods, 1995). For example, N1 has multiple subcomponents with N1a, at approximately 75 ms poststimulus onset, being most prominent at temporal electrodes. N1b (at about 100 ms) is most prominent at vertex electrodes and is the peak most often described in the literature pertaining to audiology and hearing science. The N1c subcomponent (at approximately 130 ms) is most prominent at temporal electrodes but extends to fronto-polar and lateral central electrodes. Much of the research that appears in the audiology and hearing science literature pertains to the vertex recorded N1 (also known as N1b), even though it is not explicitly called N1b in many publications. This is also true when reviewing the P1-N1-P2 complex in this chapter. When using the term N1, we are mostly referring to the N1b vertex potential.

TABLE 18.3

Recommended Recording Parameters for MMN

Subjects	State	Awake and alert
	Eyes	Open during recording
	Attention	Ignore stimuli
Stimuli	Deviant stimuli	Use oddball paradigm with ~200 sweeps minimum to deviant, and deviant probability of 0.05 to 0.20
	Interonset interval	100–1,000 ms
	Stimulus duration	50–300 ms
	Intensity	60–80 dB peSPL
Recordings	Channels	Minimum of four channels (Fz, Cz, mastoid, and vertical EOG) or electrode cap
	Reference electrode	Electrically neutral (tip of nose or average reference)
	Eye artifact	Record vertical EOG for eyeblink artifact, also horizontal EOG if possible
	Filters	0.1–100 Hz [online], 1–30 Hz [offline]
	Amplifier gain	10,000–30,000
Response detection	Time window	–50 to at least 400 ms, depending on stimuli
	Waveform subtraction	(Waveform for deviant stimuli)–(waveform for standard stimuli)
	Visual detection	Recordings replicate well Scalp topography should be appropriate for MMN Response should be two to three times larger than the prestimulus baseline
	Statistical detection	Statistical detection is preferred over visual detection
Measurements	Many options (Duncan et al., 2009; Picton et al., 2000)	N1 latency and baseline-to-peak amplitude, integrated MMN, area under MMN, MMN duration, MMN peak latency, and amplitude For group data, use a grand mean MMN waveform to establish the latency of the MMN

The P1-N1-P2 response is an onset response and can also be described as a change detector because it is elicited by the (1) change from silence to sound (onset), (2) transitions with an ongoing sound, and (3) sound to silence (offset). The acoustic contents of the stimulus (e.g., frequency, duration, rise/fall times) all affect response morphology of the P1-N1-P2 peaks. For example, rise/fall times less than 50 ms and stimulus durations of at least 30 ms elicit the most robust responses. Slower rates are associated with larger P1-N1-P2 amplitudes. Binaural stimulation elicits responses with larger amplitudes than monaural stimulation. Although the P1-N1-P2 is described as having exogenous aspects, there can also be endogenous contributions that involve attention. Active recordings, for example, where the individual is instructed to attend to a signal in one ear while ignoring a competing message in the other ear, will also enhance N1 amplitude (Hink and Hillyard, 1976). Figure 18.4 shows passively evoked P1-N1-P2 responses elicited by a 1-kHz tone 750 ms in duration. The tone, because of its duration, evokes onset and offset P1-N1-P2 responses

that decrease in amplitude and increase in latency with decreasing intensity levels.

Table 18.2 provides a list of acquisition parameters used to record P1-N1-P2 responses. It is traditionally recorded using a block paradigm, where the same stimulus is repeated a number of times. CAEPs are usually larger in amplitude than the ABR; so fewer sweeps are necessary to obtain favorable signal-to-noise ratios (SNRs) (e.g., 50 to 300 sweeps). Response amplitude declines as a sound is repeated, thought to be related to neuronal habituation and adaptation processes with the amplitude decrement being most robust over the first five sweeps (Bourbon et al., 1987; Ritter et al., 1968). Unlike the ABR, the P1-N1-P2 complex is less robust when patients are asleep. Response amplitudes are most robust when patients are awake, even if they are not attending to the stimulus. For this reason, during passive recordings, individuals are asked to read a magazine or watch a closed-captioned video during the recording to reduce drowsiness, which can also affect response amplitude.

FIGURE 18.4 P1-N1-P2 responses elicited by a 1-kHz tone 750 ms in duration. The tone, because of its duration, evokes onset and offset P1-N1-P2 responses that decrease in amplitude and increase in latency with decreasing intensity levels. (2007) Effects of hearing aid amplification and stimulus intensity on cortical auditory evoked potentials. *Audiol Neurootol.* 12 (4), 234–246].

P1-N1-P2 Change Complex

The P1-N1-P2 is also called an obligatory potential because its presence signals the first stages of neural detection. It does not provide information about stimulus discrimination, and therefore provides little information about speech

discrimination. Instead its presence is followed by discriminatory potentials such as the MMN, P300, N400, and P600 that do reflect higher order auditory discrimination processing. With that said, it is possible to use the P1-N1-P2 to measure the neural discrimination of suprathreshold acoustic changes if long-time duration time-varying stimuli are used. Sometimes referred to as the acoustic change complex (ACC) (Ostroff et al., 1998), and originally introduced decades ago (e.g., Jerger and Jerger, 1970), the ACC signals the neural detection of stimulus change. In this respect it is a discriminatory potential because the eliciting stimulus contains acoustic contrasts, but does so using one stimulus rather than using two separate sounds like those used in the oddball paradigm for MMN and P300. Figure 18.5 shows how the acoustic change response can be used to quantify the neural detection of sound onset (silent to sound) as well as the detection of an acoustic change contained in an 800-ms duration vowel (seen here in a boxed area). At the 400-ms midpoint, the second formant frequency of the vowel changed creating a transition from /u/ to /i/.

Even though the P1-N1-P2 change response is not a direct measure of perception, many studies have begun to clarify the relationship between the presence of a change response and that same individual's behavioral threshold. For example, a number of studies have related an individual's P1-N1-P2 change response to that same individual's behavioral detection of the same stimulus contrast. Whereas the neural detection of sound onset evoked by short-duration stimuli has not proven to be a strong predictor of perception, good relationships between behavioral and physiological "change responses" of intensity, frequency, interaural phase, and spectral-ripple density have been documented (Harris et al., 2008; Ross et al., 2007; Won et al., 2011). As an example, Figure 18.6 shows the behavioral detection of interaural phase differences (IPDs) in relation

FIGURE 18.5 The P1-N1-P2 response acts as a change detector and here shows onset, change, and offset responses elicited by a 800-ms duration vowel stimulus. At the 400-ms midpoint, the second formant frequency of the vowel was altered, changing the vowel sound from /u/ to /i/. The onset of the sound elicits an onset response, detecting a change from silence to sound. The acoustic change at the midpoint of the vowel elicits a second P1-N1-P2 complex called the change response, indicating that the central auditory system detected the formant frequency change midway through the vowel. The offset of the sound elicits an offset response, smaller in amplitude around 900 ms, indicating the detection from sound to silence. [Modified from Martin BA, Tremblay KL, Korczak P. (2008) Speech evoked potentials: from the laboratory to the clinic. *Ear Hear.* 29 (3), 285–313.]

FIGURE 18.6 P1-N1-P2 responses for three age groups at different stimulus frequencies. Clear onset responses are observed for all groups at all test frequencies but the ability to detect an interaural phase difference (IPD) arriving at both ears diminishes as age increases. The stimuli are diodic at the beginning of the stimulus [shown in the *bottom left hand corner*], creating an onset response. The “change” response is evoked by an IPD into a dichotic signal halfway through the stimulus. [Reprinted with permission from Ross B, Fujioka T, Tremblay K, Picton TW. [2007] Aging in binaural hearing begins in mid-life: evidence from cortical auditory-evoked responses to changes in interaural phase. *J Neurosci.* 27 [42], 11172-11178.]

to the physiological detection of IPDs. For each carrier stimulus frequency, shown in the *y*-axis, there is a 180° IPD at the 2-second midpoint of the stimulus. P1-N1-P2 change responses are seen in response to stimulus onset, change, and offset. In this study, the change response is present if the central auditory system was able to detect the IPD that occurred midway within the stimulus. Open, black circles represent group averages for the upper frequency limit at which subjects made this detection behaviorally (recorded in a separate session). Note that no change responses were seen at the highest frequencies, where group members were not able to behaviorally detect the phase change. Based on these results, it can be said that the upper frequency limit of IPD detection deteriorates with advancing age. It is important to note that the P1-N1-P2 onset response (latency, amplitude) does not approximate a person’s ability to perceive these sounds; but rather, it is the “change” response that corresponds well to a person’s behavioral ability to discriminate the stimuli. In other words, the change from silence to sound is so robust that all age groups can detect it. It is the change in acoustic information, from one auditory signal to another, which shows age-related decreases in temporal processing related to the neural encoding of IPD. Similar approaches using gap detection, voice-onset time, and other time-varying stimuli have been used to study

temporal processing in older adults, with and without hearing loss, and have yielded similar findings (for a review, see Billings et al., 2012a; Picton, 2013).

Advantages of using ACC over other discriminative responses such as the MMN and P300 include the following: (1) Reliably recorded in individual subjects (with fewer trials needed), (2) good intrasubject test-retest reliability (Tremblay et al., 2003b), (3) the use of a passive recording paradigm, and (4) evokes distinct waveform morphologies that reflect some of the acoustic content of speech sounds. It can therefore be used to examine the neural detection of important acoustic aspects of speech, like speech envelope, even when presented through a hearing aid (Tremblay et al., 2006a) or cochlear implant (CI) (Friesen and Tremblay, 2006; Friesen et al., 2009; Kim et al., 2009). Friesen et al. (2009), for example, used P1-N1-P2 change responses to show how the number of CI channels affected the neural detection and perception of vocoded CVC stimuli. The amplitude and latency of P1-N1-P2 responses were modulated by the amount of auditory information provided by increasing channel numbers. For example, neural conduction time (latency) decreased as the number of spectral channels increased. Perception of the CVC stimuli also improved with increasing the number of spectral channels; however, coinciding changes in P1-N1-P2 morphology did not fully predict changes in

perception. Even the ACC has its limits because it best reflects time-varying cues, like speech envelope, and less about the spectral content contained in a signal.

Mismatch Negativity

The MMN involves a recording paradigm that is much different than the P1-N1-P2 change complex. To elicit the MMN, stimuli must be presented via an oddball paradigm. The number of deviant stimuli, the percent ratios, and types of stimulus contrasts vary across studies. One example of a sound contrast used to elicit the MMN is tones of different frequencies, where tones of 1,000 and 990 Hz may serve as standard and deviant. Different speech sounds, sound durations, and sounds differing in spatial location can also be used to elicit an MMN. Whatever the stimulus might be, the order of stimulus presentation (standard versus deviant) is pseudo-randomized, and the amplitude of the MMN is greater when deviant stimuli are not presented consecutively. A reason for this has to do with insufficient buildup of auditory memory trace required by repeated presentations of the standard stimulus.

The MMN is seen as a negativity following N1 in the latency window of approximately 100 to 300 ms (Näätänen et al., 1978). It does not appear in Figure 18.1 because the MMN waveform is obtained by subtracting the waveform for the deviant stimulus from the waveform to the standard stimulus. This oddball paradigm involves presenting a standard sound the majority of the time (e.g., 80%) and presenting a deviant sound the rest of the time (e.g., 20%). In this example, the 1,000-Hz tone, the standard, would be presented 80% of the time, whereas the remaining 20% of presentations would consist of a 990-Hz tone, the deviant. If deviant stimuli are presented in close proximity (e.g., one

to two intervening standard stimuli) to each other, then the response is less robust than when more intervening standard stimuli are presented between deviant sounds. Figure 18.7 illustrates the basic concept of MMN recording.

MMNs are best recorded from individuals who are awake and alert, although they do not have to actively pay attention to the stimulus. Other recording approaches that include multiple deviants as well as reversed order control conditions can be used as well. Although the response is optimally seen at electrode site Fz, the scalp topography and distribution of the MMN are also informative. For example, MMN and P1-N1-P2 responses observed over frontal electrode locations will reverse in polarity when viewed over temporal electrode sites, because electrodes are now on the opposite field of neural generators arising from superior temporal gyri. Seeing the polarity reversal assures the clinician that what was seen at frontal recording sites is in fact neural rather than eye blink or other possible confounding artifacts. For a detailed review of the MMN and the types of stimuli that are capable of eliciting the MMN, the reader is referred to Picton et al. (2000).

One of the initial reasons why scientists and clinicians first became interested in the MMN response is related to the potential application for assessing children with auditory-based learning problems and who are diagnosed as having SLI or central auditory processing disorders (CAPD) (Kraus et al., 1996). When people with communication disorders are assessed using a behavioral task, poor performance might relate to the demands related to test administration and not the content of the test (an inability to sit, attend, follow verbal or written instructions). No overt task is required to acquire the MMN, and the patient does not have to pay attention to the stimuli, so it was thought that the MMN would evolve into an assessment tool that

FIGURE 18.7 A visual illustration of the oddball stimulus condition used to evoke the MMN. [Reprinted with permission from Nagai T, Tada M, Kirihara K, Araki T, Jinde S, Kasai K. [2013] Mismatch negativity as a “translatable” brain marker toward early intervention for psychosis: a review. *Front Psychiatry*. 4, 115.]

could be used to objectively identify children with abnormal sound discrimination problems such as SLI and CAPD. The presence and magnitude of the MMN show reasonable agreement with behavioral discrimination performance, thereby making it a sensitive tool to assess the neurophysiological capacity of an individual's auditory discrimination abilities. However, a major obstacle in adopting the MMN as a clinical tool is the difficulty associated with quantifying it in individual people, thereby limiting its ability to diagnose individual patients. Although efforts to resolve this issue are underway, another important consideration is the sensitivity and specificity of the MMN. The MMN is sensitive to abnormal discriminative and memory processes related to audition; however, it does not appear to be specific to a particular disorder. Abnormal MMNs are being reported in a wide range of populations diagnosed with schizophrenia, personality disorders, and alcoholism (Marco-Pallares et al., 2007). Thus, it is difficult at this time to conclude how the clinical significance of an abnormal MMN would add to the audiologic assessment and rehabilitation of people with hearing loss.

Additional obstacles include the amount of time needed to collect the MMN response and the challenge of defining the MMN in individuals. A large number of trials are needed to achieve a sufficient SNR in which to view the MMN. This makes it more time consuming and less feasible for clinical application. The oddball paradigm involves a trade-off between how novel a sound is and how many sweeps are recorded to that deviant stimulus. A lower percentage of deviant stimuli are associated with a higher degree of novelty, but that lower percentage will result in a smaller number of sweeps recorded to the deviant, resulting in a less favorable SNR. Approximately 200 accepted sweeps to the deviant are necessary to obtain a favorable

SNR, and even then it can be difficult to visualize the MMN in an individual subject. Subjective visual detection is often used to determine the presence or absence of an MMN; however, various statistical detection algorithms do exist (e.g., point-by-point *t*-tests and the bootstrapped, integrated MMN; Duncan et al., 2009; Picton et al., 2000). With that said, MMNs are not always detectable in recordings from a single individual, even when that individual can behaviorally discriminate the standard and deviant sounds. Collectively, because MMNs are not always present in individual data, and because of the SNR problems, MMN studies often need to use average waveforms from all individuals within a group, or group average waveforms, to optimize the detection of MMNs.

P300

The P300, or P3, is another CAEP that can reflect physiological processing of discrimination. It was first reported over 40 years ago (Sutton et al., 1965). The P3 is generated within auditory and nonauditory areas of the brain (e.g., frontal cortex) and is seen as a positive peak at approximately 200 to 300 ms in response to novel stimuli presented in an oddball paradigm (Figure 18.8). The reader is referred to Naatanen (1992) and Polich and Criado (2006) for a thorough review. Recording the P3 is similar to the approach used to record the MMN (see Table 18.3). However, the subject often attends to the deviant stimuli instead of ignoring them as in the "passive" MMN paradigm. Tasks for the subjects may include counting the number of deviant stimuli or pressing a button each time they perceive the deviant sound. Similar to the MMN, a wide variety of stimulus contrasts can be used to elicit the P3 such as differences in frequency, timing, or speech sounds.

FIGURE 18.8 Illustration of how P300 and MMN are recorded in active and passive conditions, respectively. *Upper row of panels* shows how the P300 is present in the active condition (**left panel**) when an individual attends to the deviant stimulus; in the **right panel**, an enhanced negativity is seen when an individual ignores the stimuli. *Bottom row of panels* illustrates the difference waveforms [standard wave subtracted from deviant wave] where the enhanced positivity for the P300 (**left panel**) and enhanced negativity from the MMN (**right panel**) are seen. [Reprinted with permission from Martin BA, Tremblay KL, Korczak P. [2008] Speech evoked potentials: from the laboratory to the clinic. *Ear Hear.* 29 [3], 285–313.]

In general, it can be said that the morphology of the P3 changes as a function of stimulus discrimination ability. P3 amplitudes are larger for easy to discriminate stimuli and amplitudes decrease when the discrimination task becomes more difficult. The same can be said for latency. P3 latency decreases for easy discrimination tasks and increases for difficult tasks (Fitzgerald and Picton, 1983). P300 amplitude (μV) is defined as the difference between the mean prestimulus baseline voltage and the largest positive-going peak of the ERP waveform within a time window (e.g., 250 to 500 ms). Latency (ms) is defined as the time from stimulus onset to the point of maximum positive amplitude within a time window. P300 scalp distribution is defined as the amplitude change over the midline electrodes (Fz, Cz, Pz), which typically increases in magnitude from the frontal to parietal electrode sites and is sometimes referred to as a P300b when recorded over Pz in response to difficult stimulus contrasts. When the stimulus contrast is easy, a “P300a” can be seen even in the absence of a task (Squires et al., 1975).

A multitude of nonpathologic and pathologic subject factors influence the P300. For example, pathologic factors of dementia, depression, and dyslexia affect the P300, as do nonpathologic factors of fatigue, handedness, and personality (Polich, 2004). Considering the myriad of factors that can affect the P300, like the MMN, the clinical utility of this response, for audiologic purposes, is often debated. One of the arguments against using the P300 in the audiology clinic has to do with the active task used to evoke it. What

additional information does that P3 offer to the clinician if a person is able to provide reliable behavioral responses, providing evidence of what that person can and cannot discriminate auditorily? For research purposes, however, it can be argued that it is important to have the brain active to define the neural mechanisms that are contributing to the perceptual event of interest. And in turn, the information that is obtained might translate into new technology or information that is relevant to the assessment and rehabilitation of people with communication disorders.

N400/P600

Other cortical CAEPs exist for the purpose of defining normal and disordered auditory processing, but they are not readily accessible to audiologists for many of the same reasons as the MMN. CAEP peaks appearing as late as 1,400 ms, for example, appear in the audiology literature as a means of assessing word comprehension (Mehta et al., 2009). Two additional examples are the N400 and P600 that are used in research laboratories and are related to linguistic processing. The N400 is a negative response occurring at approximately 400 ms and reflects language processing related to semantic incongruity (Kutas and Hillyard, 1980). Stimuli for the N400 are sentences with incongruous semantics, such as “the box is walking.” The P600, on the other hand, is a positivity that occurs at approximately 600 ms and is elicited by violations of a language’s rules, such as syntax. Figure 18.9 shows how

FIGURE 18.9 Event-related potentials elicited in response to an auditory target work at electrode sites Cpz within the -200 to $1,000$ time window. **A:** The control group shows a clear distinction between all three conditions, commencing around 250-ms post-target stimulus. Negative polarity is plotted up. **B:** the TBI group shows a reduction in the N400 [shown between two vertical lines at 300 to 500 ms] compared to the control group between the three conditions. [Reprinted with permission from Knuepffer C, Murdoch BE, Lloyd D, Lewis FM, Hinchliffe FJ. [2012] Reduced N400 semantic priming effects in adult survivors of paediatric and adolescent traumatic brain injury. *Brain Lang.* 123 [1], 52–63.]

the N400 was used to examine the neural correlates of linguistic processing deficits reported following pediatric and adolescent traumatic brain injury (TBI). Participants in the TBI group had a history of pediatric or adolescent TBI, whereas participants in the control group never reported an insult to the brain. Three stimulus conditions were used to elicit the N400. The auditory target word was either preceded by a prime picture that was congruent, that is, the picture of an apple followed by a read-out of the word “apple,” incongruent, but from the same semantic category, that is, the picture of an orange followed by the word “apple,” or semantically and associatively unrelated, that is, the picture of a shoe followed by the word “apple.” Results revealed a significantly smaller N400 response in the unrelated condition in the TBI group when compared to the control group. In other words, the N400 revealed physiological differences in the way TBI patients process linguistic information, with the TBI group being less able to detect linguistic violations involving unrelated words.

PATIENT SUBJECT FACTORS—MATURATION AND AGING

Whereas the brainstem is said to be neuroanatomically mature at birth, the maturation of commissural axons, and association fibers, that provide connections within and between hemispheres, are still maturing by the age of 12 years (Moore, 2002). From adulthood through the later stages in life, many physical, biologic, chemical, and psychologic changes take place. Together, they all impact the magnitude and distribution of synaptic activity, as well as the neural generators involved. Optimal CAEP recording paradigms therefore vary, depending on the age of the participant. CAEP latencies and amplitudes, and their distribution patterns across the scalp, are also influenced by the type of stimulus presentation paradigm (block or oddball), the degree of acoustic deviation when using an oddball paradigm, sleep–awake state, the length of the interstimulus interval (ISI) (e.g., stimulus presentation rate) (see Kushnerenko et al., 2013 for a review of infant and child recordings).

As an example, the morphology of the P1-N1-P2 responses changes across the lifespan. In adults, the amplitude of P1 is small and N1 and P2 often dominate the response. In contrast, for young children, P1 dominates the response and is followed by a slow negativity (N2) (Ponton et al., 1996). However, if the stimulus presentation rate is slowed down, P1-, N1-, and P2-like responses become visible in infants and children (Wunderlich and Cone-Wesson, 2006). Later in life, N1 and P2 components become delayed in middle and old age (Tremblay and Burkard, 2007) but can also appear youthlike when slower ISIs are used. The fact that CAEPs are affected by the amount of time that separates one stimulus from another hints at changes in temporal processing abilities that take place as a function

of age (see Billings et al., 2012a). Moreover, the presence of age-related hearing loss compounds the effect by affecting both latency and amplitude of N1 and P2 peak waveforms (Martin et al., 2008; Tremblay et al., 2003a).

Maturation effects are seen for the MMN and N400 as well because neural mechanisms, and their spatial distribution, change with age (Kushnerenko et al., 2013; Martin et al., 2003). Like the P1-N1-P2, ISI greatly influences the morphology of the MMN. From birth through old age, the rate at which stimuli are presented appears to modulate the physiological index of auditory sensory memory and discrimination. It is therefore not surprising that some disorders, such as Alzheimer’s (AD) and Parkinson’s diseases (PD), have been linked to abnormal processing speed as reflected by the MMN.

CLINICAL APPLICATIONS: OPPORTUNITIES AND CHALLENGES

Hearing Loss and Hearing Aids

The ABR is typically the audiologist’s tool of choice for estimating audiometric thresholds; however, the P1-N1-P2 is also a useful tool for this purpose. An advantage of using the P1-N1-P2 response is that the magnitude of the evoked response pattern is larger than the ABR (improved SNR); so fewer sweeps are necessary, resulting in a shorter test time than the ABR. An additional advantage of the P1-N1-P2 response for threshold estimations is that it indirectly provides an indication that sound reached the auditory cortex. The presence of any CAEP, however, does not imply that auditory pathways and cortical function are entirely normal because CAEPs only measure a small fraction of overall auditory function. Also, keep in mind that the P1-N1-P2 response is affected by maturation and sleep, and so it is best applied to adults who are awake. If it is used to estimate hearing thresholds in infants or young children, sleep state should be monitored and the child’s age should be considered when interpreting waveform morphology (see Stapells, 2009). Unlike ABRs, there are no published norms for clinicians to use for P1-N1-P2 responses because the peak latencies and amplitude vary depending on the stimuli used to evoke it (e.g., rise time, duration, speech, tones).

P1-N1-P2 threshold estimates can be obtained in normal-hearing individuals as well as individuals with hearing loss, and CAEP thresholds typically fall within 10 dB of behavioral thresholds (Van Maanen and Stapells, 2005). Polen (1984), for example, used speech sounds to evoke CAEPs and reported a prolongation of N1, P2, N2, and P3 latencies, as well as a reduction in P2 and N2 amplitudes, in people with moderate to severe sensory/neural hearing loss. Readers are referred to Martin et al. (2008) for a complete review, but an overarching conclusion is that decreased

sound energy (attenuation because of middle ear or cochlear pathology), entering the CAS, results in increased CAEP peak latencies and decreased amplitudes. The effects of decreased audibility on the P1-N1-P2 complex can be seen in Figure 18.2. The MMN, P300, and N400 are not shown but they are similarly affected. For example, Kraus and colleagues used the MMN to test two listeners with sensory/neural hearing loss using a /da/-/ga/ oddball paradigm. Whereas the subject who could easily behaviorally discriminate the /da/-/ga/ contrast evoked a clear MMN, the subject who could not easily discriminate the two sounds had no MMN (Kraus et al., 1995). Once again, extending this direction of work into a clinic protocol has been problematic because of the difficulties recording MMNs in individual patients as well as insufficient data pertaining to sensitivity and specificity of the MMN.

There is also interest in using CAEPs (P1-N1-P2 and ACC) to quantify the effects of hearing aid amplification on the brain. As described by Billings (2013), there are different approaches to recording aided CAEPs; the most common is to have an individual wearing the hearing aid while stimuli are presented in sound field. Another approach is to record the hearing aid output, either in a coupler or a mannequin (e.g., Knowles Electronics Manikin for Acoustic Research (KEMAR)) or the Brüel and Kjær Head and Torso, and presenting the sounds through earphones to the participant. Stimuli can also be presented through a hearing aid, using direct audio input. Finally, hearing aid processing can be simulated using a master hearing aid approach, using signal-processing software, and then presenting the modified sound through insert earphones to the patient. Whereas the first approach is more familiar to audiologists, is more ecologically similar to everyday listening experiences, and best resembles current clinical practice, the last three methods have the advantage of minimizing extraneous variables related to sound field testing such as the effects of head movement and standing waves. With that said, there are a number of studies showing that CAEPs can be reliably recorded in individuals, with and without hearing loss, in sound field (Tremblay et al., 2006a, 2006b; see also Billings, 2013; Martin et al., 2008 for reviews).

One purpose of using aided CAEPs is to assist in the verification and validation of hearing aid fittings; another is to examine plasticity-related changes in the brain (for a review see Tremblay and Moore, 2012). From the ear to the brain, spectral and temporal acoustic information contained in the signal is represented using place and timing codes to reflect perceptually relevant acoustic speech cues and these codes are impacted by hearing loss, sometimes referred to as “deprivation- or injury-related plasticity.” When sound is reintroduced to the auditory system, there is “use-related plasticity”; modifications to sensory maps, synaptic alterations, and neurochemical changes (Irvine et al., 2001). When fit with a hearing aid, additional forms of plasticity are presumed to take place (Willott, 1996). For example, when a

hearing aid increases the intensity of a signal, areas of the auditory system that were once deprived of sounds are now being stimulated. Then, the amplified sound that comes out of a hearing aid stimulates new neural networks and people need to learn how to make use of these new modified sounds. The duration of hearing loss, the age of the patient, and the length of amplification are all believed to contribute to the neuroplastic effects.

The idea that brain measures might provide valuable audiologic information related to hearing aid use and plasticity is not new. ABR recordings have been recorded in response to auditory stimuli presented in sound field and amplified by hearing aids. They proved to be unsuccessful because the short-duration signal (click, tone-pip) interacted with the hearing aid circuitry in a way that introduced ringing and other artifacts (Gorga et al., 1987). Anderson and Kraus (2013) revisited this concept by using speech-evoked ABRs (also called the FFR). They showed that it is possible to record FFRs while a person is wearing a hearing aid; however, this direction of research is still new and it will be necessary to explore some of the opportunities and obstacles recently uncovered when using CAEPs.

Rapin and Graziani (1967) were among the first to use CAEPs such as the P1-N1-P2 response to assess the effect of increased audibility related to hearing aid use. They found that the majority (5/8) of 5- to 24-month-old subjects with severe-to-profound sensory/neural hearing loss showed an improved P1 morphology in the aided testing condition, presumably reflecting improved audibility provided by the hearing aid. However, two of the infants showed no change in their cortical CAEP thresholds across the aided and unaided conditions and these types of inconsistencies are still present in the literature almost 50 years later. Glista et al. (2012), for example, reported instances when cortical P1-N1-P2 responses were absent in normal-hearing children.

Although there is converging evidence in the literature to show that CAEPs (P1-N1-P2 responses as well as the ACC) to tones and speech sounds can be reliably recorded in individuals while wearing a hearing aid, and that different speech sounds evoke different aided CAEP patterns (Billings et al., 2007; Tremblay et al., 2006a, 2006b), there is also evidence to show that CAEPs do not reliably reflect hearing aid gain and may be affected by many different signal-processing functions (Billings, 2013; Billings et al., 2012b; Marynewich et al., 2012). To better understand amplification and the brain, and to move the field forward, Tremblay et al. (in press) and Tremblay (2013) edited special issues to explore the relationship between “hearing aids and the brain.” These publications summarize the current status of hearing aid verification and validation using evoked potentials and indicate the many opportunities and challenges in doing so. One challenge that is discussed in this special issue is that CAEPs do not reliably reflect hearing aid gain even when different types of hearing aids (analog and digital) and their parameters (e.g., gain, frequency response)

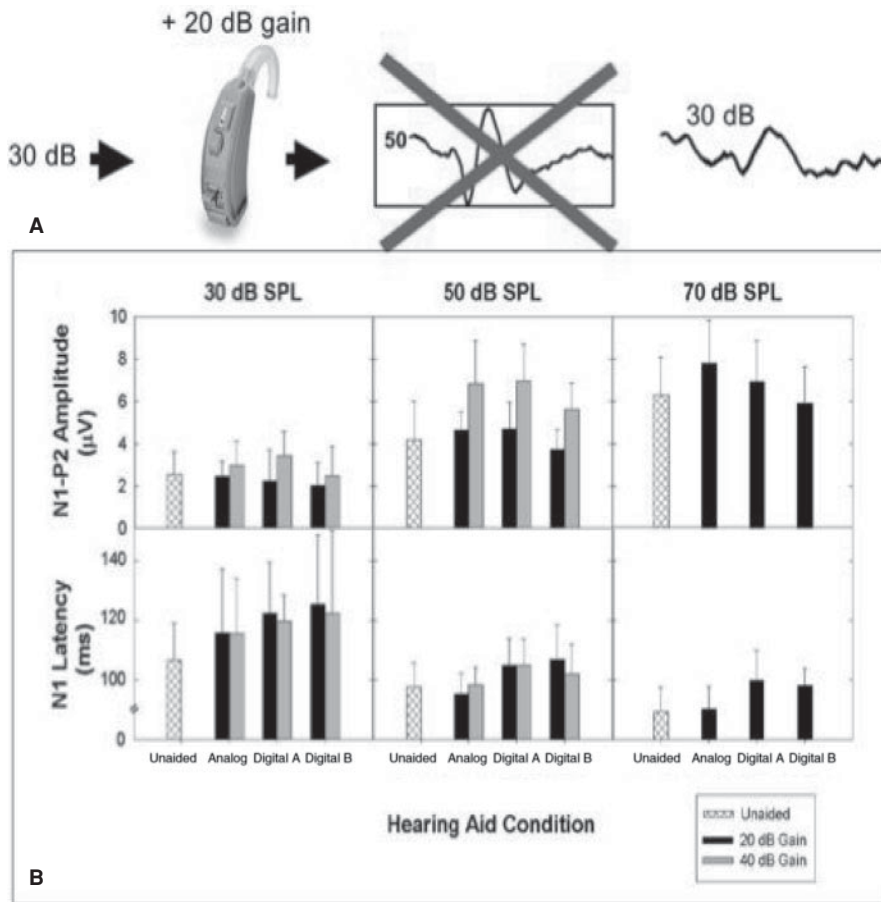

FIGURE 18.10 P1-N1-P2 peaks are earlier in latency and larger in amplitude when evoked by a 50-dB SPL signal compared to a 30-dB SPL signal (A). But when a 30-dB signal is processed through a hearing aid, and 20 dB of gain is provided, the resultant waveform does not reflect the increase in signal level (B). Despite the fact that a 50-dB signal is being transmitted to the cochlea, the aided waveform still appears similar in morphology to the response elicited by the 30-dB signal. [Reprinted with permission from Marynewich S, Jenstad LM, Stapells DR. [2012]. Slow cortical potentials and amplification-part I: n1-p2 measures. *International journal of otolaryngology*. 2012, 921513. doi:10.1155/2012/921513.]

are manipulated (Billings et al., 2007, 2011, 2012b; Jenstad et al., 2012; Marynewich et al., 2012). Figure 18.10A shows how 30 dB of sound input, amplified by 20 dB of gain, does not result in a CAEP generated by a 50-dB signal. Instead, the resultant waveform is similar to that generated by a 30-dB input signal. Marynewich et al. (2012) reported similar findings that are summarized in Figure 18.10B. N1 latency and N1-P2 amplitudes were not significantly affected when a hearing aid provided 20 or 40 dB of gain. One of the reasons for not seeing these gain effects has been attributed to the SNR of the signal coming out of the hearing aid. Billings et al. (2012b) demonstrated that the signal that comes out of the hearing aid is in fact amplified, but so is the noise level. Therefore, the SNR entering the hearing aid is not any different than the SNR being delivered to the brain. CAEPs, such as the P1-N1-P2, are sensitive to SNR, in a way that obscures the effectiveness of hearing aid gain.

The example of SNR is discussed here but there are many other signal-processing issues (channel-specific compression time constants, noise reduction algorithms, and adaptive directionality) that can impact P1-N1-P2 (and ACC) and subcortical responses because they are driven by the acoustic content of the signal. So, whereas the absence of change (in peak latencies or amplitudes) across time could be interpreted to mean a lack of neuroplasticity related to

sound transmission from the ear to the brain, an alternative explanation could be that the pattern of evoked neural activity reflects the individual signal-processing strategies of the device (e.g., changes in SNR) rather than brain plasticity. It would also be possible to appropriately fit a hearing aid (for degree and configuration of the hearing loss) in a client who showed no evoked brain response or no improvement from the unaided cortical response. Therefore, earlier studies championing the use of CAEPs as a clinical tool for assessing hearing aid functioning (Martin et al., 2008) have been tempered somewhat by more recent studies showing some of the challenges and limitations still needing to be addressed. Despite these concerns, commercial equipment is being marketed to clinicians for the purpose of measuring amplified CAEPs (Munro et al., 2012). If it becomes possible to resolve some of these issues, and take advantage of the opportunities amplified brain measures could provide, it will then be up to the clinicians to determine whether or not aided CAEPs are helpful enough to justify the additional testing time and expense of including it as an additional clinical procedure.

CAEPs and Cochlear Implants

CAEPs can also be recorded from CI users. CAEPs have been used to track developmental changes (maturation) following

cochlear implantation as well as to assist in the programming of CIs (Brown et al., 2008). Ponton et al. (1996), for example, used the P1-N1-P2 complex to define the normal maturation of auditory pathways in children with and without hearing loss. More specifically, he tracked maturational changes associated with the P1 component (because of the age group) and showed neuroplastic changes (inferred from decreased neural conduction times (latency) and increased amplitudes) following the reintroduction of sound using a CI. These findings are important because the central auditory system was thought to be hard-wired at one time, resistant to change following periods of deprivation. Ponton et al.'s results also provide further physiological evidence to reinforce the importance of early identification of hearing loss so that intervention can be achieved as early as possible, so as to capitalize on the plasticity of a developing central auditory system.

The issues described here pertaining to hearing aids also apply when sound is delivered in sound field and processed by a CI. Like hearing aids, CIs have a microphone and automatic gain controls. The signal goes through a speech processor and is then directed to select locations (channels) along an electrode array that affect place-pitch mapping as well as current intensity. SNR is not as problematic in CIs compared to hearing aids, because the level of noise is not audible to the listener. However, CAEP peak latency and amplitude values are affected by the number of channels that are active (Friesen et al., 2009), the electrode location being stimulated (Brown et al., 2008), as well as the stimulus type, level, and rate (Davids et al., 2008; Firszt et al., 2002). CAEP morphology can therefore vary widely from one CI user to the next, solely based on signal processor settings. Moreover, CI speech processors are inherently nonlinear; increases in the level of an acoustic signal presented in the sound field may or may not translate into a change in the amount of current provided by the CI. These issues pose a problem when cross-sectional designs are used to track changes over time because CAEPs are averaged across individuals who are wearing different devices. Because each individual is wearing an implant that is programmed differently, these implant settings are what will drive CAEP latencies and amplitudes. Therefore, when auditory stimuli are presented in sound field, and CI controls affecting stimulus level and location are not held constant, it is possible that CAEP neural response patterns reflect device rather than experience-related changes in brain activity (Sharma et al., 2002).

The Ponton et al.'s (1996) stimuli were delivered directly to the electrode array, bypassing the implant processor. Thus, implant settings likely did not confound the latency and amplitude of the P1 changes observed following cochlear implantation. This approach also helps to minimize the amount of implant artifact that can contaminate EEG recordings. However, understanding the functional significance of P1 changes in relation to speech discrimination and language development is an area that is still being

explored. Although Sharma and Dorman (2006) report a correlation between CAEP latency and speech and language skills, there is also evidence that P1 onset response, evoked by a brief synthetic stimulus, is not specifically related to sound discrimination. For example, P1 latencies are abnormal in alcoholics who do not have speech and language problems (Campanella et al., 2009). P1 latencies are normal in older adults who do have speech perception difficulties (Tremblay, 2005; Tremblay et al., 2003a). When people improve their perceptual skills through auditory training, there is no change in P1 latency with improved speech perception. Also, when compared to the ACC or P1-N1-P2 change response, the P1 component (signaling the onset of sound) does not correspond to behavioral discrimination thresholds; it is the change response (see Figure 18.8 as well as Won et al., 2011). As shown in Figure 18.9, P1 latencies to sound onset do not appear to be different across groups or conditions even though the TBI group showed difficulty with linguistic processing. Thus, it appears that the change responses and later discriminative CAEP responses could provide much information to the clinician if they proved to be sensitive to communication problems, specific to known disorders, and feasible to execute in the clinic.

Because CAEPs are modulated by HA and CI settings, this means CAEPs can also be used to examine the effects of different signal processing on evoked neural activity. And of all the discriminative CAEPs, the ACC might be the one that proves to be most helpful to clinicians when programming CIs. Brown et al. (2008) demonstrated that it is possible to record P1-N1-P2 change responses in CI patients by bypassing the speech processor and directly stimulating different electrode positions. In doing so, the authors demonstrated the feasibility of using the ACC in response to changes in stimulating electrode position so that the effect of different stimulation patterns on perception can be studied. He et al. (2013) showed that the ACC can be used to evaluate electrode-discrimination capacities in children who wear CIs and can serve as an objective tool for evaluating spectral-pattern detection in such subjects as well as their potential speech perception performance.

To summarize, the basic principles of EEG/MEG do not apply when stimuli are delivered through a hearing prosthesis (hearing aids and CIs). Hearing aids and CIs introduce artifact and alter the acoustic/electric properties of the incoming stimulus into the ongoing EEG/MEG, making it difficult (but not impossible) to separate biology from technology. It is therefore necessary to understand the interaction between the signal processing introduced by the hearing aid or CI and the CAEPs before clinical protocols can be considered.

CAEPs and Auditory Training

Thus far CAEPs have been described as having been used to assess the neural detection and discrimination of sound.

However, CAEPs have also been used to characterize how a person makes use of sound through various types of interactions, including auditory training exercises, music training, and other forms of auditory learning. For example, the P1-N1-P2 response has been used in human speech sound training experiments and has shown that neural response patterns change quite rapidly (Ben-David et al., 2011; Tremblay et al., 1998), precede changes in perception, and are retained for months (Tremblay et al., 2010). These points are important to the rehabilitation of people with hearing loss because they provide information about brain–behavior relationships, as well as their time course. One of the motivations underlying this area of research is the hope that EEG recordings might someday assist clinicians with aural rehabilitation. If changes in neurophysiology of a hearing/language impaired person occur following a series of auditory training sessions, this would imply that the brain’s representation of sound is changing neurally and would reinforce the use of the current (re)habilitation strategy. However, a change in neurophysiology without a change in behavior may suggest that the intervention method being used is successfully altering the brain’s ability to code the sounds, but that behavioral changes may be lagging in time or impaired because of other intervening issues such as cognition and motivation. In contrast, if there is no evidence of physiological discriminability, the audiologist could readjust device settings, or training approach, so as to improve the neural detection, discrimination, and use of the incoming signal.

ABRs (see Chapter 13) have also been used to examine the effects of different forms of training (music, commercially available clinical training programs, etc.) on brain–behavior relationships. The connection between brainstem and cortical processing, and how they work together, is nicely summarized by Shahin (2011), who also goes on to explain how learning to play a musical instrument can modify neural circuitry in a way that improves one’s ability to perceive speech more clearly in noisy environments. Importantly, auditory training exercises have been shown to partially reverse age-related declines in neural temporal precision that have been described in this chapter, as well as other publications (Anderson et al., 2013).

SUMMARY

A future goal for clinician scientists is to find ways of quantifying brain activity in a way that can better quantify the real-world processing events that are involved in perception and communication. An additional challenge is to define brain–behavior relationships in a way that is sensitive and specific to communication disorders, using methodologic approaches that can be integrated into

everyday practice. Here we reviewed how CAEPs are being used to achieve this goal. Although there are many types of neuroimaging tools (MEG, fMRI, PET), the feasibility and affordability of most preclude their use in routine clinical situations. EEG, however, is already in place in most audiology clinics and is within the audiologists’ scope of practice.

Of all the CAEPs described here, perhaps the most clinic-ready CAEP is the P1-N1-P2 complex and its use as a change response. The presence of the P1-N1-P2 complex indicates the detection of speech at the level of auditory cortex. The presence of ACC indicates that the auditory cortex can discriminate the acoustic change contained in a speech signal, and therefore provides information about speech discrimination capacity. Together, these two measurements provide tremendous insight into the capacity of the patient to access and make use of sound. If that sound happens to be amplified, or delivered by a CI, then it will be important to understand how the prosthesis is contributing to the observed CAEPs.

FOOD FOR THOUGHT

1. Which of the discriminatory cortical AEPs has the most clinical utility, being robust when recorded from individuals?
2. What is meant by the following sentence “the basic principles of CAEPs do not apply when stimuli are delivered through a hearing prosthesis or cochlear implant?”
3. Do you see the need for CAEPs being used in the clinic to assist with hearing aid and CI fittings?

Otoacoustic Emissions

Beth Prieve and Tracy Fitzgerald

INTRODUCTION

Otoacoustic emissions (OAEs) are an auditory phenomenon of interest to both auditory scientists and clinicians. OAEs are sounds that result from energy generated in the cochlea that are propagated through the middle ear and into the ear canal where they can be measured using a sensitive microphone. OAEs were first described by David Kemp in 1978, and since that time, OAEs have become a standard part of the diagnostic test battery and a screening for hearing loss. The goal of this chapter is to introduce students and clinicians to the theories underlying OAE generation, the types of OAEs, and their measurement and clinical use.

HYPOTHESES OF OAE GENERATION AND THEIR RELATIONSHIP TO AUDITORY FUNCTION

The Traveling Wave and the Cochlear Amplifier

A healthy, living cochlea demonstrates nonlinear behavior and refined frequency specificity at low stimulus levels, similar to the characteristics demonstrated by individual hair cells and auditory nerve fibers (Rhode, 1971). Active biologic mechanisms, often referred to as the “cochlear amplifier,” are believed to be responsible for the nonlinear characteristics of cochlear responses, as well as the exceptional sensitivity and frequency selectivity seen in a healthy cochlea as compared to a damaged or dead cochlea. The cochlear amplifier is hypothesized to contribute additional energy that enhances the vibration of the basilar membrane at the peak of the traveling wave, particularly at low stimulus levels (Davis, 1983). Evidence indicates that outer hair cells (OHCs) contribute to this process. Investigators have reported reduced auditory sensitivity, broader tuning, and abnormal response growth when OHCs are damaged or missing (e.g., Dallos and Harris, 1978; Liberman and Dodds, 1984). OAEs measured in the ear canal are thought to be a byproduct of the cochlear amplifier and normal OHC function.

OAEs and Outer Hair Cells

OAEs are a pre-neural phenomenon and can be measured even when the eighth nerve has been severed (Siegel and Kim, 1982). Unlike neural responses, OAEs are unaffected by stimulus rate (Kemp, 1982) and reverse polarity along with the stimulus (Schmiedt and Adams, 1981). In addition, OAEs, particularly those evoked using low stimulus levels, are vulnerable to such agents as acoustic trauma (Schmiedt, 1986), hypoxia (Rebillard and Lavigne-Rebillard, 1992), and ototoxic medications (Brown et al., 1989), which cause hearing loss and damage to OHCs (Dallos and Harris, 1978). OAEs do not appear to be vulnerable to selective loss of inner hair cells (IHCs) (Liberman et al., 1997).

Two hypotheses regarding the OHCs’ role in the cochlear amplifier have been explored: Somatic motility of OHCs and nonlinear mechanics of the OHC stereocilia bundle. OHCs demonstrate rapid changes in length in response to electrical stimulation (Ashmore, 1987; Brownell et al., 1985). “Prestin” is the molecular motor responsible for somatic OHC motility (Zheng et al., 2000). Reduced OHC length, absence of OHC motility, and IHC and OHC loss in the basal portion of the cochlea were observed in mice when the prestin gene was deleted. The mutant mice had thresholds elevated by 35 and 60 dB when measured by auditory brainstem responses (ABRs) and OAE thresholds (Liberman et al., 2002).

It seems unlikely that somatic motility of OHCs is the sole source of cochlear amplifier energy and OAEs. OAEs have been measured from species that do not have OHCs (e.g., Manley et al., 1996). OAEs measured in nonmammalian species, whose hair cells are not capable of somatic motility, have been attributed to active hair bundle movements of the hair cell stereocilia (Ricci et al., 2000). Hair cell stereocilia bundles demonstrate frequency selectivity, can provide amplification, and have a force-generating component, all properties needed for the cochlear amplifier. Both OHC somatic motility and stereocilia may contribute to the production of OAEs in mammals, and their contributions may be stimulus-level dependent (Liberman et al., 2004).

OHCs receive the majority of the ear’s efferent innervation (Warr et al., 1986), which may act as a regulatory system that allows higher neurologic centers to exert control over cochlear processes such as OHC motility. Direct electrical

stimulation of efferent fibers has been shown to reduce or enhance OAE responses (Siegel and Kim, 1982). Indirect stimulation of the efferent system by means of ipsilateral, contralateral, or binaural sound stimulation has also been shown to alter OAE levels (Berlin et al., 1995; Collet et al., 1990).

Two OAE Generation Mechanisms

Initially, all OAEs were thought to arise from the same mechanism, that is, nonlinear electromechanical distortion within the cochlea resulting, at least in part, from OHC somatic motility (e.g., Kemp and Brown, 1983). The theory that OAEs arise from at least two different mechanisms has changed the way researchers talk about the sources of OAEs and OAE classification (Shera and Guinan, 1999; Talmadge et al., 1999). In early work, Kemp and colleagues studied phase changes as a function of stimulus frequency for different types of OAEs and found two distinct patterns (Kemp,

1986; Kemp and Brown, 1983). Shera and Guinan later attributed the two patterns to different mechanisms: Nonlinear distortion and linear coherent reflection. Nonlinear distortion emissions are attributed directly to the action of OHCs. The source of nonlinear distortion, or “wave-fixed,” emissions is believed to follow the traveling wave envelope of the stimulus (e.g., Shera and Guinan, 1999). Therefore, because the shape of the traveling wave does not change significantly as the stimulus is swept in frequency, the phase at any point moving with the traveling wave envelope will not change significantly, as schematized in the left panel of Figure 19.1. Thus, nonlinear distortion emissions are characterized by gradual phase changes as the stimulus frequencies are increased.

Reflection, or “place-fixed,” emissions are characterized by phase that rotates rapidly with changes in stimulus frequency, shown by a schematic diagram in the right panel of Figure 19.1. These emissions are proposed to be the result of the incoming traveling waves scattering off of

FIGURE 19.1 Schematic illustrations of the phase behavior for emissions arising from either nonlinear distortion (**left panel**) or coherent linear reflection (**right panel**) mechanisms. In either panel, the f_2 traveling wave at two frequencies is shown, one peaking at a more apical location than the other (*top*) along with the corresponding phase lag versus the distance along the basilar membrane (*bottom*). The phase lag function for the more apical wave lies above that for the more basilar wave. For ease of viewing, the f_2 traveling waves have been exaggerated relative to the size of the stapes, the f_1 traveling waves are not shown, and the distortion and reflection sources are idealized as single points (*asterisks*). As seen in the panel on the left, as f_2 is changed to a higher frequency (more basal), the distortion source moves with the wave; therefore, the phase of the wave at the source remains constant as frequency is increased. In the right panel, as f_2 is changed to a higher frequency, the reflection source remains fixed; therefore, the phase at the source changes rapidly as frequency is increased. [Reprinted with permission from Kalluri R, Shera C. [2001] Distortion-product source unmixing: a test of the two-mechanism model for DPOAE generation. *J Acoust Soc Am*. 25 [2], 86–97; ©2001, American Institute of Physics.]

random impedance perturbations in the mechanics of the cochlea or impedance mismatches present at or near the largest displacement of the traveling wave (e.g., Shera and Guinan, 1999). The source of the impedance perturbations is not known, but hypotheses include variations in OHC arrangement or variations in OHCs at the cellular level (Shera, 2004). Shera and Guinan (1999) explain the non-linear behavior of reflection emissions, such as compressive growth functions, as the result of level-dependent amplification of the forward and reverse traveling waves because of the action of the cochlear amplifier. In this way, reflection emissions, although not generated by the action of OHCs, would be acted on by these forces and would, therefore, still be vulnerable to changes in OHC function.

OAEs measured in the ear canal are thought to be a combination of energy from both mechanisms (Knight and Kemp, 2000; Shera and Guinan, 1999). At this time it is not known whether emissions arising from the two mechanisms might be used differently to provide information about cochlear function. Shera (2004) and others have suggested that by “un-mixing” the energy from the two mechanisms and examining each separately, diagnostic and screening tests with OAEs might be improved. This issue is addressed later in this chapter.

MEASUREMENT OF OAEs

A general recording setup for measuring OAEs includes a sensitive, miniature microphone that fits in the ear canal. Typically, the microphone is housed in a small probe that is coupled to the ear with a foam or rubber tip. The probe contains one or two speakers that allow for presentation of sound stimuli. The microphone measures the OAE coming from the ear and, in the case of some OAEs, also measures the stimuli presented to the ear. The output of the microphone is then amplified. Typically, the amplified output is sampled via an analog-to-digital converter, housed either in a computer or in a stand-alone piece of equipment. The output is then appropriately analyzed for the type of OAE.

The noise level arising from a combination of environmental and internal sources has a significant effect on OAE recordings. High noise levels can obscure low-level OAEs. When high noise levels are present, the number of averages collected must be increased, thereby increasing the test time necessary to obtain a clear OAE recording. Several factors can aid in reducing the effects of noise. First, it is essential to minimize the amount of environmental noise by choosing a quiet or, if possible, sound-treated room as the location for testing. Nonessential equipment, such as fans, should be turned off. Second, the state of the patient being tested must be assessed and addressed. The high noise levels produced by an infant or child that is crying, talking, or generally restless will make testing impossible or extremely difficult. Instructing parents ahead of time as to the nature of the test and that an infant should be asleep during testing

can be extremely helpful. Adult patients and older children should be given clear instructions to remain still and quiet during testing. Finally, the importance of an adequate probe fit cannot be overemphasized. A snug and secure probe fit will generally reduce the effects of environmental noise, as well as prevent the loss of low-frequency stimulus energy.

TYPES OF OAEs

Before the recent classification of OAEs based on generation mechanism (e.g., Shera and Guinan, 1999), OAEs were classified into two types based on the recording paradigm, spontaneous and evoked. As the name suggests, spontaneous OAEs (SOAEs) are recorded in the absence of any external stimulation. Evoked OAEs (EOAEs) are measured during or following presentation of an acoustic stimulus to the ear. EOAEs are further subcategorized by the type of stimulus used and related measurement procedure. The clinical literature continues to use this traditional taxonomy; therefore, we will use it here for description of OAEs and their clinical applications.

Spontaneous Otoacoustic Emissions

SOAEs are measured in the absence of external stimulation. They can be measured by viewing what is recorded by the microphone in the frequency domain. As Figure 19.2 illustrates, SOAEs appear as puretone-like signals coming from the ear. This ear has multiple SOAEs, that is, SOAEs at more than one frequency.

SOAEs are measurable in approximately 50% of normal-hearing children and adults. The actual estimates range from 40% (Strickland et al., 1985) to as high as 72% (Talmadge et al., 1993). The wide range of estimates could be because of

FIGURE 19.2 An example of SOAEs measured from a normal-hearing human. Three SOAEs are measurable. [Modified and used with permission from Lonsbury-Martin BL, Whitehead ML, Martin GK. [1991] Clinical applications of otoacoustic emissions. *J Speech Hear Res.* 34 [5], 964–981; ©1991, American Speech-Language-Hearing Association.]

small sample sizes and recording systems with different noise floors. SOAEs can be measured in ears having hearing loss no greater than 25 to 30 dB HL (Bright and Glattke, 1986). Because they can be measured in only 50% of normal-hearing ears, they are not a useful clinical test. For example, if an individual does not have SOAEs, the clinician cannot distinguish whether that ear has normal hearing or hearing loss. Statistical analyses based on grouped data indicate that the prevalence of SOAEs is higher in females than in males and in right ears than in left ears. Having an SOAE in one ear increases the likelihood that an SOAE will be present in the other ear (Bilger et al., 1990).

Following Kemp's (1979) first report of SOAEs, speculation arose that they might be an objective correlate of at least some forms of tinnitus (Moller, 1989). Studies examining the connection between SOAEs and tinnitus have generally reported that the two phenomena appear to be independent events (Penner and Burns, 1987). Reports of a possible causative relationship between SOAEs and tinnitus have been limited to a few case studies of patients who had normal-hearing sensitivity in at least some frequency regions (Penner, 1988).

Stimulus-Frequency Otoacoustic Emissions

Stimulus-frequency OAEs (SFOAEs) occur at the same frequency and at the same time as a continuous puretone applied to the ear. The microphone in the ear canal records the combination of the puretone being presented to the ear and the SFOAE evoked by the puretone; therefore, specialized measurement techniques must be used to extract the SFOAE from the total signal measured in the ear canal. Common techniques involve introducing a second stimulus differing in intensity or frequency that takes advantage of the nonlinear properties of the SFOAE (e.g., Brass and Kemp, 1991; Schairer and Keefe, 2005). For example, using a tone that is slightly higher or lower in frequency than the evoking stimulus suppresses the SFOAE. A vector subtraction can be made between the sound pressure level in the ear canal when the tone is presented alone (tone plus SFOAE) and the SPL when the tone is presented in the presence of the suppressor (tone alone). The difference between the two conditions is attributed to the SFOAE, or depending on the specifics of the second tone, the portion of the SFOAE that remains unsuppressed by the second tone (e.g., Shera and Guinan, 1999). Other methods, employing three or four condition intervals, have also been used and produce similar results (Brass and Kemp, 1991; Schairer and Keefe, 2005).

Auditory researchers have used SFOAEs to examine various aspects of cochlear function, including cochlear tuning (Shera and Guinan, 2003), and function of the efferent auditory system (Guinan et al., 2003). SFOAEs have not been used as a routine clinical measure, and there are no commercial devices designed to record SFOAEs. Ellison and Keefe (2005)

demonstrated that SFOAEs identified hearing loss as well as other EOAEs at 1,000 and 2,000 Hz and were superior to other EOAEs in identifying hearing loss at 500 Hz in their sample of 85 ears. Improvements in measurement techniques and further research on SFOAEs measured under clinical conditions may open the door to future use in general clinical settings.

Transient-Evoked Otoacoustic Emissions

Transient-evoked OAEs (TEOAEs) were the first type of OAE reported in the literature (Kemp, 1978). As their name suggests, TEOAEs are measured following the presentation of a transient or brief stimulus. A click or toneburst is presented to the ear, and the response occurs following a brief time delay. Measurement of TEOAEs is accomplished using time-synchronous averaging. Although the averaging reduces the amount of noise in the trace, it does not remove the stimulus artifact at the start of the recording. The stimulus artifact under typical recording conditions is much larger than the recorded TEOAE. The energy from the stimulus may also persist in the ear canal long enough to obscure the onset of the TEOAE response. Therefore, the first few milliseconds of the trace are usually eliminated from the final averaged waveform to remove energy because of the stimulus.

Figure 19.3 is an example of TEOAE waveform evoked by a click recorded from an adult ear. This example was obtained using Otodynamics ILO88 software and accompanying hardware, the first commercially available program for recording TEOAEs. When a click is used as the stimulus, the resulting TEOAE is often referred to as a click-evoked OAE (COAE or CEOAE). The waveform of the click stimulus is located in the upper left-hand corner of the display. The amplitude spectrum of the click is displayed in the box under the heading "Stim = 80.0 dB." The click used to

FIGURE 19.3 An example of a COAE recorded from the ear canal of an adult using the Otodynamics ILO88 system.

evoke the COAE was 80 dB pSPL. The largest portion of the display in the lower right contains the waveform of the COAE in the time domain. Notice that the first 2.5 ms have been eliminated to remove the stimulus artifact. If you look closely, you can see that the response is actually composed of two waveforms that have been superimposed. During testing, TEOAE measurement software alternately stores an averaged response in each of two separate buffers, resulting in two averaged traces (labeled “A” and “B” in Figure 19.3).

Comparison of these two waveforms allows the software to determine several TEOAE parameters. For instance, the software calculates the difference between the two waveforms and reports this as the noise level in dB SPL, displayed next to “A–B” in the right-hand column (1.8 dB SPL). The cross-power spectrum of the two waveforms is also calculated and displayed. The cross-power spectrum can be seen in the upper right portion of the display under the heading “Response FFT” (response fast Fourier transform). TEOAE levels are indicated by the dark-shaded regions, whereas the noise levels are indicated by the superimposed lighter-shaded regions.

TEOAEs are often evaluated in terms of level, percent reproducibility, and TEOAE/noise (sometimes called signal-to-noise ratio or SNR). The level of the TEOAE is usually expressed in dB SPL. The level in the example is 10.7 dB SPL and can be found next to the term “Response” in the right-hand column. Below the heading “Band Repro% SNR dB,” the percentage reproducibility of the TEOAE in each of the linear frequency bands beginning at 1,000, 2,000, 3,000, 4,000, and 5,000 Hz is listed. Percent reproducibility in this case refers to how well the two TEOAE traces correlate with one another. The software computes inter-waveform correlations in each frequency band, as well as for the broadband waveform, and displays them as percentages. TEOAE/noise or SNR is a ratio of the level of the TEOAE (the “signal”) to the level of the noise expressed in dB. TEOAE/noise may be given for the overall TEOAE response or in separate frequency bands. TEOAE/noise levels in Figure 19.3 are listed for the same linear frequency bands under percent reproducibility.

BASIC CHARACTERISTICS OF TEOAEs AND THE EFFECTS OF STIMULUS AND RECORDING PARAMETERS

Kemp noted in his initial report on TEOAEs that the different frequency components of the evoked responses emerge at different times. Kemp called this phenomenon “frequency dispersion” (Kemp, 1978, p 1387). The dominant period of oscillation changes over time such that higher frequency components of the response appear first, followed by lower frequency components. Typically this phenomenon is described in terms of “latency”: higher frequency components have shorter latencies, whereas lower frequency components have longer latencies. Although the measured

latencies vary across individuals, the pattern of increasing latency with decreasing frequency remains constant across individuals (Kemp, 1978).

The spectrum of a TEOAE is dependent upon several factors related to the stimulus and recording parameters. One such factor is the spectrum of the evoking stimulus. Broadband click stimuli generally evoke broadband responses. Toneburst-evoked OAEs (TBOAEs) are more frequency specific and typically limited to the frequency range of the narrowband stimuli used to evoke them (Probst et al., 1986). Figure 19.4 displays TBOAEs evoked by tonebursts with carrier frequencies at 1,000 (panel A) and 4,000 Hz (panel B) that were measured with the Otodynamics ILO88 system. The features of the display are identical to those in Figure 19.3. The spectrum of TBOAE energy is narrower than that of the broadband COAE response shown in Figure 19.3.

TEOAE spectra are also influenced by the filter setting and recording time window. As mentioned previously, the stimulus artifact must be removed from the start of the

FIGURE 19.4 Examples of TBOAEs recorded from adults using tonebursts centered at **(A)** 1,000 Hz and **(B)** 4,000 Hz. The recordings were obtained using the Otodynamics ILO88 system.

FIGURE 19.5 A COAE growth function recorded from an adult. The *filled circles* indicate COAE levels in dB SPL. The *small Xs connected by dotted lines* indicate the corresponding noise floor levels in dB SPL. The COAE level grows linearly with increases in stimulus levels at low-to-moderate levels of stimulation; however, the COAE level begins to saturate at higher levels of stimulation [60 to 70 dB pSPL].

averaged trace. Unfortunately, the removal of the first few milliseconds from the trace may also result in the loss of some high-frequency components of the response. The greater the number of milliseconds eliminated from the start of the trace, the greater the amount of high-frequency energy that is potentially eliminated. Conversely, reducing the length of the response time window can result in the loss of some low-frequency energy. The exact TEOAE spectrum and the latency of the different frequency components measured are unique to each individual (Kemp, 1978). These individual TEOAE features are stable within a given ear over time, barring changes in hearing sensitivity (Antonelli and Grandori, 1986).

TEOAE level varies with stimulus level. TEOAE level displays nonlinear growth characteristics in the majority of ears. An example of a TEOAE growth or input/output (I/O) function can be seen in Figure 19.5. At low-to-moderate stimulus levels, growth is fairly linear. However, at higher levels of stimulation, typically between 50 and 80 dB pSPL depending on the type of stimulus used, growth functions show saturation (Zwicker, 1983). As the stimulus level is increased at these high levels, little or no growth in the TEOAE level is noted. The growth function in Figure 19.5 shows saturation between click levels of 60 and 70 dB pSPL.

TEOAE level also varies widely across individuals. For example, Robinette (1992) reported COAE levels for a group of 265 normal-hearing adults that ranged from 0.1 to 22.3 dB SPL in response to clicks presented at a mean level of 81 dB pSPL (SD = 2.7 dB). Results from studies in our laboratory have indicated that the standard deviation for

COAE levels recorded at click levels from 40 to 80 dB pSPL is approximately 5 dB (Prieve et al., 1997a).

It is important to keep in mind the spectrum of the stimulus when examining TEOAE growth functions and, in particular, when making comparisons between COAEs and TBOAEs. Although a toneburst and click may have the same overall peak level, the energy from the click is distributed across a much broader range of frequencies. This will result in a lower spectrum level at any given frequency for the click. When click and toneburst stimuli are equated for spectrum level, levels and growth behavior of TEOAEs evoked by the two stimuli are similar (Prieve et al., 1996).

Distortion-Product Otoacoustic Emissions

Distortion-product OAEs (DPOAEs) are measured simultaneously with the presentation of two puretone stimuli, called “primaries”, to the ear. The frequencies of the primaries are conventionally designated as “ f_1 ” and “ f_2 ” ($f_1 < f_2$) and the corresponding levels of the primaries as “ L_1 ” and “ L_2 .” When f_1 and f_2 are reasonably close in frequency, interaction of the two primaries on the basilar membrane results in the output of energy by the cochlea at other discrete frequencies that are arithmetically related to the frequencies of the primaries (e.g., $f_2 - f_1$, $2f_1 - f_2$, $3f_1 - 2f_2$, $2f_2 - f_1$). DPOAEs can therefore be measured using narrowband filtering centered at the frequency of interest. The spectrum in Figure 19.6 displays

FIGURE 19.6 A spectrum showing two input primaries [$f_1 = 1.807$ kHz, $f_2 = 2.002$ kHz, $L_1 = 65$ dB SPL, and $L_2 = 60$ dB SPL] and the resulting DPOAEs from the ear of a 16-month-old child. Several DPOAEs occurring at frequencies below the primaries [$4f_1 - 3f_2 = 1.222$ kHz, $3f_1 - 2f_2 = 1.417$ kHz, $2f_1 - f_2 = 1.612$ kHz] and above the primaries [$2f_2 - f_1 = 2.197$ kHz] are labeled.

the primaries and DPOAEs measured in the ear canal of a 16-month-old child (using the Otodynamics ILO92 software). Notice that DPOAEs are present at frequencies both lower (e.g., $2f_1-f_2$, $3f_1-f_2$) and higher (e.g., $2f_2-f_1$) than the primaries.

DPOAEs measured in the ear canal are a combination of energy from a nonlinear distortion component originating at the region of overlap between the primaries and a reflection component originating from the region of the DPOAE frequency (e.g., Shera and Guinan, 1999). The mechanism that dominates the response seems to depend on which DPOAE is being measured, as well as the primary levels and the frequency relationships between the primaries (Knight and Kemp, 2000). Additional sources located basal to the f_2 primary tone may also contribute to the $2f_1-f_2$ DPOAE level under some measurement conditions (Martin et al., 2011).

DPOAE measurement systems provide a measure of both the DPOAE and surrounding noise level. The noise level is most often determined by averaging the levels in several frequency bins on either side of the DPOAE of interest. The presence of a particular DPOAE is determined by comparing the level measured within its frequency bin with the noise levels in the surrounding frequency bins and employing some difference criterion. For instance, the DPOAE might be considered present if its level is 3 dB or more above the level of the surrounding noise floor, or if its level exceeds 2 standard deviations above the mean noise level.

On average, the $2f_1-f_2$ DPOAE has the largest level in human and other mammalian ears compared to other DPOAEs (Gaskill and Brown, 1990). As a result, $2f_1-f_2$ is the DPOAE that has been the most extensively investigated, particularly for clinical purposes. The $2f_1-f_2$ DPOAE has sometimes been referred to as the cubic difference tone (CDT). Unless otherwise specified, the use of the term DPOAE will henceforth refer to $2f_1-f_2$.

BASIC CHARACTERISTICS OF THE $2F_1-F_2$ DPOAE AND THE EFFECTS OF STIMULUS AND RECORDING PARAMETERS

DPOAE levels vary widely across individual ears. Typical DPOAE levels reported for adults range from 45 to 75 dB below the level of equal-level primaries (Lonsbury-Martin et al., 1990). Early studies revealed that $2f_1-f_2$ level is highly dependent upon various parameters of the primary tones, including their frequency, frequency separation, level separation, and overall level (Gaskill and Brown, 1990; Harris et al., 1989). The frequency separation of the two primaries, generally described as the f_2/f_1 ratio, influences the DPOAE level that will be measured. Figure 19.7 displays DPOAE level as a function of f_2/f_1 as measured from an individual adult ear for $f_2 = 4,000$ Hz and L_2 levels of 40, 50, and 60 dB SPL when $L_1-L_2 = 15$ dB. As f_2/f_1 is decreased from larger values (~ 1.5) to progressively smaller values, DPOAE level increases to a broad maximum and then progressively

FIGURE 19.7 A graph of DPOAE level as a function of f_2/f_1 ratio from an adult ear at three different stimulus levels [$f_2 = 4,000$ Hz]. The primary levels used to evoke the DPOAEs were $L_1 = 75$ and $L_2 = 60$ dB SPL [circles], $L_1 = 65$ and $L_2 = 50$ dB SPL [squares], and $L_1 = 55$ and $L_2 = 40$ dB SPL [triangles]. As the ratio f_2/f_1 is decreased from a value of approximately 1.5, the DPOAE level increases to a broad maximum at ratios of 1.2 to 1.3 and then declines as the ratio is further decreased. The band-pass-shaped function is typical in both infants and adults.

decreases. The exact shape of the function and the f_2/f_1 that produces the maximum DPOAE level vary across individuals, stimulus levels, and frequencies (Neely et al., 2005). However, when data are averaged across many persons, the largest DPOAE levels have repeatedly been obtained with an f_2/f_1 of approximately 1.2 (Harris et al., 1989). As a result, an f_2/f_1 ratio of approximately 1.2 is a common default setting for DPOAE measurement in the clinic. The general shape and features of f_2/f_1 functions appear to be the same for newborns and adults (Abdala, 1996).

The decrease in level at large ratios, that is, when the two primary frequencies are widely separated, is not surprising. The further apart the primaries are from one another, the less the interaction of their respective traveling waves on the basilar membrane. At small ratios, the most likely scenario is that interaction of waves from two or more sources within the cochlea results in cancellation of some energy (Stover et al., 1999). Clinical studies have fixed f_2/f_1 to values approximating 1.2 to evoke maximal DPOAE levels in the greatest number of persons.

The level difference between the two primaries (L_1 vs. L_2) also affects the measured DPOAE level. The level difference that produces the largest DPOAE levels depends on overall primary levels. Equal-level primaries produce the largest DPOAEs at high levels of stimulus presentation; however, the level difference between the two primaries that produces the largest DPOAEs increases ($L_1 > L_2$) as the overall level of the primaries decreases (Gaskill and Brown,

1990; Harris et al., 1989). Kummer et al. (1998) suggested using the equation $L_1 = 0.4 \times L_2 + 39$ dB (for $L_2 < 65$ dB SPL) to set the primary levels to generate maximal DPOAE levels. The equation was based on earlier data (Gaskill and Brown, 1990) and designed to allow for level-dependent changes in the overlap between the two primaries at the f_2 place. Later work by Neely and colleagues indicated that larger DPOAE levels could be measured if the L_1 and L_2 relationship varied with f_2 frequency as well as with L_2 level (Johnson et al., 2006; Neely et al., 2005); however, customizing level and frequency ratios has not improved identification of hearing loss (Johnson et al., 2010).

As would be expected, changes in the overall levels of the primaries also affect DPOAE level. As with TEOAEs, the effects of overall primary levels on DPOAE level are usually graphed as a growth function. With the primaries fixed at a specific pair of frequencies, the DPOAE level is recorded as the levels of the primaries are increased. In general, DPOAE level increases as the level of the primaries increase. Growth functions that include data averaged across a group of persons usually display growth similar to that seen for TEOAEs (e.g., Lonsbury-Martin et al., 1990). However, individual growth functions have a variety of shapes.

TEOAEs and DPOAEs and Patient Characteristics

Whenever a measurement tool is proposed for clinical use, an important step is to determine normative values. One part of this process is to determine whether measured differences can be explained by patient characteristics such as age or gender. TEOAE and DPOAE levels change with development from infancy to adulthood; however, the exact time course remains uncertain. Early group data established that COAE and DPOAE levels in neonates (infants less than 1 month of age) are larger than in adults (Kok et al., 1993). TEOAEs and DPOAEs are also significantly larger in infants than in toddlers, older children, and adults (Prieve et al., 1997a, 1997b). Differences in level with development are frequency dependent, with infants and children having higher EOAE levels than older children and adults for the higher frequencies but not lower frequencies (Prieve et al., 1997a, 1997b). The differences in EOAE levels across age groups have most often been attributed to anatomical changes in the outer or middle-ear systems that occur with development (e.g., Keefe and Abdala, 2007).

The effect of increased age on COAEs and DPOAEs has been more difficult to study, because behavioral thresholds tend to worsen with increasing age, creating a confounding factor. Several early studies reported decreasing COAE and DPOAE levels with increasing age; however, they did not control for auditory threshold (Bonfils et al., 1988). The results of most studies that attempted to control for behavioral thresholds indicated no aging effects on TEOAEs (Stover and Norton, 1993). Older ears have lower DPOAE

levels at 8,000 Hz, but the difference is small and has little clinical significance (Dorn et al., 1998).

There are small but significant differences in TEOAE levels depending on ear and gender. Females, on average, have larger TEOAEs than males and right ears, on average, have larger TEOAEs than left ears. The exact reasons for these differences are unknown, although investigators hypothesize that the smaller size of the female ear canal on average compared to the male ear canal may result in the higher TEOAE levels measured in female ears (Robinette, 1992). The greater number of SOAEs measured in right ears as compared to left ears and in females as compared to males may also contribute to the noted TEOAE level differences (Bright and Glatke, 1986). For DPOAEs, some researchers have found that DPOAE levels are larger in females than in males (Gaskill and Brown, 1990). Others have reported significant differences between the sexes at only select frequencies (Lonsbury-Martin et al., 1997). Lonsbury-Martin et al. (1997) reported no significant differences in DPOAE levels between the right and left ears. Both TEOAE and DPOAE levels are generally larger in ears with measurable SOAEs compared to ears without any measurable SOAEs (Prieve et al., 1997a, 1997b). The presence of SOAEs also affects the spectrum of TEOAEs. SOAEs can synchronize to the evoking stimulus, resulting in peaks at those frequencies in the TEOAE spectrum (Probst et al., 1986).

OAEs ARE EXCELLENT CLINICAL TESTS

Before beginning a discussion of clinical applications of EOAEs, it should be noted that middle-ear status has an effect on EOAE measurements. Stimuli used to evoke the EOAE must pass through the middle ear to stimulate the cochlea, and the EOAE energy must pass through the middle ear for it to be detected in the ear canal. Middle-ear pathology may reduce OAE amplitude or eliminate the ability to measure OAEs entirely, depending on the type and severity of the pathology (Owens et al., 1992; Prieve et al., 2008). The majority of the clinical research studies of OAEs have attempted to include only ears free of middle-ear pathology, usually confirmed by routine immittance testing and/or the absence of any air-bone gaps on the audiogram. Obtaining middle-ear measures to elucidate middle-ear function is essential for interpretation of OAE results, particularly when using OAEs for differential diagnosis.

Any clinical test must be robust and accurately identify diseased and nondiseased systems. In his original paper, Kemp (1978) demonstrated that individuals with at least moderate hearing loss had no TEOAEs for low-level stimuli. As audiologists, the critical questions are, given an EOAE test result, what is the expected hearing loss, and what is the range of error? The first step in addressing these questions is to view distributions of EOAEs in normal-hearing and hearing-impaired populations. The goal is to select appropriate

FIGURE 19.8 Frequency distributions of TEOAE level [dB SPL] evoked by 80-dB pSPL clicks (nonlinear recording mode) for normal-hearing [solid bars] and hearing-impaired ears [striped bars]. [Modified and reprinted with permission from Prieve BA, Gorga MP, Schmidt A, Neely S, Peters J, Schultes L, et al. [1993] Analysis of transient-evoked otoacoustic emissions in normal-hearing and hearing impaired ears. *J Acoustic Soc Am.* 93, 3308–3319; ©1993, Acoustical Society of America.]

criteria that will classify a person as either normal or hearing-impaired. Figure 19.8 illustrates histograms for TEOAE level evoked by 80-dB pSPL clicks from normal-hearing participants (solid bars) and hearing-impaired participants (striped bars). Normal-hearing participants tend to have TEOAEs with higher levels (bars further to the right on the x-axis) and hearing-impaired participants tend to have TEOAEs with lower levels (further to the left on the x-axis). However, some overlap exists between the two groups of participants, that is, there are some normal-hearing and hearing-impaired participants who have similar TEOAE levels. Unfortunately, this overlap means that it will not be possible to separate the two groups with complete accuracy using EOAEs as they are currently measured, although test performance, as we will see, is still fairly good.

One way to evaluate how well EOAE levels identify hearing status as normal or impaired is to use statistical decision theory. This theory underlies signal detection theory (Green and Swets, 1966, 1974) and clinical decision analysis (Weinstein and Fineberg, 1980). To complete these analyses, data must be collected on a large group of participants for whom hearing status is known. Audiometric threshold is used as the “gold standard” against which the EOAE results are compared. An audiometric criterion is

chosen to classify each person as normal hearing or hearing impaired. A typical criterion is 20 dB HL; those with audiometric thresholds of 20 dB HL or better would be classified as having normal hearing whereas those with thresholds higher than 20 dB HL would be classified as having hearing impairment. Second, various EOAE parameters and criteria (e.g., range of EOAE levels in dB SPL, range of EOAE/noise, range of percent reproducibility) are varied to determine the percentage of “hits” and “false alarms” for each EOAE criterion. The percentage of hits (“hit rate”) can be plotted as a function of the percentage of false alarms from all the two-by-two tables, resulting in a relative operating characteristic (ROC) curve. Example ROC curves from Prieve et al. (1993) for overall TEOAE level (squares), TEOAE/noise (circles), and percent reproducibility (triangles) are shown in Figure 19.9. The dotted lines illustrate theoretical ROC curves and their corresponding d' , which is a measure of the distance between two means of populations having equal-variance, Gaussian distributions.

The less overlap there is between the two populations, the more accurately the test will identify members of the two groups and the more the data in the ROC curve will be located in the upper left-hand corner of the plot. One way to measure the accuracy of the test is to measure the area under the ROC curve, referred to as $P(A)$. The area under the curve

FIGURE 19.9 ROC curves for broadband responses from the ILO88. TEOAE level, TEOAE/noise, and percent reproducibility are represented by different symbols. [Modified and reprinted with permission from Prieve BA, Gorga MP, Schmidt A, Neely S, Peters J, Schultes L, et al. provides an approximation of the hit rate averaged across all false alarm rates. A perfect test that completely separates the two groups would yield a $P(A)$ of 1.0 (hit rate rises to 1.0 whereas false alarm rate remains at 0) whereas a test that separates the two groups no better than chance would yield a $P(A)$ of 0.5 (equal hit and false alarm rates for the various criteria).

TEOAEs

For broadband TEOAEs, the ability to separate normal and hearing-impaired ears is good, and equally so for the three different TEOAE parameters analyzed. The areas under the ROC curves shown in Figure 19.9 are all 0.92. For this analysis, the broadband TEOAE data were compared to the worst threshold at either 500, 1,000, 2,000, or 4,000 Hz. To determine if reduction or absence of TEOAEs in a particular frequency band could predict hearing loss at the corresponding audiometric frequency, the broadband TEOAE was parsed into one-octave bands. The ROC curves for each of the bands are shown in Figure 19.10. Again, all three TEOAE parameters perform almost equally well for separating normal-hearing from hearing-impaired ears. Identification of hearing loss is excellent at 2,000 and 4,000 Hz, indicated by the fact that the ROC curves fall into the upper left-hand corner of the plots and the $P(A)$ values are high. Identification of hearing loss is fair at 1,000 Hz and there is virtually no separation in the responses from normal-hearing and hearing-impaired ears at 500 Hz. These results suggest that TEOAEs evoked by 80-dB pSPL clicks parsed into frequency bands identify hearing loss well at 2,000 and 4,000 Hz, but not at lower frequencies. Prieve et al. (1993) also found that ROC curves were best when using audiometric criterion of 20 or 25 dB HL to separate normal-hearing and hearing-impaired ears.

Subsequent studies have expanded on this early research to determine if improvement in identification of hearing loss can be obtained when using tonebursts, different stimulus levels, and combinations of toneburst and click stimuli presented at different levels (Vinck et al., 1998). Tonebursts centered at 500 Hz provide better separation of normal and hearing-impaired ears than using a 500-Hz band analyzed from a wide-band, click-evoked TEOAEs, but TEOAEs evoked by 2,000-Hz tonebursts were not better than the 2,000-Hz band of a click-evoked response (Lichtenstein and Stapells, 1996). Various stimulus levels have also been studied. Harrison and Norton (1999) reported that the hit rate for identification of hearing loss given a 5% false-positive rate is higher for 80-dB peSPL clicks than for 86-dB peSPL clicks. Vinck et al. (1998) reported that TEOAEs evoked by 86-dB peSPL clicks have a lower hit rate, but higher correct rejection rate, than those evoked by 65-dB peSPL clicks. Based on these results, it appears that mid-level clicks (65 to 80 dB pSPL) may be best for identification of hearing loss.

Investigators have performed multivariate analysis to determine whether combining information from several different TEOAE parameters (such as TEOAE level and the surrounding noise) for various frequencies can identify hearing loss better than using a single parameter to identify hearing loss at the corresponding frequency. The assumption is that a multivariate approach may take advantage of any interactions across frequency and result in an improvement of identification of hearing loss. Hussain et al. (1998) measured TEOAEs over a 12.5-ms window evoked by 80-dB pSPL clicks in participants having normal-hearing and hearing loss. They used two types of multivariate analysis, discriminant analysis and logistic regression, to analyze TEOAE and noise levels in octave bands centered at 1,000, 2,000, and 4,000 Hz. The areas under the ROC curves were calculated and univariate results (TEOAE level,

FIGURE 19.10 ROC curves for octave bands centered at 500, 1,000, 2,000, and 4,000 Hz. Bands were analyzed from the broadband TEOAE response. [Modified and reprinted with permission from Prieve BA, Gorga MP, Schmidt A, Neely S, Peters J, Schultes L, et al. [1993] Analysis of transient-evoked otoacoustic emissions in normal-hearing and hearing impaired ears. *J Acoust Soc Am*. 93, 3308–3319; ©1993, Acoustical Society of America.]

TEOAE/noise) were compared to multivariate results (those obtained using discriminant analysis and logistic regression). Hussain et al. (1998) found significant improvement in identification of hearing loss at 1,000 Hz using multivariate analysis.

Vinck et al. (1998) used two stimulus levels (86 and 65 dB pSPL) and two stimulus types (tonebursts and clicks) to determine if these combinations would result in better identification of hearing loss. Using discriminant functions, they found that hearing status at 4,000 and 8,000 Hz could be classified into three groups (<20, 20 to 35, >35 dB HL) with 100% accuracy by using two click levels and four tonebursts presented at two levels. The studies using multivariate analyses suggest that combinations of OAEs at more than one frequency will predict auditory status with the greatest accuracy.

DPOAEs

For clinical purposes, DPOAE levels are examined as a function of primary tone frequency. The primary tone levels, level difference, and frequency ratio are held constant whereas the primaries are changed in frequency. The resulting graph of DPOAE level as a function of frequency has been called a “DP-gram.” Figure 19.11 is an example of a DP-gram from an adult ear. Most commonly, DPOAE level is graphed as a function of f_2 frequency. This convention is a result of evidence suggesting the principal source of DPOAEs was the

FIGURE 19.11 A DP-gram measured from an adult. The DPOAE level in dB SPL, indicated by the Xs, is graphed as a function of f_2 frequency. The shaded areas indicate noise levels in dB SPL. [Adapted from the output of the Otodynamics ILO92 system.]

nonlinear distortion component originating in the region of overlap between the primaries (Kummer et al., 1995; Martin et al., 1987).

Typical stimulus parameters for measuring a DP-gram are levels of $L_1 = 65$ dB SPL and $L_2 = 55$ dB SPL with the f_2/f_1 ratio set to approximately 1.2. The use of these parameters resulted primarily from the laboratory research investigating the stimulus parameters that produced, on average, the largest $2f_1 - f_2$ in ears with normal hearing (e.g., Harris et al., 1989) discussed previously. Early animal research indicated that DPOAEs evoked by low-level stimuli more accurately reflected changes in the “active” mechanism of the cochlea (e.g., Schmiedt and Adams, 1981) and that $2f_1 - f_2$ DPOAE levels evoked by low- and mid-level stimuli were greatest when unequal-level primaries were presented (Gaskill and Brown, 1990). Later work by Stover et al. (1996) used unequal-level stimuli ($L_1 = L_2 + 10$ dB) at nine different frequencies and 12 different L_2 levels to evoke DPOAEs in a group of normal-hearing and hearing-impaired participants. They found that areas under the ROC curves were greatest for L_2 levels of 55 dB SPL, regardless of the frequency. In addition, using several different L_2 levels did not improve the accuracy of identification of hearing loss. DPOAEs identified hearing loss best at frequencies above 500 Hz.

Based on this preliminary work by Stover et al. (1996), Gorga and his colleagues tested 1,267 ears using primary levels of $L_1 = 65$ dB SPL and $L_2 = 55$ dB SPL in a clinical setting. The data were analyzed in many ways to determine the best way to use DPOAEs to diagnose hearing loss. Gorga et al. (1997) reported how well hearing loss could be identified at a particular audiometric frequency by using the DPOAE evoked by an f_2 of the same frequency. ROC curves indicated that identification of hearing loss was best at 4,000 and 6,000 Hz, with good identification at 1,500, 2,000, 3,000, and 8,000 Hz. They found that DPOAE/noise was marginally superior at identifying hearing loss for most frequencies.

To investigate whether identification of hearing loss could be improved, multivariate analyses were performed. Discriminant function analysis and logistic regression were used to probe whether DPOAE level and noise at other frequencies could aid in the prediction of hearing loss at a chosen frequency. The logistic regression analyses provided the best identification of hearing loss and provided the highest $P(A)$ values. The results of the multivariate analysis suggest that taking into account DPOAE level and noise at various frequencies can improve DPOAE test performance at a given audiometric frequency (Dorn et al., 1999).

In 2005, Gorga and colleagues published a follow-up study that confirmed and expanded on the earlier data set published between 1997 and 1999. DPOAEs were collected from 345 ears of 187 participants. Their ages ranged from 2 to 86 years, with a median of 29.7 years. Data were collected using the same paradigm as the previous studies; however, a commercially available system was used (Bio-logic Scout 3.45) instead of the custom system used in the previous

studies. DPOAE test performance, measured by $P(A)$ areas under ROC curves, that matched an f_2 frequency with an audiometric frequency was similar to their previous report (Gorga et al., 1997). They used the coefficient constants generated by the logit functions (LFs) from the logistic regression analyses performed on data from their previous work (Dorn et al., 1999) to ensure they could be generalized to routine clinic use. The $P(A)$ s of ROC curves were similar to their previous study, confirming that the equations could be generalized to new data sets. They found that calculating the LF scores resulted in improved identification of hearing loss, especially for lower frequency primaries, and that many participants with mild hearing loss met passing criteria, similar to their previous work. In summary, the results from the studies on the $2f_1-f_2$ DPOAE indicate that it is an excellent tool for identifying hearing loss. Identification of hearing loss is better at mid-to-high frequencies than at lower ($\leq 1,000$) and higher (8,000 Hz) frequencies. Furthermore, taking into account DPOAE parameters at frequencies other than the frequency of interest improves identification of hearing loss.

CLINICAL USE AND INTERPRETATION OF EOAEs

Identification of Hearing Loss as Part of a Diagnostic Test Battery

Accurate interpretation of EOAE results is essential for providing the best care for patients. Clinicians have interpreted OAEs using different techniques, including templates, ranges from normally hearing ears, and a priori-selected criteria. Each of these techniques is discussed below, along with the strengths and limitations of each technique.

TEMPLATES

Gorga et al. (1997) were the first to construct an OAE template for clinical evaluation of hearing loss. To determine criteria that should be used clinically to identify hearing loss, they plotted cumulative distributions of DPOAE level and DPOAE/noise for groups of normally hearing and hearing-impaired ears at each f_2 frequency. Figure 19.12 illustrates the cumulative distributions for an f_2 frequency of 4,000 Hz. In this graph, the percent of persons having a DPOAE/noise value equal to or less than that shown on the x -axis is plotted. Data from normal-hearing participants are represented by solid lines and data from hearing-impaired participants are represented by dotted lines. By plotting data in this manner, the value that represents the lowest 5% of DPOAE/noise from normal-hearing ears and the DPOAE/noise that represents the highest 5% from hearing-impaired ears can be determined. The panel for 4,000 Hz illustrates how these cumulative distributions can be used. The 95th percentile of DPOAE/noise for hearing-impaired ears (read

FIGURE 19.12 Cumulative distributions for DPOAE/noise from normal-hearing [solid line] and hearing-impaired ears [dotted line] for $f_2 = 4,000$ Hz. [Modified and used with permission from Gorga MP, Neely ST, Ohlrich B, Hoover B, Redner J, Peters J. [1997] From laboratory to clinic: a large scale study of distortion product otoacoustic emissions in ears with normal hearing and ears with hearing loss. *Ear Hear.* 18, 440-455; ©1997, Lippincott Williams and Wilkins.]

from the y -axis) is at 20.0 dB (read from the x -axis). The 5th percentile for the normal-hearing persons is at 10.5 dB.

Gorga and colleagues incorporated the DPOAE levels corresponding to the 5th and 10th percentiles from normal-hearing ears and the 90th and 95th percentiles from hearing-impaired ears into a plot that can be used clinically, shown in Figure 19.13. The top panel is a template for DPOAE level and the bottom panel is one for DPOAE/noise. In the top panel, the top solid line represents the 95th percentile of DPOAE level for the hearing-impaired ears. The top of the darkened area is the 90th percentile of DPOAE level from the hearing-impaired ears. The lowest solid line represents the 5th percentile of DPOAE level from the normal-hearing ears, and the bottom of the solid portion represents the 10th percentile of DPOAE level from the normal-hearing ears. The solid area represents DPOAE level from the 10th percentile from the normal-hearing ears to the 90th percentile for the hearing-impaired ears. This template allows the clinician to classify the DPOAE level as “normal,” “abnormal but present,” or “absent.” First, the clinician determines whether the DPOAE is higher than the noise floor for each frequency. If the DPOAE is ≥ 6 dB and an individual’s DPOAE level falls above the top line, the audiologist can be confident that hearing at the f_2 frequency is within normal limits. If the patient’s

FIGURE 19.13 DPOAE level (**top panel**) and DPOAE/noise (**bottom panel**) plotted as a function of f_2 frequency. The *top-most solid line* represents the 95th percentile of responses from hearing-impaired ears. The *bottom-most solid line* represents the 5th percentile of responses from normal-hearing ears. The *area with diagonal lines on the bottom of the darkened area* represents the 5th to 10th percentile of responses from normal-hearing ears. The *area with diagonal lines at the top of the darkened area* represents the 90th to 95th percentile of responses from hearing-impaired ears. [Modified and used with permission from Gorga MP, Neely ST, Ohlrich B, Hoover B, Redner J, Peters J. DPOAE level falls below the lowest solid line, the audiologist determines that hearing at that f_2 frequency is impaired. The solid area is the “area of uncertainty.” If an individual’s DPOAE level falls in that range, the clinician cannot be sure whether hearing at that f_2 frequency is impaired or normal, although often, a mild hearing loss is suspected. The clas-

sification would be “abnormal level, but present.” Templates are also available for TEOAEs for ages 1 to 27 years collected using the ILO88 equipment (Nicholson and Widen, 2007) and for DPOAEs using discriminant function and logistic regression analyses (Dorn et al., 1998).

Using templates increases confidence in clinical interpretation because EOAEs from individual ears can be evaluated relative to a large group of normal-hearing *and* hearing-impaired ears. The limitation of using a template is that the patient’s age should be within the range of participant ages for which the template was constructed. EOAEs should be measured using similar stimulus and recording parameters to those used to construct the templates. Care must be taken while using DPOAE/noise comparisons if the number of averages differs from those used to construct the template.

A PRIORI CRITERIA

Interpretation using *a priori criteria* means that some EOAE criterion is used to determine whether an EOAE is present or absent at each frequency tested. The presence of EOAEs at a given frequency is assumed to indicate normal OHC function and likely normal hearing at that frequency. Over the years, clinicians have typically adopted SNR criteria for TEOAEs or DPOAEs or percent reproducibility for TEOAEs. Using *a priori criteria* has been common for TEOAE interpretation. Specifically, a TEOAE SNR of ≥ 6 dB is often used as the criterion for the presence of TEOAEs in a given frequency band.

The question arises, how does a clinician choose a certain criterion, and how well does it identify hearing loss? Gorga et al. (1999) investigated identification of hearing loss using common *a priori* DPOAE criteria of 3-, 6-, and 9-dB DPOAE/noise ratios for various combinations of audiometric data. They found that if only one f_2 frequency was evaluated, sensitivity never reached 100%. Sensitivity improved if three to five frequencies were required to meet the criteria, which would result in an interpretation for the ear as a whole, not interpretation of frequency by frequency within an ear. They concluded that clinicians should not assume that *a priori criteria* identify all ears with hearing loss, even using a stringent criterion of 9 dB.

The strength of using SNR is that it is age independent, but there are severe limitations. First, EOAEs can only be classified as present or absent using this method; there is not an alternative interpretation of present but abnormal. Second, on a particular test, there may be spurious patient or room noise that can affect an SNR, often for only some frequencies, making frequency-by-frequency interpretation difficult. Finally, continued averaging reduces the noise and even small-level EOAEs may meet a criterion SNR. If clinicians feel they must use *a priori criteria* for interpretation, we recommend that the test be run twice to ensure repeatability.

COMPARISON TO RANGE FOR NORMALLY HEARING EARS

Another approach to interpret OAEs is to have a range of OAE levels from normally hearing ears and compare OAE levels from individual ears to it. The range of values is either the mean ± 1 or 2 standard deviations or the range of OAE levels between the 10th and 90th percentiles from a group of normally hearing ears. In this paradigm, if the responses from the tested ear are within the range from normally hearing ears, the OAE is considered “normal.” If it is lower than the normal range, but higher than the noise, it is considered “abnormal.” Finally, if the OAE level is the same or lower than the noise level, the OAE is considered “absent.” The determination of normal, present but abnormal, or absent is made on a frequency-by-frequency basis for both ears and included in the patient’s report relative to the audiogram. The strength of this method is that hearing loss can be interpreted into three categories. The limitations of this method are that the patient’s age must be in the age range as the participants used to construct the normal range. In addition, there is no indication of what DPOAE levels might be like in ears with hearing loss and how those levels overlap with those from normal-hearing ears. This approach is often used for DPOAEs, and many manufacturers provide their own normative range on their DPOAE equipment. This method has not been routinely used for TEOAEs; however, such data could be easily collected.

Differential Diagnosis of Hearing Loss

In addition to identifying hearing loss, EOAEs enhance the audiometric test battery for cases of differential diagnosis. Because EOAEs are generated in the cochlea independent of afferent fiber activation, they allow us to test for a “mechanical” versus an IHC or neural hearing loss. One type of auditory disorder that can now be identified is auditory neuropathy. In these cases, the EOAEs are normal, ABRs and acoustic reflexes are abnormal or absent, and hearing thresholds range from mild to profound in severity.

The addition of EOAEs to the test battery for patients with vestibular schwannoma is also an important consideration. Although most patients having tumors also do not have EOAEs, which is thought to be because of interrupted blood supply to the cochlea, there are a small number of patients that have EOAEs in spite of poor behavioral thresholds. In these cases, the audiologist could recommend that a surgical procedure that preserves the cochlea be taken, so that any residual hearing may be saved (Robinette et al., 2002).

OAE measures identify damage because of drug ototoxicity or noise exposure prior to increases in thresholds (e.g., Stavroulaki et al., 2002). OAEs may be useful for deter-

mining susceptibility to noise (Lapsley Miller and Marshall, 2007). Some researchers are investigating the possibility that EOAEs are altered in unique ways in individuals with Meniere’s disease (Kusuki et al., 1998; Sakashita et al., 1998).

Newborn Hearing Screening

The Joint Committee on Infant Hearing (JCIH, 2007) recommends universal newborn hearing screening, meaning that all newborn infants are screened for hearing loss. The JCIH has recommended that newborns cared for in the well-baby nursery (WBN) be screened with either EOAEs or ABRs (JCIH, 2007). Because EOAEs do not detect auditory neuropathy or dys-synchrony, EOAEs are not recommended for use as the primary screening tool in the neonatal intensive care nursery.

When used as a screening tool, EOAE results from each ear are evaluated using criteria chosen by the screening program directors. If the criteria are met in both ears, then a newborn is said to “pass” the newborn hearing screening. If the criteria are not met in both ears, the newborn is considered to have “failed” the in-hospital screening, and either returns at a later time for a rescreening or referred for diagnostic testing. EOAEs have been widely used in large-scale screening programs that included both high-risk and large-scale universal newborn hearing screening programs (e.g., Spivak et al., 2000; Vohr et al., 1998). The referral rates for outpatient retesting reported by these programs range between 3% and 10%. After a second, outpatient screening before 1 month of age, referral for diagnostic testing is less than 2% (e.g., Vohr et al., 1998).

A large-scale study, funded by the National Institutes of Health (NIH) directly compared the screening tools of DPOAEs, TEOAEs, and screening ABR (SABR). The NIH study was conducted on 4,478 infants cared for in the NICU, 353 well-babies with risk indicators for hearing loss, and 2,348 infants cared for in the WBN with no risk indicators for hearing loss, with data pooled from seven different institutions across the United States. TEOAEs, DPOAEs evoked by two different primary level pairs, and ABRs evoked by 30-dB nHL clicks were measured in random order from both ears of each infant using a computerized test program that included passing criteria, response filtering, noise/artifact rejection, and minimum, maximum, and low-noise stopping rules specifically chosen for each measure (Gorga et al., 2000b; Norton et al., 2000a; Sininger et al., 2000). One of the important findings from the NIH study is that the percentage of infant passes was similar for SABRs, TEOAEs, and DPOAEs ($L_1 = 65$, and $L_2 = 50$ dB SPL).

To determine the sensitivity and specificity of each screening tool, 4,911 infants were tracked for follow-up behavioral hearing testing at 8 to 12 months corrected age. Sixty-four percent of infants targeted for follow-up returned for audiometric testing, and of those, 95.6% could be reliably tested using visual reinforcement audiometry with

insert earphones. Minimal response levels (MRLs) were determined using frequency-modulated tones at frequencies of 1,000, 2,000, and 4,000 Hz and speech awareness threshold (SAT) was determined using speech presented by live voice through a microphone. MRLs higher than 20 dB HL indicated hearing loss, and infant responses at 20 dB HL were considered normal (Widen et al., 2000). ROC curves were constructed for SABR, TEOAEs, and DPOAEs using several gold standards. The gold standards were MRL at 1, 2, or 4 kHz; the SAT or puretone average (PTA) of 2 and 4 kHz; or a PTA including 1, 2, and 4 kHz. The criterion for normal was ≤ 20 dB HL (Norton et al., 2000b). The areas under the ROC curves for all four tests ranged from 0.70 to 0.94 and were similar to each other for most measures, indicating that each test identified hearing loss well. None of the areas were 1.0, indicating that no test identified hearing loss with 100% accuracy. There were slight differences among the measures. ROC curves for DPOAEs evoked by equal primary levels of 75 dB SPL had lower areas than those for DPOAEs evoked by primary levels of $L_1 = 65$ and $L_2 = 50$ dB SPL, indicating that DPOAEs evoked by higher level primaries were not as good at identifying hearing loss as those evoked by mid-level primaries. TEOAEs, DPOAEs at 65/50 dB SPL, and SABR performed similarly for MRLs of 2, 4 kHz, PTA including 2 and 4 kHz, and SAT. TEOAEs and DPOAEs at 65/50 dB SPL outperformed SABR slightly for most of these measures. Finally, SABR outperformed TEOAEs and DPOAEs for an MRL at 1,000 Hz and was slightly better for a PTA that included 1,000 Hz. An analysis of failure rate based on severity of hearing loss was performed for a hit rate of 80%. The majority of moderate, severe, and profound hearing losses were identified at a rate at or close to 100% using any of the measures. Mild hearing loss was the severity most incorrectly identified, with 40% to 50% of ears with mild hearing loss meeting the screening criteria (Norton et al., 2000b). An extensive set of data is provided by this study and can help guide clinicians in understanding EOAE and ABR tools as newborn hearing screening tools. Additionally, clinicians should be aware that ABR and EOAE screening are equally effective at identifying moderate, severe, and profound hearing loss.

CLINICAL EOAEs IN THE FUTURE

In the past, the majority of research on the clinical use of EOAEs has focused on the identification of hearing loss or screening for hearing loss. Based on early literature, both TEOAEs and DPOAEs identify hearing loss well (e.g., Gorga et al., 1993; Norton et al., 2000b; Prieve et al., 1993) and are “frequency specific,” meaning that either can provide information about hearing loss in a specific frequency region. Although EOAEs have turned out to be excellent at identifying hearing loss, the future use of EOAEs in probing the auditory system for hearing loss could see many changes.

Using DPOAE Components to Diagnose Hearing Loss

Current clinical interpretation of DPOAEs ignores the two-source taxonomy of DPOAE generation. DPOAEs measured in the ear canal are a composite of OAEs from two different generation mechanisms from at least two different places in the cochlea. When DPOAEs are measured in small frequency steps (< 50 Hz) or with a sweeping tone (Long et al., 2008), large variations in the DPOAE level, termed “fine structure,” are evident (He and Schmiedt, 1993). An example of DPOAE fine structure recorded from an adult is shown in Figure 19.14. Fine structure is the result of the interaction of energy from the nonlinear distortion and reflection components. Depending on the phases of these two sources, they may combine constructively, such that a higher DPOAE level is measured in the ear canal (peaks), or destructively, such that a lower level is measured (dips) (Talmadge et al., 1999).

One approach to improve identification of hearing loss is to suppress the EOAE due to the reflection component, leaving the EOAE due to the generator component (Heitmann et al., 1998). The rationale behind the procedure of this work is that reducing the reflection component reduces the fine structure and thereby reduces the variability of the DPOAE level measured in the ear canal. Johnson and colleagues (2007) used a suppressor to reduce the reflection component on a large number of ears but did not note any improvements in the diagnosis of hearing loss. However, others have found minor improvements in identification when the reflection component is suppressed and optimal calibration and stimulus parameters are taken into account (Kirby et al., 2011).

A second approach is to improve identification, etiology, and/or severity of hearing loss by separating the compound DPOAE into the two underlying components and interpreting them both. Support for looking at both components comes from research indicating that the two components are differentially affected by hearing loss

FIGURE 19.14 DPOAE level plotted as a function of $2f_1 - f_2$ frequency in an adult. DPOAEs were collected using sweeping-tone primaries which allow observation of fine structure.

(Mauermann et al., 1999), development (Abdala and Dhar, 2012) and aspirin (Rao and Long, 2011). Although separation of DPOAEs into the two subcomponents has been done for years in research settings (Shera, 2004), only recently has it been attempted in large-scale studies with clinical intent (Poling et al., 2014).

As an alternative to measure both DPOAE components, clinical testing could use TEOAEs, which are basically a reflection-type emission (Kalluri and Shera, 2007), and DPOAEs evoked by mid- to high-level primaries to enhance clinical diagnosis. It has been known for many years that DPOAEs can be measured in ears with greater hearing loss than TEOAEs (Harris and Probst, 2002); however, systematic studies of using the two types together are lacking. There are case study examples that indicate absent or abnormal TEOAEs in the presence of DPOAEs (see case study no. 3 in this chapter).

Extended High Frequencies

Extending EOAE measurement to high frequencies (10 to 16 kHz) has been studied in research settings for both DPOAEs (Dreisbach and Siegel, 2001) and TEOAEs (Goodman et al., 2009) and more recently in a large sample of ears (Poling et al., 2014). High-frequency click-evoked TEOAEs identify sensory/neural hearing loss up to 12.7 kHz with excellent accuracy (Keefe et al., 2011). Measuring high-frequency EOAEs is important for understanding age-related changes early in life and for monitoring effects of ototoxic drugs. Presentation of high-frequency stimuli and EOAE recording requires specialized speakers and calibration. Calibration using forward pressure level and techniques to detect standing waves in the ear canal has improved identification of hearing loss using DPOAEs even up to 8,000 Hz (Kirby et al., 2011; Reuven et al., 2013).

Measurement of Input/Output Functions

Another characteristic of EOAEs that can be measured is the input/output (I/O) function. To measure a DPOAE I/O function, the stimulus frequencies (f_1 and f_2) and ratio (f_2/f_1) are fixed and both stimulus levels (L_1 and L_2) are increased from low to high levels. From the resultant DPOAE I/O function, the slope of the function can be evaluated and a threshold can be determined. Typically, threshold is defined as the lowest stimulus level producing a DPOAE that is 3 dB above the noise floor with subsequent growth in level for successively higher stimulus levels. DPOAE I/O functions in human ears with cochlear impairment reveal elevated thresholds, reduced compression, and a steeper slope of the I/O function in comparison to normal ears (Kummer et al., 1998). EOAE thresholds can be estimated by I/O functions; however, they cannot accurately predict behavioral

thresholds or provide accurate identification of hearing loss (Gorga et al., 2003; Stover et al., 1999). Input/output functions differ between neonatal ears with middle-ear and cochlear hearing loss (Janssen et al., 2005).

Different DPOAEs

Although almost all research on DPOAEs has focused on $2f_1-f_2$, the $2f_2-f_1$ DPOAE has been evaluated for clinical testing in a few studies. Results indicated that $2f_1-f_2$ predicted hearing status (normal vs. impaired) better than $2f_2-f_1$ at all test frequencies (Fitzgerald and Prieve, 2005; Gorga et al., 2000a), even when stimulus parameters were set to obtain the most robust $2f_2-f_1$ levels (Fitzgerald and Prieve, 2005). Combining information from both $2f_1-f_2$ and $2f_2-f_1$ using multivariate analyses improved prediction of hearing status, but the improvements were very slight compared to the performance of $2f_1-f_2$ alone (Fitzgerald and Prieve, 2005; Gorga et al., 2000b).

CASE STUDIES

Case Study No. 1: Adult COAEs

Patient no. 1 is an 18-year-old adult male with bilateral high-frequency sensory/neural hearing loss. The patient reported that he had been hearing impaired since birth but that the etiology of the hearing loss was unknown. A hearing evaluation revealed a unique pattern of thresholds with two frequency regions of extremely low thresholds in the right ear. The top half of Figure 19.15 is the patient's audiogram for the right ear. Hearing levels improved from borderline-normal at 250 to 500 Hz to extremely low values (−10 dB HL) at 1,000 and 1,500 Hz and back to 15 dB HL at 2,000 Hz. His hearing levels then sloped to a mild-to-moderate hearing loss from 3,000 to 4,000 Hz, followed by another rise to −10 dB HL at 6,000 Hz and a borderline-normal value of 25 dB HL at 8,000 Hz.

A TEOAE was measured from the right ear using clicks presented at approximately 82 dB pSPL. The display from the ILO88 system is shown in the bottom half of Figure 19.15 with the COAE analyzed into half-octave bands. COAEs were present in the half-octave bands from 1,000 to 2,000 Hz, where hearing levels were within normal limits. As expected, no COAE energy was present in the 3,000- to 4,000-Hz bands where hearing loss is indicated on the audiogram. The COAE screening does not yield information above 4,000 Hz for comparison with the normal and borderline-normal thresholds obtained in this patient at higher frequencies. However, this case does illustrate good correspondence between the presence/absence of COAEs and the measured hearing levels from 1,000 to 4,000 Hz. Also of note are the excellent probe fit and low noise level that are typically easy to obtain in a cooperative adult.

FIGURE 19.15 Audiogram and TEOAEs for case study no. 1: TEOAEs in an adult.

Case Study No. 2: TEOAEs from a Child

Patient no. 2 was referred to us when he was 3:3 (years: months). His parents had first suspected he had a hearing loss by the time he was 1:0. He was taken to an ENT, who inserted ventilating tubes into his eardrums when the child was 1:6. At 2:1 this patient had a hearing evaluation, which revealed a moderate-to-severe mixed hearing loss bilaterally. Expressive and receptive language and phonologic skills were significantly reduced. At that time, the patient underwent a second surgery for PE tubes and afterward was fit with binaural hearing aids. Because the patient did not seem to be responding well to hearing aids, and was difficult to test behaviorally, he was seen for hearing and OAE testing.

The top panel in Figure 19.16 illustrates the patient's audiogram, which was obtained after several visits. Patient no. 2 has a mild, sloping-to-profound sensory/neural hearing loss bilaterally. Because the patient was not responding well to hearing aids, it was important to rule out auditory neuropathy. The middle panel in Figure 19.16 illustrates the TEOAEs measured from the left ear and the bottom panel illustrates the TEOAE from the right ear. Click stimuli pre-

sented at approximately 80 dB pSPL were used. No TEOAEs are present, consistent with OHC pathology. Notice the unusual click stimulus waveform, a typical finding when open ventilating tubes are present. Because of the absence of TEOAEs in the presence of a mild-to-profound sensory/neural hearing loss, it was felt that this child's hearing loss contained a cochlear component and that amplification was an appropriate method of rehabilitation. As the child matured, became adjusted to his hearing aids, and received special services, the child became more verbal and compliant in behavior.

Case Study No. 3: Sensory/Neural Hearing Loss in an Infant

Patient no. 3 was referred because she failed a newborn hearing screening before hospital discharge. She was seen at 8 months of age, after having audiologic evaluations at other facilities on three different occasions. Figure 19.17 shows estimates of behavioral thresholds, depicted by triangles, based on ABRs evoked by tonebursts collected during natural sleep. Figure 19.17A shows data for the right ear and Figure 19.17B shows data for the left ear. ABR thresholds estimate a mild-to-severe sensory/neural hearing loss

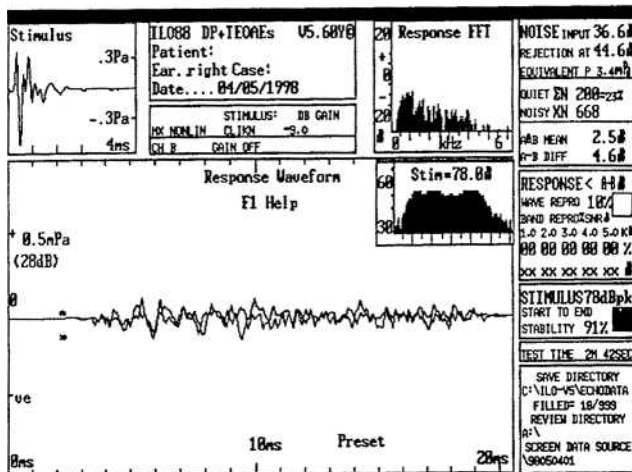

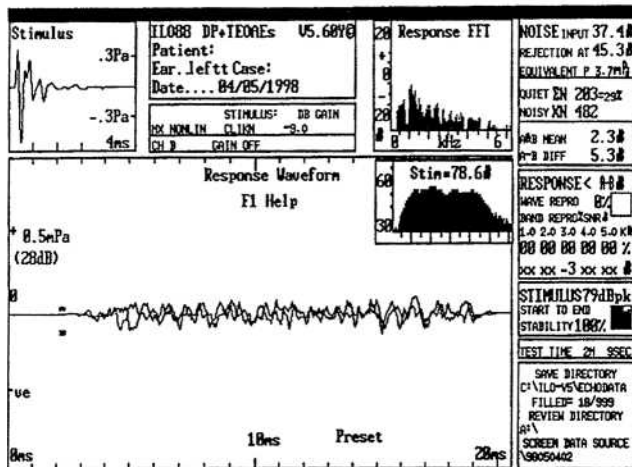

FIGURE 19.16 Audiogram and TEOAEs for case study no. 2: TEOAEs in a child.

in the left ear and a mild hearing loss in the right ear at 4,000 Hz. Tympanometry was within normal limits for both ears. TEOAEs and DPOAEs were absent in the left ear. In the right ear, TEOAEs were present in 2,000- and 3,000-Hz half-octave bands, but were absent in the 4,000-Hz band. DPOAEs were higher than 2 standard deviations above the noise floor between 1,500 and 4,000 Hz. Behavioral thresholds obtained using visual reinforcement audiometry are shown on the audiograms using typical conventions (x for left ear, circle for right ear). ABR estimates of behavioral thresholds were in good agreement with actual behavioral thresholds except for 4,000 Hz in the right ear. The behavioral threshold was 20 dB HL, which is a slight, rather than mild hearing loss, as suggested by ABR threshold estimates. Lack of TEOAEs in the 4,000-Hz band was consistent with the slightly higher thresholds.

Case Study No. 4: Conductive Hearing Loss in an Infant

Patient no. 4 is a baby aged 4 months who passed his newborn hearing screening at birth, but had developed middle-ear effusion because of a congenital disorder. Based on ABR thresholds, it appeared that patient no. 4 had a conductive hearing loss in the right ear at 500 Hz. A tympanogram using a 1,000-Hz probe tone was flat. Figure 19.18 shows that TEOAEs in the right ear (lower panel of the figure) were of low level, but had >4-dB OAE-to-noise ratio from 2,000 to 4,000 Hz. Patient no. 4 underwent a myringotomy 1 week after testing. The pediatric otolaryngologist noted effusion in the right ear. Although one might expect that middle-ear pathology would eliminate EOAEs, TEOAEs were present in this infant despite an air–bone gap based on toneburst ABR, a flat tympanogram, and confirmed effusion.

FOOD FOR THOUGHT

1. To what extent do otoacoustic emissions change our ability to identify “sensory” and “neural” hearing loss separately, rather than the combined category of “sensorineural” hearing loss?
2. What are the possible errors if you are assessing hearing loss in a 4-month old infant and you use a DPOAE template constructed from data that included patients aged 1–96 years?
3. What are the sources of noise in an OAE recording? Can you reduce the noise from these sources, and if so, how can it best be done?

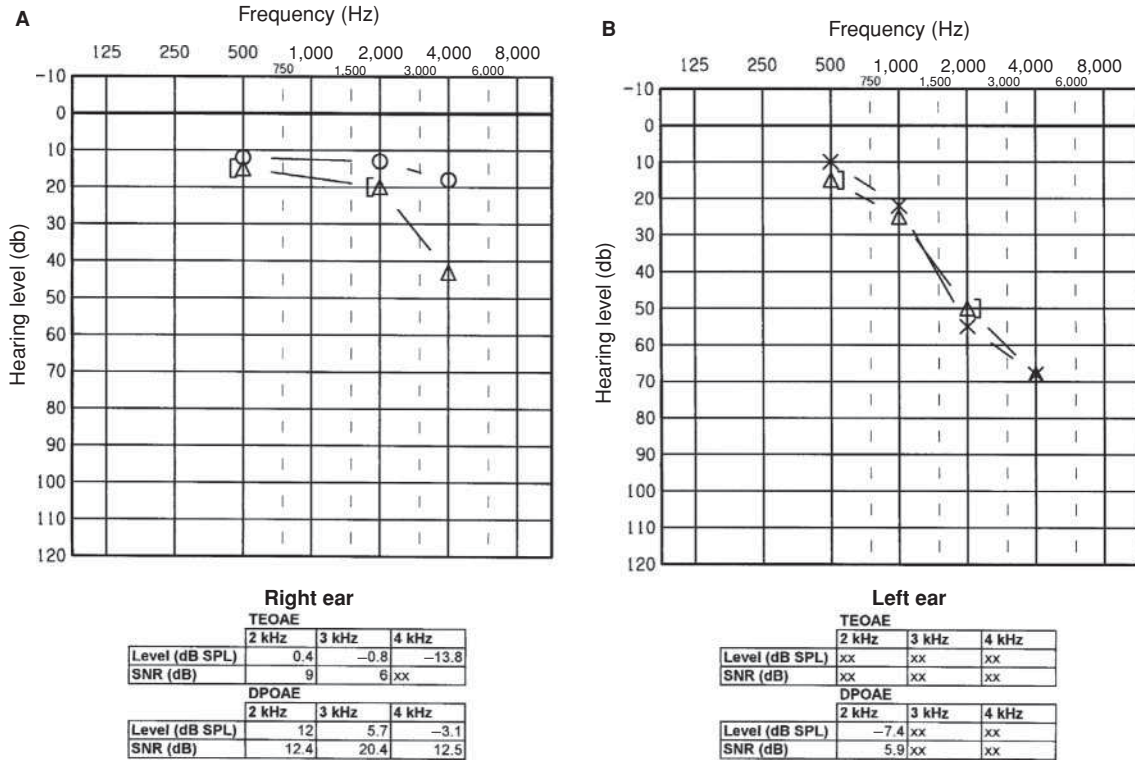

FIGURE 19.17 Case study no. 3. Behavioral thresholds based on toneburst auditory brainstem response, behavioral thresholds measured with visual reinforcement audiometry at 8 months of age, and TEOAEs and DPOAEs measured at 3 months of age.

FIGURE 19.18 Case study no. 4. TEOAEs for an infant aged 3 months with middle-ear dysfunction in both ears. Middle-ear effusion was confirmed surgically 1 week after audiological measures were obtained.

Clinical Neurophysiology of the Vestibular System

Erin G. Piker and Douglas B. Garrison

INTRODUCTION TO THE VESTIBULAR SYSTEM

The vestibular system serves the basic function of translating movement of the head into an electrical signal. The vestibular system detects head movement and responds with compensatory reflexive eye movements and postural adjustments that allow us to maintain clear vision and prevent us from falling. Spatial orientation is maintained because of the vestibular system's complex role of driving the reflexes that stabilize our vision and balance. Unlike other sensory systems (e.g., auditory, visual), most individuals are unaware of the vestibular system during routine activities, that is, until the system ceases to function normally. A sudden loss of function from one vestibular end organ can result in a profound disability because of vertigo, imbalance, nausea, and vomiting.

Vestibular function is difficult to assess directly in humans. Current clinical tests of vestibular function evaluate secondary motor responses (i.e., reflexes) used to maintain eye position or postural control during movement. Because there is no direct sensory potential clinically available, the accurate interpretation of current vestibular diagnostic tests requires knowledge and understanding of the anatomy and physiology of the peripheral vestibular system and its central connections. There are entire volumes of books on this complex subject, and the reader should refer to those for a more comprehensive description (Baloh and Kerber, 2011). The purpose of this chapter is to provide a basic background in the anatomy and clinical physiology needed to understand and assess the vestibular system.

OVERVIEW OF VESTIBULAR ANATOMY AND PHYSIOLOGY

Peripheral Vestibular System

The vestibular end organs are housed in a series of tunnels located in the petrous portion of the temporal bone referred to as the *bony labyrinth* (Figure 20.1). The bony labyrinth is a carved out portion of the temporal bone that creates space for the membranous labyrinth. The

membranous labyrinth is filled with *endolymph* fluid (higher concentration of potassium and lower in sodium) and is suspended within the bony labyrinth by *perilymph* (lower concentration of potassium and higher in sodium) and supportive connective tissue. Embedded within the membranous labyrinth are the five vestibular sensory organs: three *semicircular canals* (SCCs) and two *otolith end organs* (Figure 20.2).

SEMICIRCULAR CANALS

The SCCs convert angular acceleration and deceleration into electrical signals that are transmitted through the vestibular nerve to the vestibular nucleus. There are three SCCs in each inner ear, one horizontal and two vertical, extending from the utricle (Figure 20.2). They are known as the *lateral/horizontal*, *anterior/superior*, and the *posterior/inferior* SCCs. Each SCC responds best to angular motion in one plane and they are roughly orthogonal to each other such that they can sense any rotation in three-dimensional space. Additionally, the canals in the right and left inner ears are arranged in complementary coplanar plains. The lateral SCCs from the right and left inner ears lie in the same plane, whereas the plane of each anterior canal is roughly coplanar to that of the posterior canal of the opposite side (Figure 20.3C).

Each SCC is filled with endolymph and forms a closed ring with a shared cavity in the utricular sac. The lateral SCC communicates at both ends with the utricle. The vertical canals (anterior and posterior) communicate with the utricle at one end and join together at the other end. Each SCC is dilated at one end closest to the utricle forming the ampulla. The ampulla is the location of the *crista*—the sense organ of balance.

OTOLITH ORGANS

Whereas SCCs respond to angular acceleration in specific directions, the hair cells in the *saccul*e and *utricle* respond to linear acceleration and deceleration (i.e., changing velocity, not constant velocity as with a train). The saccul is oriented vertically and responds to linear vertical (up/down) translation whereas the utricle senses tilt and linear

FIGURE 20.1 Outer, middle, and inner ear, including bony labyrinth. From American Chart Company.

horizontal translations (side/side, front/back). Figure 20.4 shows a three-dimensional representation of otolith orientation. The utricle is located above the saccule in the elliptical recess and is approximately parallel to the plane of the lateral SCC. The saccule is located on the medial wall of the vestibule and is approximately perpendicular to the plane of the utricle (Baloh and Kerber, 2011). The saccule and utricle are filled with endolymph and each house a sensory organ called the *macula*.

STRUCTURE OF HAIR CELLS

Both the SCCs and the otolith organs utilize specialized hair cells much like the ones in the auditory system. It is the hair cells that transduce mechanical force into nerve action potentials. There are two types of hair cells in mammalian vestibular systems (Figure 20.5). *Type I* cells are globular or flask shaped (i.e., the cell body is narrower at the apex and wider at the base) with a large nerve terminal surrounding the base. *Type II* cells are cylindrical with multiple nerve terminals at their base, including direct contact with efferent nerve endings. On the apical end of each hair cells is a *cuticular plate*, from which *stereocilia* protrude.

Each hair cell possesses several shorter stereocilia and a single tall *kinocilium* at one margin of the cell (Figure 20.5). These ciliated sensory hair cells contain vesicles that possess neurotransmitters. The tips of the cilia are connected by *tip links* that open and close mechanosensory channels (Vollrath et al., 2007). Deflection of the cilia toward the kinocilium opens the mechanosensory channels at the tips causing an influx of potassium effectively depolarizing (i.e., exciting) the cell (Figure 20.6B; Hudspeth, 2005). This opens voltage-gated calcium channels releasing neurotransmitters

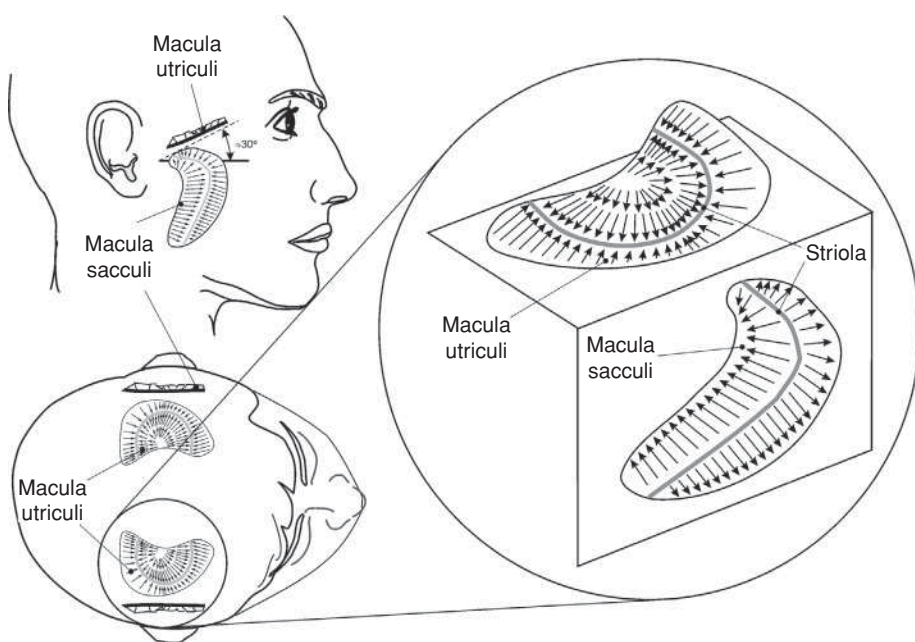

FIGURE 20.4 Orientation of the utricle and saccule. The direction of the excitatory responses of the hair cells is indicated by the arrows. [Katz, 6th ed. Figure 19.10, p. 440].

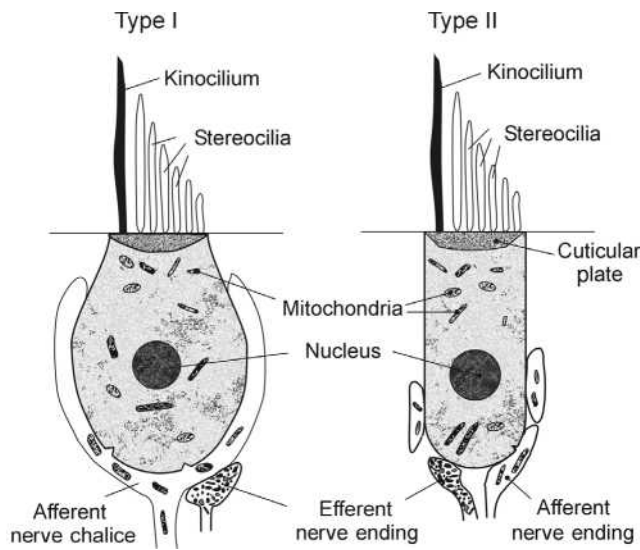

FIGURE 20.5 Type I and Type II hair cells in the vestibular system [Katz, 6th ed. Figure 19.5, p. 436].

from the hair cell and thus increasing the firing rate of the vestibular nerve associated with the hair cell. Deflection of cilia away from the kinocilium results in hyperpolarization (i.e., inhibition) of the cell causing a decrease in neural firing (Figure 20.6C). The hair cells release neurotransmitters even when they are not stimulated (Figure 20.6A; Baloh and Honrubia, 1995). In other words, the axons in the vestibular nerve are always firing at a baseline rate but can be adjusted to fire more or less depending on the direction of head movement.

THE CRISTAE AND THE MACULES

Within each SCC is a dilation called the *ampulla*. Each ampulla contains a *crista*, the receptor organs of the SCCs. The upper surface of the crista contains ciliated sensory hair cells that are embedded in a gelatinous material called the *cupula* (Figure 20.3A; Dohleman, 1971). The cupula is akin to a swing-door device that extends to the top of the ampulla and separates the endolymph of the SCC from the

FIGURE 20.6 Firing rate of the primary afferent neurons as a function of stereocilia displacement. **A:** Neurons at rest. **B:** Depolarization as a result of bending toward the kinocilium [excitatory response]. **C:** Hyperpolarization as a result of bending away from the kinocilium [inhibitory response]. Kc, kinocilium; Sc, stereocilia; ANE, afferent nerve ending; ENE, efferent nerve ending; Nu, nucleus [Katz, 6th ed. Figure 19.6, p. 437].

endolymph of the utricle. The hair cells of the crista, which project into the cupula, are oriented with their kinocilia in the same direction. Deflection of the stereocilia toward the kinocilium results in an increase in the firing rate of the vestibular fiber associated with the hair cell, whereas deflection away from the kinocilium results in a decrease in the firing rate of the vestibular fiber. In the lateral SCC the kinocilia are directed toward the utricular side of the ampulla (as shown in Figure 20.3A), so the firing rate increases when endolymph moves toward the utricle and ampulla (*ampullopetal*; Figure 20.3B). In contrast, the kinocilia of the posterior and superior SCCs are directed toward the canal side of the ampulla so that the firing rate increases when endolymph flows away from the utricle and ampulla (*ampullofugal*).

The cupula has the same specific gravity as the surrounding endolymph (Money et al., 1971). Because of this, the cupula is not displaced by gravitational force. The forces that are associated with angular head acceleration displace the cupula and bend the hair cells of the crista within each of the SCCs. Head acceleration in the plane of a SCC naturally causes movement of the bony labyrinth in that plane. Because of inertia, the endolymph within the membranous labyrinth of that canal lags behind structures within the ampulla so that the endolymph moves in the opposition direction relative to the head (Figure 20.3B). Inside the ampulla, pressure exerted by the endolymph deflects the cupula which results in a shearing of the stereocilia and either excites or inhibits the hair cells. Stimulation of the SCC produces eye movements in the plane of that canal.

The utricle and saccule are sac-like structures that contain a patch of sensory hair cells called the *macula*. The hair cells in the macula of the otolith organs, which are similar to those in the cristae, are embedded in the *otolith membrane*, a gelatinous structure that contains a large number of hexagonal prisms of calcium carbonate called *otoconia* (Figure 20.7A; Lundberg et al., 2006). The distribution of Type I and II hair cells in the macula are such that polarization is along a line that bisects the end organ. This bisected, curved area is called the *striola*. Hair cells and their stereocilia are oriented in opposite directions on each side of the striola such that the kinocilium of the hair cells within each macula are oriented in all possible directions (Figure 20.7C).

Unlike the cupula in the SCCs, the density of the otoconia is much greater than the surrounding endolymph (Money et al., 1971). Because of this, the otolith membrane is displaced by the force of gravity or linear acceleration (Figure 20.7B). Such displacement bends the stereocilia and, depending on the polarity of the cell, either causes an increase or a decrease in the number of impulses in the associated vestibular nerve fiber. As shown in Figure 20.7C, the striola of the utricle divides the macula into a medial

2/3 and a lateral 1/3. Hair cells on either side are polarized so that stereocilia deflection toward the striola is excitatory. The striola of the saccule divides the macula roughly in half and the stereocilia are oppositely polarized (i.e., away from the striola; Figure 20.7C).

CRANIAL NERVE VIII

The vestibular division of the vestibulocochlear nerve (cranial nerve VIII) arises from Scarpa's ganglion and consists of bipolar neurons organized into inferior and superior branches (Figure 20.2). These fibers travel from the membranous labyrinth through the internal auditory canal and terminate in the vestibular nuclei (VN) at the pontomedullary junction (Baloh and Honrubia, 1995). The vestibular nerve is highly organized. The inferior portion of Scarpa's ganglion comprises the nerve fibers from the crista of the posterior SCC and the macula of the saccule (Figure 20.2). The superior portion comprises the nerve fibers from the anterior SCC, lateral SCC, and utricle (Figure 20.2). The nerve fibers are organized into small bundles and travel together allowing the organization of the sensory epithelium to be retained in the vestibular nerve much like the tonotopic organization seen throughout the auditory system.

The vestibular nerve consists of ~15,000 single nerve fibers that discharge spontaneously at rates from 10 to 100 spikes/second (Barin and Durrant, 2000). This means, at any moment, there can be >1,000,000 spikes/second passing through the central vestibular system. There is a range of spontaneous firing rates and the primary vestibular afferents are classified as having a regular or irregular spontaneous discharge rate (Goldberg et al., 1987).

BLOOD SUPPLY

The blood supply to the membranous labyrinth is shown in Figure 20.8. The *labyrinthine artery*, the main source of blood supply to the membranous labyrinth, originates from the *anteroinferior cerebellar artery* (AICA; Lee et al., 2004). After entering the inner ear, the labyrinthine artery divides into two main branches: the *common cochlear artery* and the *anterior vestibular artery*. The cochlear artery also divides into two branches: the *posterior vestibular artery* (blood supply to the inferior part of the saccule and the ampulla of the posterior SCC) and the *main cochlear artery* (blood supply to the cochlear structures). The anterior vestibular artery, the other branch of the labyrinthine artery, is the blood supply to the utricle, superior portion of the saccule, and the ampulla of the anterior and lateral SCCs. The vestibular system is susceptible to ischemic events because the arteries lack collateral connections with other major arterial branches. It has been noted that a 15-second interruption in blood supply can cause

FIGURE 20.7 Macule. **A:** Structural organization of the utricular macula. **B:** Mechanisms of hair cell activation with static tilt. **C:** Orientation of saccular and utricular macules. Arrows indicate the direction that the kinocilia point toward. [**A** and **B:** Kiernan JA. [2004] *Barr's The Human Nervous System*. [1976] *Manual of Electronystagmography*. St. Louis, MO, CV Mosby.]

impairment of the vestibular sensory receptors, and different sensory receptors can be selectively damaged (Kusakari et al., 1981).

Central Vestibular System

VESTIBULAR NUCLEI

There are four main VN within the brainstem: superior, lateral, medial, and inferior/descending (Figure 20.9; Straka et al., 2005). The VN receive primary input from the vestibular portion of cranial nerve VIII, but they are innervated by multiple nerve fibers, not just direct vestibular connections. For example, the VN receive visual and proprioceptive afferent information in addition to the primary vestibular

signals (Angelaki and Cullen, 2008). Outputs from the VN project to the contralateral VN, ipsilateral and contralateral abducens, trochlear nuclei, and oculomotor nuclei and to the motor spinal cord via the medial vestibulospinal tract (MVST), lateral vestibulospinal tract (LVST), and the reticulospinal pathway (Figure 20.9; Baloh and Kerber, 2011). The VN also send projections to the cerebral cortex for perception of motion and to cerebellar pathways to coordinate compensatory eye and head movements and postural changes.

CEREBELLUM

Afferents from the medial and inferior VN project to the flocculus, nodulus, uvula, and fastigial nucleus of the

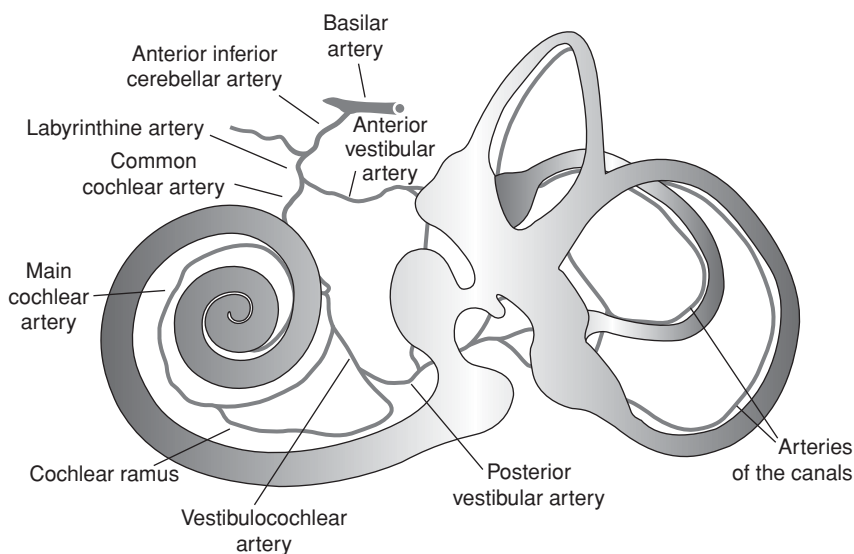

FIGURE 20.8 Blood supply to the membranous labyrinth. [From Schuknecht HE. (1974) *Pathology of the Ear*. Cambridge, MA: Harvard University Press; Figure 2.63, p. 62.]

cerebellum (Baloh and Kerber, 2011). These areas of the cerebellum are collectively known as the *vestibulocerebellum*. The efferent cerebellovestibular pathway extends from the vermis, flocculus, and fastigial nuclei and terminates on the lateral VN. Stimulation of this pathway results in an inhibition of VN activity (Ito, 1993). This pathway is implicated in vestibulo-ocular reflex (VOR) suppression and central vestibular compensation.

ROLE OF THE VESTIBULAR SYSTEM

The vestibular end organs sense head rotation and linear accelerations and send that information to secondary neurons in the VN. Secondary vestibular neuron signals diverge to many areas of the central nervous system and serve as

FIGURE 20.9 VCR and VOR pathways. S, superior vestibular nucleus; L, lateral vestibular nucleus; M, medial vestibular nucleus; D, descending vestibular nucleus. [From Canalis RF, Lambert PR. (2000) *The Ear: Comprehensive Otolology*. Philadelphia, PA Lippincott Williams & Wilkins; Figure 12, p. 125.]

a key relay in at least two important vestibular reflexes: the VOR and the *vestibulospinal reflex* (VSR; Figure 20.9). Neurons encode head movement and form synapses with ocular motor nuclei that generate patterns of extraocular muscle (EOM) contraction and relaxation required for driving the VOR, which stabilizes gaze. These neurons also synapse with spinal motor neurons that drive the VSR, which is used to stabilize posture and adjust gait. Additional central nervous system areas also receive this input including (1) autonomic centers, which receive input regarding posture with respect to gravity resulting in an adjustment of hemodynamic reflexes to maintain cerebral perfusion; (2) cerebellum, which is required for coordination and adaptation of vestibular reflexes when abnormal changes occur such as injury to the vestibular system; and (3) cerebral cortex, which is used to mediate perception of movement and orientation. Thus, the 10 vestibular sensory organs (five on each side) provide input to multiple areas of the central nervous system resulting in an intricate network used to maintain balance.

Extraocular Muscles and Ocular Motility

To understand the VOR, it is important to understand the anatomy of the six EOMs that control eye movement and the connections from the peripheral vestibular system to the ocular motor neurons (Figure 20.10). The lateral rectus and medial rectus control horizontal movement; the superior rectus and inferior rectus control vertical movement; and the superior oblique and inferior oblique control torsional movement (Table 20.1). These EOMs are often described by paired agonist and antagonist counterparts where the contraction of one muscle occurs concomitantly with the relaxation of its muscle pair (e.g.,

FIGURE 20.10 The six extraocular muscles of the eye. [Courtesy of Patrick Lynch, Yale University School of Medicine.]

TABLE 20.1

Extraocular Muscle Pairs and their Plane of Action

Muscle Pairs	Primary Plane of Action
Lateral rectus and medial rectus	Horizontal
Superior rectus and inferior rectus	Vertical
Superior oblique and inferior oblique	Torsional

contraction of the lateral rectus results in relaxation of the medial rectus). The orientation of the SCCs matches the plane of movement controlled by one pair of eye muscles. For example, as shown in Table 20.2, the lateral canal has an excitatory connection with the ipsilateral medial rectus and contralateral lateral rectus as well as inhibitory connections with the contralateral medial rectus and ipsilateral lateral rectus. Figure 20.11 shows an illustration of the excitatory and inhibitory connections between the SCCs and the EOMs.

Three ocular motor nuclei innervate the eye muscles. Signals to the lateral rectus are routed through the abducens (sixth) nucleus (Figures 20.11B and 11E). Signals to the superior oblique are routed through the trochlear (fourth) nucleus (Figures 20.11C and 11D). The remaining EOMs are innervated by the oculomotor (third) nucleus (Figure 20.11). The three ocular motor nuclei receive signals from the VN via the medial longitudinal fasciculus (MLF), ascending track of Dieters, or the reticular formation.

OCULOMOTOR CONTROL SYSTEMS THAT INTERACT WITH THE VOR

The purpose of the VOR is to stabilize gaze during head movement. Similarly, the primary purpose of the ocular motor system is to stabilize gaze by moving the eyes to view an item of interest. Objects are viewed most clearly at the center of the retina, known as the *fovea*, because of the higher concentration of sensory cells in that area. The center of the fovea, the *foveola*, provides even greater resolution. The interested reader is referred to Leigh and Zee (2006) for a more detailed description of the anatomy and physiology of the ocular motor system.

Saccades are rapid eye movements whose function is to place the image of interest on the fovea. Saccades are different from other eye movements because they move at very high velocity and vision is impaired during the movement. Generation of horizontal saccades involves the paramedian pontine reticular formation (PPRF) as well as multiple sites within the central nervous system. Impairment of saccadic eye movements often localizes to lesions of the brainstem or cerebellum (Leigh and Zee, 2006).

The saccadic system interacts with the vestibular system during head movement. When the head turns, the VOR initiates a slow eye movement (i.e., the “slow phase” of nystagmus) in the opposite direction of head movement. The saccadic system is responsible for bringing the eyes back to midline (i.e., the “fast phase” of nystagmus) after the vestibular system has driven the eyes from primary position.

Smooth pursuit eye movements are intended to keep an object of interest on the fovea by matching target velocity with eye velocity. The smooth pursuit system generally requires a moving target to be activated, but is unable to reach high velocities so the system makes predictions about where the target will be and programs accordingly (Leigh and Zee, 2006). If this fails, or if the object is simply moving too quickly, the saccadic system is used to refocus the target on the fovea. The smooth pursuit system relies on multiple sites within the central nervous system, including the pons and cerebellum.

The smooth pursuit system is used for tracking moving objects while the head is stationary. It is also activated when one tries to fixate on a stationary object during head movement. Specifically, head movements activate the VOR effectively moving the eyes resulting in the stationary image of interest moving across the fovea. This act triggers the smooth pursuit system to override the VOR, which suppresses the slow phase of vestibular nystagmus and allows one to fixate on the object of interest. This is referred to as *fixation suppression*.

Optokinetic nystagmus (OKN) is a repetitive series of fast and slow eye movements responsible for maintaining stable vision during movement of the visual surround. OKN and pursuit are both tracking responses and are often activated at the same time. OKN shares pathways with other eye movements, but the nucleus of the optic tract plays an important role (Leigh and Zee, 2006).

The OKN system contributes to gaze stabilization when an image moves across the retina. This system is important

because the peripheral vestibular system does not provide accurate information during very low frequency–sustained movement. For this type of movement, the OKN system is activated and attempts to stabilize a moving image by moving the eyes in the same direction. Together, optokinetic and vestibular nystagmus are combined to provide stable vision across a wide frequency range of movement.

Vestibulo-ocular Reflex

The VOR contributes to ocular stability when the head is in motion. The eye movements induced by the vestibular system (i.e., the VOR) are compensatory (Leigh and Zee, 2006). That is, they oppose head movements or changes in head position and act to keep the fovea of the retina on an object of interest. To put things in perspective, a quick turn of the head to the left sends input through multiple ocular motor nuclei resulting in a compensatory reflex pulling the two eyes to the right. The horizontal VOR (hVOR) is the focus of most clinical vestibular testing and is what we will discuss here.

A simplified description of the hVOR pathway is shown in Table 20.3. When the head turns to the left, endolymph lags behind the head movement because of inertia and the left cupula in the horizontal SCC is deflected toward the kinocilium whereas the right cupula is deflected away from the kinocilium. Thus, discharge from the left SCC increases and discharge from the right SCC decreases. Increase in activity from the left SCC results in an increase in activity in the left VN, causing an excitatory output to the right lateral rectus muscle and the left medial rectus muscle (i.e., pulling the eye to the right) while inhibiting the right medial rectus and left lateral rectus (i.e., the paired agonist and antagonist eye muscle counterparts; Table 20.2). Since the right cupula is deflected away from the kinocilium, the right SCC sends a signal decreasing the activity of the right VN, causing a decrease of excitatory output to the left lateral rectus and the right medial rectus (Table 20.2). The end result is movement of the eyes to the right (to compensate for the head turn to the left) with a fast saccade back to the left (i.e., left-beating nystagmus; Figure 20.12).

TABLE 20.3

6. Effector muscles [medial and lateral rectus]

Nystagmus is a biphasic, rhythmic, repetitive movement that has a well-defined slow and fast phase (Markham, 1996). Conventionally, it is named (i.e., right or left) by the direction of the eye during the fast phase. The vestibular system mediates the slow phase of the nystagmus; as such vestibular nystagmus (i.e., nystagmus provoked by head movement) is typically quantified by its maximum slow-phase velocity (SPV). Following the slow phase of the nystagmus, the PPRF neurons produce a saccade bringing the eyes back to midline (i.e., the fast phase of nystagmus).

Neural Integrator and Velocity Storage

The vestibular system responds to input frequencies between 0.003 and 5 Hz (e.g., 0.01 Hz is a very slow postural sway and 5 Hz is akin to an active head turn during walking). Because of the mechanical properties of the cupula, the system is less sensitive to input frequencies less than 0.8 Hz and greater than 5 Hz. However, the vestibular system has a brainstem-mediated process for enhancing the sensitivity to low frequencies, called the *neural integrator*, located in the VN (specifically the caudal pons) that is under the control of the cerebellum (i.e., nodulus and uvula).

The time taken for the slow-phase eye velocity to decline to 37% of its initial value after the onset of a velocity test stimulus is called a *time constant* (TC). In response to continual earth axis rotation, cranial nerve VIII produces neural activity until the cupula in the lateral SCC returns to neutral position (TC = 6 seconds). The nystagmus intensity of the VOR shows rise similar as the VIIIth nerve; however, the nystagmus duration is considerably longer (TC = 16 seconds). In other words, the eye response of the VOR persists for a longer period of time than the drive from the peripheral end organ. The prolongation of nystagmus beyond the duration of the peripheral drive is attributed to the neural integrator. The neural integrator acts to extend the low-frequency response of the VOR by one order of magnitude, a function that has been referred to as *velocity storage* (Raphan et al., 1979). Loss of velocity storage affects low-frequency sensitivity of the vestibular system and is identified in clinical assessment by a change in the timing properties of the VOR (i.e., decreased TCs on trapezoidal testing or increased phase on sinusoidal harmonic testing).

The central pathways of velocity storage are not fully understood but there appears to be both “direct” and “indirect” pathways driving the VOR. The “direct” pathway is mediated by the electrical signal originating from the lateral SCC, passing through the first-order neurons in the VIIIth cranial nerve, to the second-order neurons leaving the medial VN and synapsing on the ocular motor nuclei and abducens nuclei, and finally the third-order neurons terminating on the ocular motor muscles. The “indirect” pathway travels from the vestibular nerve through a series of neural connections and terminates on the midline cerebellum. The

FIGURE 20.12 Head turn to the left results in left beating nystagmus. [From Canalis RF, Lambert PR. [2000] *The Ear: Comprehensive Otology*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 13, p. 127.]

cerebellum plays an important role in velocity storage function, specifically the efferent portion of the “indirect” pathway extending from the midline cerebellum (i.e., nodulus and uvula) and projecting to regions of the superior and medial VN. Output from the “indirect” pathway persists for a longer period of time than the input it receives from the periphery (Galiana and Outerbridge, 1984). Both the “direct” and “indirect” velocity storage pathways are integrated centrally by a commissural network originating in the brainstem.

In summary, velocity storage is dependent on the electrical drive from the peripheral vestibular end organ, the integrity of the VN, commissural fibers in the brainstem,

and connections between the cerebellum and VN. Under normal circumstances, it serves to widen the dynamic range of the vestibular response. In the case of vestibular dysfunction, abnormal velocity storage is the most sensitive parameter on rotary chair testing and is used in conjunction with ear-specific measures to provide valuable information as to the status of the peripheral and central vestibular system.

Vestibulospinal Reflex (VSR)

The VSR is used to produce transitory contractions of muscles to maintain posture, equilibrium during movement, and muscular tone. Whereas the effector organs of the VOR

are the EOMs, the effector organs of the VSR are the extensors of the neck, trunk, and extremities. Stimulation of the SCCs and the otolith receptors leads to a variety of patterns of activation of neck and body muscles. A push–pull mechanism exists between the extensor muscles (e.g., triceps) and flexor muscles (e.g., biceps). The VSR requires a coordinated action of both extensor and flexor muscles to respond to postural disturbances.

Connections from the VN to the spinal cord are through three main pathways, the MVST, the LVST, and the reticulospinal tract. The MVST and LVST provide direct connections to neck motoneurons and indirect connections through spinal interneurons. The reticulospinal tract has indirect connections with the VN through the reticular formation.

The MVST receives input from both the saccule and utricle via the medial VN, but the saccular input is more prominent. The MVST also receives afferent input from all SCCs, though the input from the lateral and superior SCCs is more prominent than the posterior SCC input. The MVST pathway descends bilaterally through the MLF into the spinal cord (Barmack, 2003).

The main afferent input to the LVST is from the utricle and posterior SCC via the lateral VN. Fibers from the LVST descend into the ipsilateral central funiculus of the spinal cord (Barmack, 2003). Both the MVST and LVST send fibers to the spinal cord, but the MVST is more important for coordinating the muscles and providing tonic input to motor neurons that stabilize the head position in space (i.e., neck and cervical muscles). The LVST results in the activation of extensor motor neurons and inhibition of flexor neurons in the upper and lower extremities.

The *vestibulocollic reflex* (VCR), part of the VSR, is the focus of most clinical vestibular testing as it is what we assess with the cervical vestibular–evoked myogenic potential (cVEMP) test. The basic pathway is shown in Table 20.4. The saccule sends an electrical signal through the inferior vestibular nerve to the medial vestibular nucleus. A signal is then sent to the spinal cord motor neurons via the MVST, resulting in an increase in the ipsilateral activation of the extensor motor neurons and inhibition of the flexor motor neurons in the neck and cervical region. Clinically, the

LESIONS OF THE VESTIBULAR SYSTEM

What Happens to the VOR in Unilateral Impairment

The severity of signs and symptoms of vestibular impairment is predicated on the degree of damage, the speed of onset, and whether the damage is unilateral or bilateral. In an acute unilateral impairment, vertigo symptoms are usually severe. With gradual unilateral loss, it is possible that the symptoms associated with an acute event never occur because incremental changes in vestibular function are offset by incremental compensation in the central nervous system. Similarly, a patient with gradual bilateral loss may also not experience vertigo, but instead report oscillopsia and ataxia under dynamic conditions.

This section will examine what happens in an acute unilateral impairment of one vestibular end organ, in this case the right side (Figure 20.13B). A right-sided impairment results in a decrease in the electrical drive from the right end organ to the nerve and to the VN on that side. The result is in an electrical code similar to that created during a leftward rotational (counterclockwise) head movement resulting in a slow-phase eye movement toward the right, followed by fast-phase movement to the left (i.e., motion-induced left-beating nystagmus shown in Figure 20.13A). In the case of an acute impairment, the nystagmus will continue whereas the asymmetry between sides remains. In this example, the lesion of the right vestibular nerve will result in a continual left-beating nystagmus creating the illusion of movement of the surroundings, often perceived by the patient as vertigo. In the acute period, the nystagmus will be direction fixed and occur in all directions of gaze and will follow Alexander's law (i.e., amplitude of nystagmus increases when gazing in the direction of the fast phase; Jacobson et al., 2008). The nystagmus augments when vision is denied.

Central Compensation

Acute unilateral peripheral vestibular impairment yields an asymmetry in neural firing causing a persistent nystagmus and retinal slip that triggers a central compensation process (Zee, 1994). Static compensation is complete when the tonic electrical activity of the two VN is restored. Keeping with the example of right peripheral vestibular damage, the compensation process would begin within hours of the initial lesion to the right side. The first step is to eliminate the tonic asymmetry in the firing rate of vestibular neurons. The asymmetry in neural firing rates and the spontaneous nystagmus is reduced when the cerebellum downregulates

FIGURE 20.13 Vestibular compensation after lesion to the right peripheral vestibular system. **A.** Normal physiology following leftward head rotation. **B.** Acute loss of vestibular function on right side. **C.** Cerebellar clamping reduced acute symptoms. **D.** Release of cerebellar clamping. **E.** Static compensation is complete. [Canalis RF, Lambert PR. (2000) *The Ear: Comprehensive Otolaryngology*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 19, pp. 136–137.] *[continued]*

FIGURE 20.13 [Continued]

the electrical activity of the VN on the left (intact) side (i.e., “cerebellar clamping”; Figure 20.13C). Typically, within 1 week of the lesion, neural activity returns to the right VN (Figure 20.13D). The activity does not originate from the right vestibular end organ or nerve; it originates from central sources (i.e., vestibulocerebellum). The activity in the left VN then begins to increase as the downregulation from the cerebellum ceases (i.e., a release from clamping; Figure 20.13D). After 3 weeks, static compensation should be complete. The electrical firing returns to its prelesion level on the left side and neural tone is restored to the VN on the right side (Figure 20.13E). The central nervous system is “guessing,” based on the electrical input from the left side, what activity it would have received had the right peripheral vestibular system been intact. When static compensation is complete, the patient’s vertigo stops, spontaneous nystagmus disappears, and postural control is restored. Retinal slip still occurs during rapid head movements and the patient may report some oscillopsia.

Dynamic compensation occurs when the gain of the vestibular pathway is modified to accommodate unilateral loss of input during head movement. Continuing with the previous example, after static compensation has occurred, the tonic resting rate at the level of the VN is equal between the right and left side. Head rotation generates the neural asymmetry at the level of the VN required for awareness of rotation. However, the size of the asymmetry is half of that generated by two functioning inner ears (since, in our example, only the left vestibular end organ is functioning) and as such the velocity of the slow phase of nystagmus is too low to match the head movement resulting in retinal slip. During dynamic compensation, the central vestibular pathways are “recalibrated” (Zee, 1994). That is, the gain of the VOR pathway must essentially be doubled to generate the same compensatory eye movement generated before the lesion. The retinal slip that occurs with rapid head movements drives the neural integrator to decrease velocity storage (i.e., increase electrical flow). The increase in outflow of

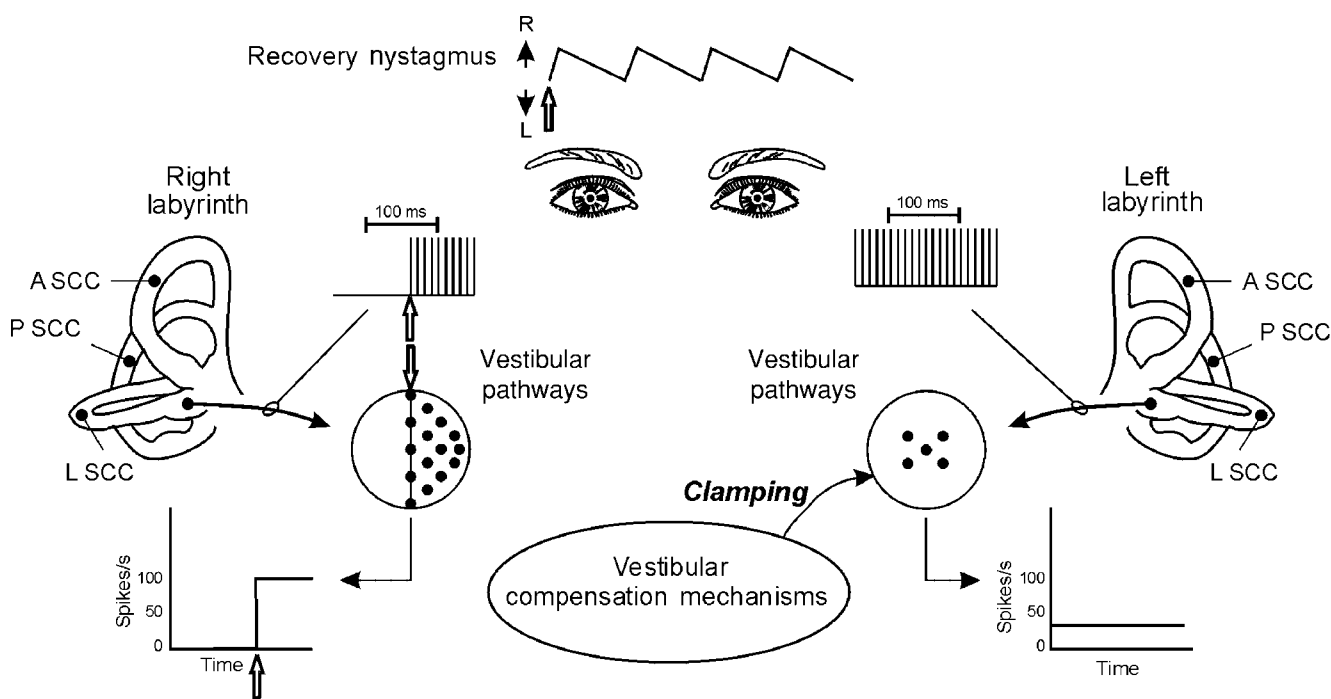

FIGURE 20.14 Recovery nystagmus [Katz, 6th ed. Figure 19.20, p. 455].

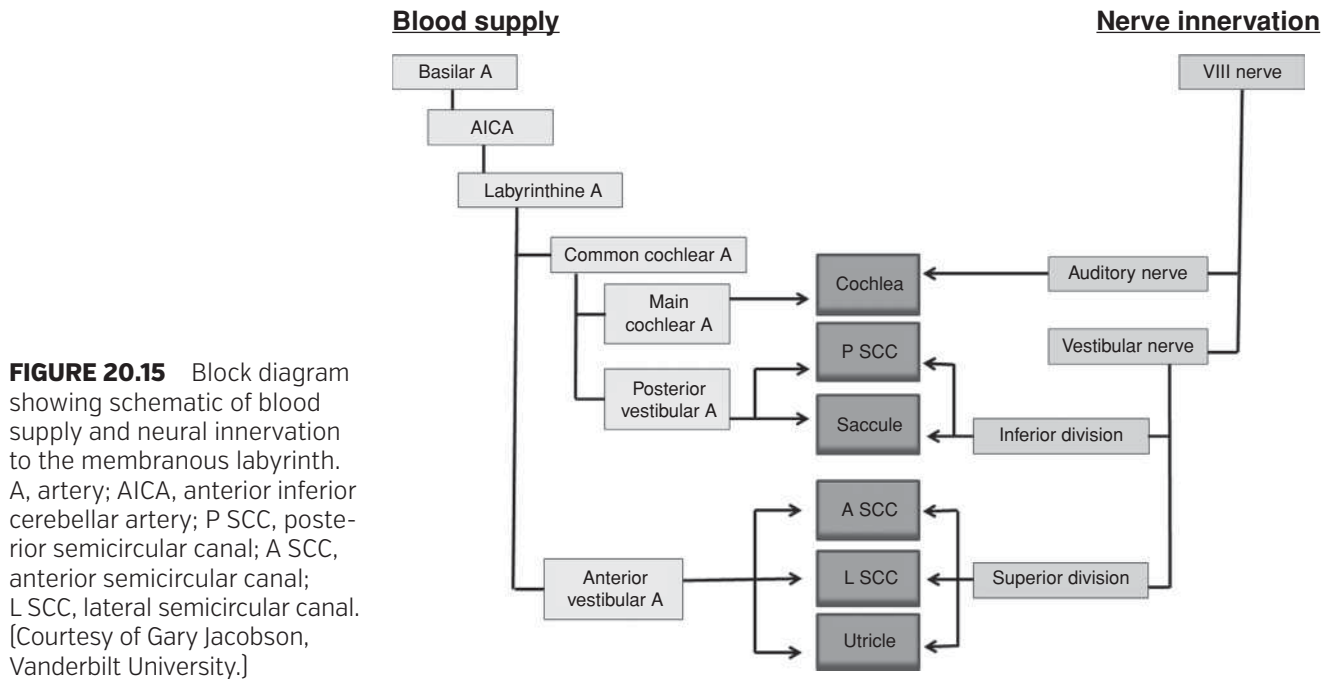

the velocity storage mechanism increases the gain (electrical output) of the neural integrator and increases the gain of the VOR so that compensatory eye movements occur during dynamic head movements (Figure 20.13F). Consequently, diminishing the storage capacity of the neural integrator degrades low-frequency VOR performance (i.e., recall the purpose of the neural integrator is to enhance the vestibular system's sensitivity to low frequencies). Complete dynamic compensation results in the elimination of VOR asymmetry and oscillopsia (retinal slip); however, degradation of low-frequency VOR performance often remains (Leigh and Zee, 2006).

It is possible, during central compensation, for a spontaneous nystagmus to paradoxically beat toward the lesioned ear. This is called *recovery nystagmus* or "Bechterew's nystagmus" (Figure 20.14) and usually occurs in individuals with fluctuating vestibular impairments (e.g., Meniere's disease; Leigh and Zee, 2006). Recall, during "cerebellar clamping" the firing rate of the VN on the intact side is reduced to lessen the asymmetry between ears. Typically during this phase of compensation the level of neural activity at the VN is bilaterally reduced. In a stable impairment, static compensation will continue as described above. With a fluctuating lesion, the damaged side can spontaneously recover function. If this occurs during compensation, then an asymmetry once again exists between the sides; only this time the VN of the damaged ear shows greater neural activity relative to the intact ear (Figure 20.14). As a result, the clinician may observe a recovery nystagmus. For this reason, a spontaneous nystagmus should not be used in isolation to localize the site of lesion.

NEW TRENDS

Do blood perfusion and neural innervation patterns make it possible to have isolated end organ impairments that might be detected through quantitative testing? Figure 20.15 is a simplified block diagram showing the basic blood supply and neural innervation to the membranous labyrinth. Injury to the *superior division* of the vestibular nerve blocks the electrical signals originating from the utricle, anterior SCC, lateral SCC, and small portion of the saccule (not shown in the figure). Injury to the *inferior division* of the vestibular nerve blocks the electrical signals originating from the saccule and posterior SCC. The different neural innervation patterns of each end organ can help explain how a neuritis or ischemia can produce a focal lesion affecting only the saccule and/or posterior SCC (i.e., inferior neuritis) or the utricle, lateral SCC, and/or anterior SCC (i.e., superior neuritis).

A review of the blood supply to each end organ can provide clues as to how thrombus or emboli can produce a specific impairment. If the arterial support from the basilar artery, AICA, or labyrinthine artery is cut off the result is profound hearing loss and total loss of peripheral vestibular system function (i.e., the entire labyrinth including the cochlear and vestibular end organs loses function). If the blood supply from the common cochlear artery is interrupted the result is a profound hearing loss and loss of saccule (i.e., abnormal *cVEMP*) and posterior SCC function only (i.e., *caloric* testing and *ocular VEMP* (oVEMP) will be normal). If a lesion occurs in the main cochlear artery, the result would be a profound hearing loss and an intact peripheral vestibular system. If the posterior vestibular artery is cut off, the result would be a loss

of function in the posterior SCC and saccule (i.e., abnormal *cVEMP*) with both hearing and the remainder of the vestibular system intact. Finally, if the anterior vestibular artery is cut off, we see loss of function in the anterior SCC, lateral SCC (i.e., abnormal *caloric test*), and utricle (i.e., abnormal *oVEMP*) with normal hearing, normal saccule (i.e., normal *cVEMP*), and normal posterior SCC function.

A number of recent papers have been published suggesting that the caloric test, *cVEMP*, and *oVEMP* can vary independently and provide topologic information regarding vestibular impairments (e.g., Jacobson et al., 2011). For example, one may have an impaired saccule or inferior vestibular nerve (i.e., as assessed with a *cVEMP*) but the remainder of peripheral vestibular system is normal (i.e., normal caloric test and normal *oVEMP*). So the *cVEMP*, *oVEMP*, and caloric test results may vary independently for patients with various peripheral vestibular system impairments. Ongoing research in the utility of the video head impulse test (*vHIT*) may allow us to assess the posterior and anterior SCCs independently as well. In the near future, it may be possible to test all aspects of the peripheral vestibular system (i.e., all 10 end organs and superior and inferior divisions of the vestibular nerve). Thus, the combination of results from *cVEMP*, *oVEMP*, caloric, and *vHIT* has the potential to provide localizing information about the specific site or sites of peripheral vestibular system impairment.

FOOD FOR THOUGHT

1. The cupula is a gelatinous material that divides the SCCs from the vestibule and senses angular acceleration. Why can't the cupula sense gravity (i.e. like the macula within the saccule)?

2. Describe the vestibulo-ocular reflex (VOR) pathway.
3. If the neural connections between the cerebellum and vestibular nuclei are not intact, can central compensation following an acute vestibular lesion be completed? Why or why not?

Evaluation of the Patient with Dizziness and Balance Disorders

Troy Hale, Henry Trahan, and Tabitha Parent-Buck

INTRODUCTION

Balance disorders are common and can occur in patients of all ages, constituting a significant personal and public healthcare burden. It is often reported that dizziness is the third most common complaint among outpatient medical visits and the single most common complaint among elderly patients. Dizziness and balance disorders may result from abnormalities in a variety of organ systems including the vestibular system, central or peripheral nervous system, cardiovascular system, and cerebrovascular system. Additionally, medications taken by patients can contribute to symptoms of dizziness. When a patient presents to the balance clinic, the primary goal of the healthcare provider is to investigate the symptoms and conduct evaluations to narrow the differential diagnosis. Although most patients with dizziness have a benign condition, a small percentage may have a potentially life-threatening underlying cause involving the brain, heart, or the circulation of blood necessitating more immediate medical management. In many cases the patient with an acute balance disorder will recover spontaneously requiring only short-term treatment for the symptoms. However, patients demonstrating more chronic symptoms may require significant intervention from healthcare providers to evaluate and manage the dizziness.

More than 4 out of 10 Americans will experience an episode of dizziness sometime during their lives significant enough for them to seek medical care (NIH News in Health, 2012). Data suggest that one in five patients over 65 years of age experience problems with balance or dizziness annually. A review of data from the US Census Bureau's National Health Interview Survey, collected in 2008, provided alarming statistics on balance issues in the elderly population (Lin and Bhattacharyya, 2012). For patients 65 years of age and older, 20% or 7 million people in the United States reported experiencing dizziness or a balance problem in the previous 12 months. With respect to quality of life and functional impact, of those individuals who experienced dizziness or balance problems, 27% reported that the balance issues prevented them from participating in normal activities.

The restriction in activities included not engaging in exercise (61%), social events (46%), driving (47%), and participation in work/school (38%). Additionally, for 26% of those with balance issues, simple activities of daily living such as bathing, dressing, and eating were also reported as affected.

Epidemiologic studies relate balance disorders to the increased incidence of falls in the aging population. The Centers for Disease Control and Prevention in the United States report that roughly one-third of adults 65 years of age and older fall each year, resulting in injuries that limit activities and independent living. Of patients who fall, 20% require medical attention (Gillespie et al., 2013). In addition, falls among older adults, especially those resulting in fractures, are a leading cause of injury-related deaths. Patients suffering from dizziness or imbalance may report unsteadiness, light-headedness, vertigo, dysequilibrium, or a feeling of fainting/pre-syncope. Such conditions may ultimately lead to serious medical, physical, emotional, and social consequences such as loss of independence, isolation, and injuries from falls. Because of the impact of dizziness on the quality of life of patients and the increased risk of falls, a number of falls prevention programs have been investigated and found to provide effective methods for reducing falls (Gillespie et al., 2013).

Given the vast number of acronyms commonly used in relation to vestibular screening and diagnostic measures, Table 21.1 provides a list that will aid in recognizing many terms and their abbreviations used throughout this chapter.

CLINICAL PRESENTATION OF THE DIZZY PATIENT

Our innate ability to maintain balance and navigate safely through the environment depends on sensory information that is gathered from the visual, vestibular, and somatosensory (proprioceptive) receptors of the body. A properly functioning balance system allows us to maintain stable vision with movement, orient ourselves with respect to gravity, and make automatic postural adjustments for maintenance

TABLE 21.1

List of Screening and Diagnostic Vestibular Tests or Measures with Commonly Used Acronyms

Acronym	Test Name or Measurement
AHR	Active head rotation
BPPV	Benign paroxysmal positional vertigo
CDP	Computerized dynamic posturography
CTSIB	Clinical Test of Sensory Integration of Balance
DHI	Dizziness Handicap Inventory
DP	Directional preponderance
DVA	Dynamic visual acuity
ENG	Electronystagmography
HIT	Head impulse test
HSN	Headshake nystagmus
HVT	Hyperventilation test
OKN	Optokinetic nystagmus
SHA	Sinusoidal harmonic acceleration
SCV or SPV	Slow-phase component eye velocity/ slow-component eye velocity or slow-phase velocity
UW	Unilateral weakness [may also be referred to as reduced vestibular response [RVR]]
VFX	Visual fixation
VNG	Videonystagmography
VOR	Vestibulo-ocular reflex
VSS	Vertigo Symptom Scale
VVOR	Visually enhanced vestibulo-ocular reflex

of stability. When a person is complaining of imbalance or dysequilibrium, the first task of the audiologist is to have the patient describe the symptoms in detail. This information forms the basis for beginning to determine which sensory input system, or which combination, is contributing to the patient's complaints.

Signs and Symptoms

Many patients will report their presenting symptom as "being dizzy." The term "dizzy" is not particularly specific because it broadly refers to some perception of imbalance, disorientation in space, or false feelings of movement. Patients may describe symptoms with terms such as dizziness, dysequilibrium, spinning, swimming, light-headedness (pre-syncope), floating, turning, and perhaps even vertigo. Although the symptoms reported by patients can provide valuable information for formulating an assessment plan, caution must be taken because the terms used are subjective and can be misleading. The importance of gathering more detailed information to further charac-

terize the reported symptoms will be emphasized below under the topic of the neurotologic case history. Dizziness is often classified into distinct categories based on quality or character of presentation. Various authors have suggested from four to six general categories with the most common descriptors being vertigo, dysequilibrium, pre-syncope, light-headedness, and gait instability. Each of these is briefly described here.

Vertigo has been described as a hallucination or illusion of movement because of an imbalance in the central or peripheral vestibular system. The spinning or tilting illusion of movement can be of self, of surroundings, or a combination of both. Vertigo is often associated with nystagmus, oscillopsia (blurring or oscillation of the visual field), postural imbalance, and autonomic symptoms (e.g., sweating, pallor, nausea, and/or vomiting).

Dysequilibrium is a state of altered static (standing/sitting) or dynamic (ambulating) postural balance without vertigo. Patients presenting with dysequilibrium often complain of visual disturbance, unsteadiness, imbalance, and/or falls. Typically, this condition reflects a failure or mismatch of sensory integration among body systems (e.g., visual, vestibular, muscular, or neurologic) or a disturbance of motor control. Dysequilibrium may be further subdivided into psychologic and ocular subcategories with the former characterized by feelings of anxiety, fear, or confusion and the latter with visual integration deficits often leading to motion sickness.

Pre-syncope is a syndrome characterized by a sensation of impending loss of consciousness (as opposed to syncope, which is actual fainting) and may be associated with a cardiovascular abnormality, malaise, generalized weakness, diaphoresis, visual disturbances, nausea, facial pallor, and/or epigastric (abdominal) distress. Orthostatic hypotension is a common cause of pre-syncope, but arrhythmias, postural orthostatic tachycardia syndrome, hyperventilation, panic attacks, and other conditions can produce the sensation as well. Episodes of pre-syncope are generally relieved with lying down or reclining.

Light-headedness is another common descriptor and is generally meant to imply a head sensation that is not vertiginous or pre-syncope and not related to ambulation. Light-headedness can be transient or persistent and is often associated with anxiety or hyperventilation syndrome. Patients who complain of this sensation often say that they feel like they are floating, they are giddy, or their head is somehow detached from their body. Because light-headedness is such a vague and variable term, it may actually reflect other types of dizziness that are not properly described.

Gait instability or ataxia is an unsteadiness or inability to perform coordinated muscle movements. Gait unsteadiness can arise when there is a deficit in the central nervous system or either the central or peripheral vestibular systems. Symptoms with this type of presentation are generally constant and sometimes progressive, with patients

reporting that they feel like they are intoxicated during ambulation.

The Neurotologic Case History

Most vestibular disorders cannot be distinguished from one another based solely on laboratory studies. Additionally, laboratory studies tell us little about a particular patient's functional disability as a result of his/her condition. As such, balance function tests are best interpreted in conjunction with an in-depth neurotologic case history. The neurotologic case history begins with the acquisition of a full depiction of the patient's self-described symptoms. Several aspects must be investigated including, but not necessarily limited to, the feeling created by the symptoms, any precipitating events, the onset (e.g., when did they begin), the frequency (e.g., how often they occur), and the duration (e.g., how long do they last).

The general health condition preceding the onset of symptoms should be determined (e.g., any minor or major health issues such as a cold, gastrointestinal or respiratory problems, or head trauma). It is equally important to gather a complete drug history, including information about any medical or nonmedical care the patient has sought for the dizziness. This should include questions about the use of recreational drugs; the use of prescription medications; and the use of homeopathic or naturopathic herbs, supplements, and vitamins.

To the extent possible it is also important to identify any associated symptoms, recognizing that some of these symptoms may occur with more than one type of dizziness. Headache, for example, can occur with vertigo (e.g., migraine, brainstem ischemia), motor dysequilibrium (e.g., cerebellar infarct or hemorrhage), pre-syncope, and psychosomatic dizziness (often associated with anxiety, sleep deprivation, and caffeine overuse/withdrawal) (Sowerby et al., 2010). A careful evaluation of the patient's complaints and the answers to several simple questions can lead the audiologist to suspect whether the patient is suffering from a peripheral vestibular disorder, a central disorder, or a multifactorial disorder, which may alter the order or types of tests with which an individual is evaluated. Table 21.2 provides a summary of key areas to address during the case history process.

Although obtaining the neurotologic case history can be time-consuming, the collective sum of the patient's responses is used to initially separate out suspected vestibular versus nonvestibular disorders. This may be indicated by the patient's descriptions of onset, duration, and provoking factors of the dizziness. If the patient complains of the sensation that the room is spinning for about 1 minute after rolling over in bed or looking up, the clinician should suspect that a peripheral disorder may exist, specifically benign paroxysmal positional vertigo (BPPV). If the vertigo is continuous without fluctuation for long periods of time, such as weeks or more, a central cause should be suspected.

TABLE 21.2

Key Points to Address in the Neurotologic Case History Related to Dizziness

Area of Questioning	Probes [Preferably Asking Open-Ended Questions]
Description of the feeling/experience	What does the sensation feel like? Why are you here?
Severity	Is it mild, moderate or severe?
Onset	It is new, ongoing or changing since onset?
Duration	Is it short [seconds to minutes], intermediate [minutes to hours], long [>24 hours]?
Frequency	How often? [i.e., single episode vs. multiple and daily vs. weekly vs. occasionally]
Provoking factors	When do the attacks occur? Does anything make the dizziness occur [i.e., change in head, neck or body position; loud noise, exertion, diet, visual stimuli]?
Associated symptoms	Do you also have hearing loss, tinnitus, aural fullness, pain, headache, visual disturbances, numbness, nausea, or vomiting?
Other medical history/general health	Did any illness or health changes occur near the onset?
Drug case history	Any new medications or changes in prescriptions?
Level of disability or impact on function	No restrictions to activities to completely unable to engage in routine activities

In other instances, the preceding factors play a key role in highlighting a suspected origin for the dizziness or imbalance. For instance, if the patient reports the possibility of a viral illness prior to the sudden onset of dizziness and changes in hearing, this may point towards a viral labyrinthitis. In such cases, a hearing evaluation should be administered along with balance function assessment. Trauma to the head and/or neck may indicate neurologic involvement or, once again, BPPV. Medications that were prescribed for existing medical conditions, or to ameliorate symptoms of dizziness, could result in side effects and/or vestibulotoxicity and impaired balance function. Table 21.3 provides an overview of how the qualitative details gathered from appropriate questions can contribute to differentiating between suspected vestibular and nonvestibular sites of origin.

TABLE 21.3

Differentiating Vestibular and Nonvestibular Dizziness on the Basis of Patient Complaints

Component	Vestibular	Nonvestibular
Common descriptive wording used by patients	Off-balance, spinning (usually the environment moves), tilting, feels like car sickness, too much to drink, unsteady	Light-headed, floating on a cloud or swimming sensation, out-of-body, self-spinning but world is steady
Time course	Distinct attacks (episodic)	All day long (constant)
Common antecedent or exacerbating factors	Change in body position or quick head movements up or down or side to side	Stressful situations, heavy mouth-breathing (hyperventilating), heart thumping
Common symptoms	Nausea, vomiting, unsteadiness, ringing in ear(s), decreased hearing, blurred vision or bouncing vision	Syncope, difficulty concentrating, numbness, tension in body with or without accompanying headache

Self-Assessment Inventories

To assess the functional limitations of an individual's balance problems many health professionals employ self-assessment inventories. These can help to ascertain the patient's functional state or, stated otherwise, how the physiological problems affect the patient's quality of life. Several such self-assessment scales are reported in the literature; two of the common ones are described below.

The Vertigo Symptom Scale (VSS) (Yardley et al., 1992) was developed to assess the symptoms and the relationship between vertigo, anxiety, and emotional disturbances in an effort to examine the relative influence of vertigo and anxiety on reported handicap and distress. The VSS consists of 36 items describing common symptoms often reported by or observed from patients with vertigo. With the VSS, the patient is asked to rate the frequency of his/her experience over the preceding 12 months, and the results are summed and analyzed by the examiner in relation to vertigo and anxiety/autonomic symptom subscales.

The Dizziness Handicap Inventory (DHI) (Jacobson and Newman, 1990) is a standardized measure of self-reported limitations of daily life imposed by the patient's symptoms. The DHI consists of 25 questions that pertain to dizziness or unsteadiness and are to be answered by the patient with "yes," "no," or "sometimes." There are three subscales which investigate functional, physical, and emotional impacts on disability. Scoring ranges from 0 to 100 with those scoring above 10 indicating at least a mild handicap.

"Bedside" Screening Procedures

Evaluating patients with dizziness and/or balance disorders takes time. Often, when a patient is referred for evaluation, it may not be feasible or appropriate to perform a full vestibular test battery. Fortunately, simple "bedside" screening tools are available and, in the vast majority of patients,

produce results that coincide with the more extensive laboratory studies. Appropriately applied bedside measures can assist the clinician in the identification of site of lesion and qualification of functional impairment and, in some cases, are a useful counseling tool for patients. Screening measures, however, have limited validity and reliability. It is important to remember that a negative result on a bedside screening does not necessarily mean that the patient does not have the disorder being assessed. Sensitivity and specificity of screening measures vary widely and some have not been thoroughly investigated. In almost all cases, bedside tests should be used to direct patient management and should be corroborated by more comprehensive evaluations.

Determining which bedside tests to employ for a particular patient can be challenging. A typical screening battery may be driven by patient symptoms or may be more general, consisting of multiple measures to evaluate central ocular-motor control, as well as vestibulo-ocular and vestibulospinal reflex function. Bedside tests need not be limited to the initial patient interview either. Some screening procedures such as the swivel chair study and the Clinical Test of Sensory Integration of Balance (CTSIB) can be combined with electronystagmography (ENG) or videonystagmography (VNG) to expand the laboratory investigation, particularly when equipment such as rotary chair and computerized posturography may not be readily available. Although a comprehensive list of bedside testing is beyond the scope of this chapter, some of the common tests are briefly described below.

OCULAR MOTILITY

The ocular-motor and vestibular systems share many close anatomic and physiological connections. For this reason, eye movement can provide considerable information to assist in a preliminary evaluation. Certain patterns of nystagmus can be associated with either central neurologic or peripheral labyrinthine disorders. Prior to any examination, a quick

assessment of ocular-motor control should be performed by the clinician. This can be done quickly at the bedside using a finger or a probe. The clinician should examine the relative position of each eye within the orbit during center gaze, establish ocular range of motion, and assess the pursuit and saccadic mechanisms to get an idea of the patient's control of volitional eye movement. Central nervous system disorders or other ophthalmoparetic disorders have the potential to skew vestibular interpretation so it is advisable to identify these ahead of time. Any notable abnormalities may also indicate possible central nervous system involvement, necessitating additional referral.

HEAD IMPULSE/HEAD THRUST

The head impulse test (HIT) or head thrust test utilizes rapid passive head movements to evaluate a patient's functional vestibulo-ocular reflex (VOR) and identify the side of lesion in cases of unilateral or bilateral peripheral vestibular loss (Halmagyi and Curthoys, 1988). The patient is stationed in front of the examiner with his/her head tilted forward-down, approximately 30 degrees, to position the lateral semicircular canals coplanar (parallel) to the ground. The patient is then instructed to fixate on a target, typically the clinician's nose or forehead, and to maintain fixation on that target throughout the duration of the procedure. The examiner gently grasps the patient's head on both sides and passively guides it through a brief, unidirectional, high acceleration thrust. The movement must be rapid ($>3,000$ degree/s²), unanticipated by the patient, and not greater than a 20- to 30-degree displacement. The clinician monitors the patient's eye movements to see whether visual fixation is maintained throughout the entire excursion or whether the patient loses visual contact and must make quick corrective eye movements (termed "catch-up saccades") to reacquire the target. Patients with a significant unilateral or bilateral vestibular loss will have their eyes slip off the target when the head is thrust in the direction of the impaired labyrinth, resulting in a corrective saccade during or after the thrust. For example, a patient with a significant unilateral vestibular loss on the left side will experience a loss of visual fixation with leftward head thrust and therefore produce a catch-up saccade to the right to reacquire the target. This process occurs because of decreased neural contribution to the VOR from the ipsilateral ear and because the inhibitory signal from the contralateral ear is not sufficient to stabilize gaze during rotation. Therefore, the eyes initially travel with the head and a refixation saccade is necessary to reacquire the target. If there is no significant peripheral vestibular loss and the VOR is normal or near normal on the side of the movement, the eyes will remain fixed on the point of interest and no catch-up saccade will be necessary. Horizontal head movement in this manner assesses the lateral semicircular canals, whereas the anterior and posterior canals can also be evaluated by rotating

the head diagonally within the respective planes (Aw et al., 1996). The HIT procedure is typically repeated multiple times in an unpredictable fashion, bidirectionally within the plane of interest, until a proper assessment has been made. The head thrust exam has been shown to have good specificity ($>82\%$) but variable sensitivity (45% to 84%) in detecting unilateral or bilateral vestibular hypofunction, confirmed with caloric irrigation (Perez and Rama-Lopez, 2003; Schubert et al., 2004). Some measure of this variability between the head thrust test and caloric irrigation may be attributable to the vastly different stimuli employed by both tests, particularly as it relates to stimulus frequency. Most of the literature does suggest that the overall sensitivity of the head thrust increases as the degree of peripheral vestibular system impairment increases, particularly for those with caloric weaknesses greater than 40% (Perez and Rama-Lopez, 2003). Clinical utility of the HIT may be strengthened even further with new computerized diagnostic systems that are now available on the market.

DYNAMIC VISUAL ACUITY

The dynamic visual acuity (DVA) test evaluates a patient's ability to perceive objects correctly while actively moving his/her head. Normally, losses in visual acuity are minimized during head movement by the VOR which helps maintain gaze on a fixed target by driving the eyes in the equal but opposite direction of head movement. When the VOR is impaired, as is common in patients with bilateral vestibular hypofunction and various central disorders, visual acuity is degraded during head movement resulting in oscillopsia. The DVA test compares a patient's static visual acuity to his/her active visual acuity, measured during head rotation. The patient is seated in front of a Snellen eye chart at the appropriate distance and asked to read the letters or figures to the lowest line possible to establish the baseline static visual acuity. The examiner then gently grasps the patient's head from behind on both sides and passively guides it back and forth at a frequency between 2 and 7 Hz and with less than 20 to 30 degrees of displacement in the yaw (horizontal) plane. The patient is again asked to read the lowest line possible while the head is being moved. The lowest line at which the patient is unable to correctly identify at least half of the letters or figures is noted. Subjects with normal DVA will have no change or just a single-line change from baseline in their visual acuity during head rotation. Those with abnormal DVA will experience significant blurring in the visual field and will have line changes of two or greater during head movement (Longridge and Mallinson, 1984). Care must be taken by the clinician to avoid pausing at the turnaround points, and the patient should alternate the direction of line reading to control for letter or figure memorization. The sensitivity and specificity of the DVA test has been shown to be quite variable in the literature largely because of differing techniques and clinician experience.

HEADSHAKE

The headshake test evaluates a patient's central velocity storage mechanism. When the head is shaken vigorously back and forth for 20 to 30 seconds and then stopped, a transient vestibular nystagmus may emerge in patients with central and peripheral vestibular system disorders. This nystagmus is called headshake nystagmus (HSN) and is believed to reflect a dynamic asymmetry within the VOR. The patient is fitted with Frenzel lenses or VNG goggles (with vision denied to prevent VOR suppression) and stationed in front of the examiner with his/her head tilted forward-down, approximately 30 degrees, to position the lateral semicircular canals coplanar to the ground. The patient is then instructed to shake his/her head back and forth (actively) approximately 30 to 45 degrees from the center at a frequency of at least 2 Hz for 20 to 30 seconds. Alternatively, the head can be moved passively by the examiner. Immediately following cessation of the headshake, the patient is instructed to open his/her eyes and the clinician notes if any nystagmus is observed. In subjects with normal vestibular function, no nystagmus will be present and the test is deemed negative. In subjects with unilateral vestibular loss, a brief period of horizontal nystagmus may emerge and the test is considered positive. A test is generally said to be positive if at least five beats of nystagmus are noted within 20 seconds post-headshake (Guidetti et al., 2006).

Typically, the nystagmus will beat toward the more neurally active side, but other patterns have been described. This is believed to occur because of asymmetric neural firing of the central velocity storage integrator (Hain et al., 1987). The headshake test has been shown to have poor sensitivity for mild to moderate unilateral vestibular impairment, but with increasing degrees of vestibular hypofunction, there is general agreement in the literature that the sensitivity of the headshake test increases. Patients with bilateral vestibular impairment typically do not exhibit any post-HSN because the central neurons are not receiving asymmetric input. The presence of a vertical nystagmus after horizontal or vertical headshake has also been identified in some studies and may indicate a lesion affecting the central vestibular pathways, specifically the brainstem or cerebellum (Zee and Fletcher, 1996). The headshake test can be performed as a screening tool or as an addition to the typical ENG/VNG battery.

ROMBERG

The Romberg is a test of static balance that assesses the function of lower spinal reflexes by forcing the subject to rely solely on vestibular and proprioceptive inputs to maintain upright posture. The patient is instructed to stand with feet together and arms at the sides or folded across the chest while maintaining a quiet stance with minimal swaying. If the patient is able to do this effectively with eyes open, the stance is repeated with eyes closed. Each condition is held for

approximately 30 seconds or until a fall becomes imminent. Qualitative observations of postural adjustment, including direction and amplitude of sway, and any "falls" are made by the clinician. The test can be further modified (i.e., "sharpened") to increase the difficulty by having the patient stand in the tandem position (toe to heel) or on a foam pad. The Sharpened Romberg reduces the amount of proprioceptive feedback, therefore increasing the reliance on vestibular information. Regardless of the method, the clinician should always maintain close proximity to the patient while performing the Romberg to prevent a fall if the patient loses his/her balance. If the patient can maintain the standing position with eyes closed for 30 seconds without falling or without substantial increase in sway, the test is negative. The test is considered positive when there is increased sway or a "fall" with eyes closed. Increased sway or falls are associated with proprioceptive loss from the lower extremities. Patients with acute vestibular deficits and cerebellar dysfunction may also show a pattern of increased sway, although the latter is not typically affected by eye closure. Patients with acute uncompensated vestibular impairment may show a tendency to fall toward the side of lesion with eyes closed, but patients with compensated or chronic vestibular losses will often perform normally on the Romberg test.

FUKUDA STEPPING

The Fukuda step test is a screening measure used to identify the presence of a peripheral vestibular impairment that manifests as an asymmetry in lower extremity vestibulospinal reflex function. The Fukuda test should only be performed on patients who are able to maintain balance during eyes-closed Romberg testing. The patient is instructed to stand with eyes closed, arms extended outward in front of the body (palms down), and march in place for 50 steps. The angle, direction, and deviation from the original starting point are observed by the clinician after the stepping is complete. The patient should be able to complete this task without significant angular deviation (less than 45 degrees) and without significant linear translation (less than 1 m). A rotation of greater than 45 degrees in any direction is considered abnormal (Fukuda, 1959; Furman and Cass, 2003).

As it was originally described, patients with significant unilateral vestibular impairment would have a tendency to deviate (rotating greater than 45 degrees) in the direction of the affected labyrinth. This was a commonly held assumption for many years, but more recent investigations (Honaker and Shepard, 2012) have suggested that this may not be universally true and that the direction of rotation may be pathology dependent. For clinical purposes, the Fukuda step test should be considered positive if the angle of rotation exceeds 45 degrees or if excessive sway is noted. However, it should not be used in isolation to attempt to lateralize or localize lesions of the vestibular system as the type of pathology may produce results contradictory to the direction of rotation.

HYPERVENTILATION-INDUCED NYSTAGMUS

The hyperventilation test (HVT) is used to help identify disorders of the vestibular system and/or cranial nerve VIII. It may also be useful in identifying individuals who suffer from anxiety-related dizziness. When a patient is asked to voluntarily overbreathe for an extended period of time, a transient nystagmus may emerge in individuals with various central or peripheral vestibular disorders. This nystagmus is called hyperventilation-induced nystagmus and is believed to be caused by a change in blood gas concentration and nerve conduction. The patient is fitted with Frenzel lenses or VNG goggles (with vision denied), stationed in front of the examiner, and asked to take deep rapid breaths for a period of 30 to 90 seconds at a rate of about 1 breath per second (Minor et al., 1999). The clinician maintains close contact with the patient at all times to increase awareness of any change in patient postural stability and to minimize the risk of falling as this screening may bring about dizziness and reduced equilibrium. The examiner observes eye movement before and after the hyperventilation task and notes any evoked nystagmus or change in existing nystagmus. If the patient exhibits no nystagmus, the test is considered negative. Patients may report dizziness, a light-headed sensation, or decreased equilibrium as the result of this exam but this, in isolation, should not be interpreted as a positive result. The appearance of a new nystagmus or reversal of an existing nystagmus is considered a positive HVT. Peripheral vestibular lesions typically produce horizontal nystagmus with fast phases beating toward the side of lesion. However, in cases of total unilateral loss (e.g., vestibular nerve section), the nystagmus will typically beat away from the side of lesion (Chee and Tong, 2002). Hyperventilation-induced nystagmus may also be observed in patients with central lesions such as demyelination because of multiple sclerosis or cerebellar ischemia because of an infarct. In such cases, the direction of the nystagmus is unpredictable. If no nystagmus is provoked but the patient becomes severely symptomatic within the first 20 to 30 seconds of overbreathing, anxiety-related dizziness or dysautonomia may be suspected (Choi et al., 2007). Hyperventilation is more likely to provoke dizziness, light-headedness, autonomic symptoms, and acute anxiety attacks in patients with certain anxiety disorders than in the general population. It may also provoke light-headedness and autonomic arousal without significant anxiety in patients with autonomic dysfunction, such as hyperventilation syndrome. Sensitivity and specificity of the HVT vary widely in the literature so it should only be used in conjunction with other laboratory testing and not interpreted in isolation.

VALSALVA-INDUCED NYSTAGMUS

Increased middle-ear and intracranial pressure, as the result of Valsalva maneuver, has been shown to induce eye move-

ments and dizziness or vertigo in patients with abnormalities of the craniocervical junction and disorders of the middle/inner ear. These abnormalities may include Arnold–Chiari malformation, perilymphatic fistula, cholesteatoma, superior canal dehiscence, and anomalies of the ossicles, oval window, round window, and the saccule. To test for Valsalva-induced nystagmus, the patient is fitted with Frenzel lenses or VNG goggles (with vision denied) and asked to perform the Valsalva maneuver in two different methods. In the first approach, the subject is instructed to take a deep breath, pinch his/her nose, and then blow against a tightly closed mouth for 10 to 15 seconds as if attempting to equalize pressure in the ears while diving. This method increases air pressure within the sinuses, pharynx, and middle ear (Walker and Zee, 2000). The clinician examines the patient for any evoked nystagmus during or after the procedure. Additionally, any subjective dizziness, vertigo, or visual changes by the patient should be noted. After sufficient recovery time, the second method is attempted. For the second method, the patient is instructed to take a deep breath and strain against a closed glottis and lips for 10 to 15 seconds, as if pressurizing the lungs while attempting to lift a heavy object. This method effectively increases intracranial pressure by inducing elevated central venous pressure (Walker and Zee, 2000). Eye movement is again observed during and immediately following pressurization and relaxation. The normal patient will exhibit little to no eye movement and will experience no substantial dizziness or vertigo. The abnormal patient may exhibit a conjugate nystagmus with fast phases directed toward the affected ear. Horizontal evoked nystagmus typically indicates involvement of the lateral semicircular canals, whereas torsional and downbeating vertical nystagmus or torsional and upbeating vertical nystagmus indicates involvement of the anterior canals and posterior canals, respectively (Davies, 2004). The direction of the torsion (e.g., the top of the eyeball rotating toward or away from the nose) may also provide information regarding the laterality of the lesion. Fast phases of the torsional nystagmus will typically beat in a clockwise direction for lesions of the left ear and counterclockwise direction for lesions of the right ear. Sensitivity and specificity of the Valsalva test is variable and pathology dependent. In most cases, however, the presence of a positive Valsalva test is a good clinical indicator of an abnormal junction between either the middle ear and inner ear or the middle ear and intracranial space.

LABORATORY STUDIES OF BALANCE SYSTEM FUNCTION

Clinicians commonly utilize information gathered from a patient's medical history, physical examination, and "bed-side" screenings as a basis for ordering laboratory studies. The role of the majority of the vestibular laboratory studies is to ascertain the extent and/or site of lesion within the peripheral or central vestibular systems and to aid in the

characterization of any functional impairment. A thorough evaluation of the patient with dizziness and balance disorders may therefore require administration of one or more of the following types of procedures. Not every patient that presents in the dizziness/balance clinic receives a complete battery of all tests. The administration of tests should be limited to those that are minimally necessary to make decisions regarding management. Each of the major types of laboratory studies (ENG/VNG, active head rotation [AHR], rotational chair, otolith function testing, and computerized posturography) is discussed in this section. It is important to note that although the clinical utility of each will be discussed in turn, a detailed description of the origins, methods of delivery, and interpretations are beyond the scope of this chapter.

Electronystagmography and Videonystagmography

Nystagmography (ENG/VNG) is the most commonly practiced method of vestibular assessment. Because of the close physiological connections between the vestibular apparatus and the visual system, eye movements have classically been used to infer functional status of the peripheral vestibular organ and its associated central VOR pathways. ENG utilizes electro-oculography as a means to indirectly track eye movements as a function of time. Changes in eye position are indicated by the polarity of the corneo-retinal potential relative to surface electrodes placed around the eye. The corneo-retinal potential is the difference in electrical activity between the cornea (positively charged front portion of the eye) and the retina (negatively charged back portion of the eye). A typical ENG setup consists of at least five electrodes with one placed at the lateral canthus of each eye to record horizontal movement, one placed above and below at least one eye to record vertical movement, and a common or reference electrode placed on the forehead (Figure 21.1). When the eye is moved within the orbit, there is a corresponding increase in the electrical potential in the direction of eye movement and decrease in the opposite direction. This occurs because the positively charged cornea is now closer to the electrode in the direction of movement. ENG recordings can be performed with eyes open or eyes closed and in either a lighted or darkened environment.

VNG is a more modern and widely administered method of vestibular assessment. VNG utilizes infrared video-oculography as a means to directly record eye movements as a function of time. With VNG, the eyes are illuminated with infrared light and cameras located within the goggles track eye location and movement using the center of the pupil as a guide (Figure 21.2).

Significant differences exist between ENG and VNG systems pertaining to calibration, artifact, test environment, recording of torsional nystagmus, and associated costs. Whereas all of these areas are not discussed in detail here,

FIGURE 21.1 Typical electrode montage for monitoring eye position as a function of time in both the lateral and vertical dimensions. Note that given the dipole nature of the eyes and the use of electrodes lateral and vertical to the anterior–posterior axis of the eye, this type of configuration is not responsive to torsional movements of the eyes. [Reprinted with permission from Shepard NT, Telian SA. [1996] *Practical Management of the Balance Disorder Patient*. San Diego, CA: Singular Publishing Group.]

it is important to note a few of the more important differences. Both ENG and VNG systems utilize two-dimensional recording techniques to track eye movements in the horizontal (yaw) and the vertical (pitch) planes. The video component of VNG, however, allows for qualification in three-dimensional space by allowing the examiner to directly monitor eye movements within all planes simultaneously. This can be advantageous for identifying rotary or torsional nystagmus such as in BPPV variants. This advantage of VNG is limited, however, to the extent that the examiner observes the video of the eye movements during testing, as the actual post-exam tracings are two-dimensional for both

systems. Another primary advantage of VNG is the presence of less recording artifact. VNG is much less susceptible to contamination from myogenic activity and eye blinks which are common pitfalls with ENG systems. Although VNG can be used on the vast majority of patients, there are some situations where ENG is better suited. Those patients for whom ENG may be better suited include (1) patients with claustrophobia or who will not participate in vision-denied conditions, (2) young children who often will not tolerate goggles or for whom the goggles do not fit appropriately, and (3) patients with dark areas on or around the eye that make infrared recording difficult because of the inability of the system to differentiate the pupil from other parts of the eye (e.g., those with permanent makeup or dark areas on the sclera).

Both ENG and VNG systems are designed to record and measure nystagmus (as well as other types of eye movement, discussed later). Nystagmus is a type of eye movement that is oscillatory, that is, it moves in one direction (e.g., rightward or leftward) and then in the opposite direction (see Chapter 20). Nystagmus, in most cases, also typically follows a defined temporal pattern with slow drift in one direction and rapid return in the other direction. By convention, nystagmus is labeled by the direction of the faster phase but its strength is measured by the velocity of the slower phase (in degrees per second). Thus, a nystagmus that has a slow phase to the right and a fast phase to the left is termed a “left-beating” nystagmus. Conversely, a nystagmus that has a slow phase to the left and a fast phase to the right is termed a “right-beating” nystagmus.

Figure 21.3 shows a typical nystagmography tracing which could be recorded from either electrodes or video

recording techniques. In this figure, the rapid upward deflection of the tracing (fast-phase component of the nystagmus) is shown, followed in each case with a slower downward drift of the tracing (slow component of the nystagmus). By convention, upward deflections in the recording signify rightward (horizontal trace) or upward (vertical trace) eye movements whereas downward deflections signify leftward (horizontal trace) or downward (vertical trace) movements. For torsional eye movements, there will likely be activity reflected in both the horizontal and vertical tracings simultaneously but given the two-dimensional nature of ENG/VNG tracings (discussed previously), torsional nystagmus is best identified by direct observation. Torsional eye movements are generally referred to by the direction of the beat of the nystagmus in the horizontal plane (e.g., right-torsional nystagmus represents eye movements with the fast phase beating horizontally to the patient’s right, together with the eyes beating to the patient’s right in the roll plane). Alternatively torsional nystagmus may be referenced as clockwise or counterclockwise based on the direction of the rotation as a whole, but this convention can be somewhat confusing. Regardless of description, the principal parameter measured in the analysis of most types of nystagmus is the slope or slow-phase component eye velocity (SCV) (Figure 21.4).

The typical ENG/VNG exam consists of a series of subtests designed to assess portions of the central and peripheral vestibular systems. ENG/VNG is limited with respect to the peripheral system in that results are based predominantly on measurements of horizontal semicircular canal function with only minimal information garnered from the vertical canals or otolithic organs. As such, broad

FIGURE 21.4 Right-beating nystagmus is illustrated along with the calculation of slow-component eye velocity [SCV], the slope of the line [ab]. Upward trace deflections represent rightward eye movement with downward indicating leftward eye movement.

generalizations about vestibular function based on ENG/VNG, in isolation, are not recommended. The typical ENG/VNG exam consists of the following subtests: Ocular-motor evaluation, dynamic positioning, static positional tests, and caloric irrigations.

OCULAR MOTILITY TESTS

The first portion of the ENG/VNG exam is the ocular-motor evaluation. Tests of ocular motility are useful for investigating the central pathways that are required for the function of the VOR. Abnormalities in these tests typically indicate a central lesion or neurologic disorder. These tests may also be affected by pre-existing nystagmus and can be abnormal in patients with severe fatigue, medication effects, or general inattention. The typical ocular motility battery includes tests of gaze stability, smooth pursuit tracking, saccades, and optokinetic stimulation. Each of these subtests are recorded and quantified according to the eye movements generated

during the task and compared to established normative data.

Gaze Stability

Gaze stability testing involves measuring the patient’s ability to hold the eyes in a fixed direction of gaze without drifting off the target. Gaze is usually fixed in a central (neutral) position or at points of horizontal and vertical displacement, 20 to 30 degrees from center. The gaze-holding task is performed both with and without visual fixation and each position is typically held for at least 30 seconds. Care must be taken to ensure that the subject’s head remains still at all times and that the angle of gaze never exceeds 30 degrees. A normal physiologic endpoint nystagmus could be recorded and misinterpreted if the patient’s gaze exceeds 30 degrees past center. Abnormalities of gaze fixation typically suggest brainstem or cerebellar dysfunction.

Smooth Pursuit

Smooth pursuit testing measures the patient’s ability to track a moving target and maintain that target of interest on the fovea with continuous fluid eye movements. These movements should follow a smooth (sinusoidal) pattern without any jerking or “catch-up” corrections. During smooth pursuit the target typically moves rightward and leftward or up and down at speeds varied between 0.2 and 0.8 Hz. As the frequency of the stimulus increases so does the difficulty of the task. The recorded eye movements will cause the appearance of a sinusoid on the tracings (Figure 21.5). There are three parameters typically analyzed for smooth pursuit: Velocity gain, symmetry, and phase. Smooth pursuit is the most sensitive of the ocular-motor tests but has poor site of lesion localization because multiple pathways are involved in the response generation. Abnormalities of pursuit are

FIGURE 21.5 Smooth pursuit eye movement recording with the target at 0.71 Hz. The **top panel** is a plot of horizontal eye position as a function of time [500 ms time mark shown] for sinusoidal tracking (*dotted trace*). In the same plot (*smooth line*) the target position in degrees as a function of time is given. The panel below the eye and target position plots gives the value of velocity gain as a function of frequency of target movement. The *shaded region* represents abnormal performance.

usually indicative of vestibulocerebellar dysfunction as this area is common to all of the pursuit pathways.

Saccade Testing

Saccades are rapid eye movements designed to bring a target of interest onto the fovea of the eye. They are the fastest eye movements generated by humans and can be either reflexive or voluntary. Saccade testing therefore evaluates the ability of the patient to make quick eye movements in response to a moving target and to maintain that target on the fovea for maximum visual acuity. Typically there are two types of saccadic tests: One is a fixed position saccade and the other is a random position saccade. The time intervals between saccades can also be fixed or random. During evaluation the patient is instructed to locate the target as soon as it moves from one position to the next. The patient is asked to do this as quickly as possible without head movement and without anticipating location. The three parameters of saccadic eye movement that are analyzed include latency (how long it takes for the eyes to react), velocity (how fast the eyes move to the target), and accuracy (how well the eyes acquire the position of the target). A typical tracing is displayed in Figure 21.6. Saccade testing is not as sensitive as pursuit testing but can provide information to aid in the identification of involvement of the brainstem versus the vermis in the posterior cerebellum.

Optokinetic Testing

Optokinetic nystagmus (OKN) tests measure reflexive jerk nystagmus eye movements created by repeated visualization of objects moving horizontally or vertically across the patient's visual field. The test stimuli utilized to produce the OKN response is typically lighted bars or vertical stripes and must occupy at least 80% of the visual field. This process is

FIGURE 21.6 Schematic of eye and target position in degrees, as a function of time, demonstrating the calculations of velocity, latency, and accuracy of the saccade eye movement for analysis. [Reprinted with permission from Shepard NT, Telian SA. [1996] *Practical Management of the Balance Disorder Patient*. San Diego, CA: Singular Publishing Group.]

typically repeated with increasing stimulus velocities (20 and 60 degree/s) and the subject is generally instructed to watch or count the stimuli as they pass. Velocity gain is measured by comparing the speed of the stimulus with the slow-phase velocity (SPV) of the eye recordings. Optokinetic testing is the least sensitive of the ocular-motor tests. At present, OKN best serves as a cross check when abnormalities are seen during pursuit or saccade testing. It is also important to note that light bar stimulus arrays do not provide sufficient visual field stimulation. Therefore, responses generated under such testing conditions amount to nothing more than another form of smooth pursuit testing and not true optokinetic testing.

DYNAMIC POSITIONING

Dynamic positioning requires actively transitioning the patient from one position to another. It is most commonly utilized to assess for the presence of BPPV, which is the most common cause of vertigo in the adult population. Positioning evaluations typically include the Dix–Hallpike maneuver, the horizontal head roll maneuver, or other similar modifications. Because many different BPPV variants exist, an accurate description of any evoked nystagmus present during dynamic positioning is critical for proper identification. Each semicircular canal produces unique eye movements (see Chapter 20) which can be characterized to help localize the disorder.

The Dix–Hallpike maneuver (Figure 21.7) is the most common positioning evaluation used to determine if BPPV of the posterior semicircular canal or the anterior semicircular canal is present. The patient is seated on an examination table so when placed in a supine position (lying on the back) he/she will occupy the length of the table. The patient's head is rotated by the examiner 45 degrees to the right or to left depending on which side is being tested. The examiner stands behind or in front of the patient and briskly brings him/her down into a supine position with the head positioned to the side and slightly lower than the shoulders. Positive Dix–Hallpike responses produce a complex nystagmus with torsional (roll plane) and vertical eye movements. There is also a minor horizontal component (yaw plane) to the nystagmus with most cases of anterior–posterior canal BPPV. The fast component of the torsional nystagmus is generally directed toward the involved ear. This is typically, but not always, the underneath ear. To adequately detect this type of nystagmus, the eye movements must be visualized by the examiner or recorded with video equipment because the rotary component of the nystagmus will not show up in standard electro-oculography or video-oculography tracings, since both are two-dimensional in printed output (see earlier discussion). Torsional nystagmus, evoked in this manner, is not typically able to be suppressed by the central nervous system, so the Dix–Hallpike maneuver can be performed with vision allowed.

FIGURE 21.7 Illustrations of the technique for the Dix-Hallpike maneuver, for right side (**top**) and left side (**bottom**). Note that the patient's eyes are open and fixating on the examiner. [Reprinted with permission from Shepard NT, Telian SA. [1996] *Practical Management of the Balance Disorder Patient*. San Diego, CA: Singular Publishing Group.]

The horizontal head roll maneuver is used to determine if BPPV of the horizontal semicircular canal is present. The patient begins in the supine position with head at center, slightly elevated, and supported by the examiner. The patient's head is rotated 90 degrees to the right or to the left and held in that position for at least 30 seconds, or if nystagmus is observed, until it abates or is properly identified. The head is then turned back to the center position, pausing briefly, and then rotated in the opposite direction. Positive head roll responses produce horizontal geotropic (nystagmus that beats toward the ground) or ageotropic (nystagmus that beats away from the ground) responses. It is important to note that because the horizontal semicircular canals are coplanar, nystagmus should exist in both directions of head turn. The general convention is that the position of the head with the stronger response reflects the side of involvement for canalithiasis with loose otoconia moving within a canal, and the reverse is true for cupulolithiasis in which otoconia debris is adhered to the cupula of one of the canals. Various modifications of the Dix-Hallpike maneuver and horizontal head roll maneuver exist for those who have difficulty

moving into the supine position, such as pregnant women and those with low back pain, obesity, or arthritis.

STATIC POSITIONAL TESTING

The primary purpose of the positional evaluation is to identify nystagmus evoked during specific head and body positions relative to gravity. Some clinicians employ these tests in both the sitting and supine positions whereas others employ only the latter. Possible patient orientations include sitting head turned right, sitting head turned left, supine, supine head turned right, supine head turned left, and the "caloric" position (head elevated by 30 degrees up from the horizontal plane). If nystagmus is observed during either the head turned right or head turned left positions, or if the patient is unable to fully rotate his/her head, then side-lying right (body right) and side-lying left (body left) are also investigated. Additionally, in cases where no cervical region injuries or active pathologies are reported, use of head hanging (neck hyperextended) positions may also be added. Regardless of orientation, eye movements are monitored while the patient is held stationary and denied visual fixation (i.e., performed in darkness). Some have suggested that static positional testing should be performed both with and without visual fixation, particularly if any nystagmus is present, as the effect of fixation is the single most useful factor in differentiating nystagmus of central origin from other types. When testing in the vision-denied condition, it is also prudent to appropriately engage the patients by giving them mental "tasks" (e.g., counting or naming objects) to ensure they are alert.

A positional nystagmus may be direction-fixed (always beating in the same direction) or direction-changing (more than one direction observed during the exam). Direction-changing nystagmus is often subclassified into geotropic or ageotropic variants as discussed previously in the dynamic positioning section. Positional nystagmus is effectively a nonlocalizing finding (i.e., can be produced by either central or peripheral lesions); therefore a review of ocular-motor studies in combination with static results are necessary to help differentiate between the two. Generally speaking, the presence of a positional nystagmus is considered to be indicative of peripheral system involvement (assuming normal ocular motility tests) except in the case of (1) direction-changing nystagmus observed in a single head position or (2) if persistent vertical nystagmus is noted with no accompanying horizontal component. Both of these conditions could suggest central pathway involvement. Additionally, if a spontaneous, direction-fixed nystagmus is present and no significant change in that nystagmus occurs during static positional evaluation, then the nystagmus is taken to be reflective of the spontaneous findings and not considered as positional. This situation would suggest little or no influence of the otolith organs in the modulation or generation of the nystagmus but would not otherwise alter the general interpretation of peripheral system involvement.

Positional nystagmus is the most common abnormality described during ENG/VNG evaluations. The exact quantification of static positional nystagmus remains somewhat controversial. The following is one set of conservative criteria which relies on a combination of average SPV, direction, and number of positions in which nystagmus is present to determine if the nystagmus should be reported as an abnormal finding (Barber and Stockwell, 1980):

- SCV >5 degree/s in single position
- SCV <6 degree/s but persistent in four or more of the 8 to 11 positions
- SCV <6 degree/s—sporadic in all positions tested
- Direction-changing within a given head position

CALORIC IRRIGATION

The caloric irrigation is used to help lateralize peripheral lesions by cross-comparing nystagmus responses between the two labyrinths. The process involves timed irrigation of the external auditory canal by one of three delivery methods: Closed-loop water (water circulated inside a thin latex balloon inside the external auditory canal), open-loop water (water circulated in and out of the external auditory canal continuously), or air flow (air circulated in and out of the external auditory canal continuously). Open-loop water systems are typically the preferred method but can be contraindicated in patients with tympanic membrane perforations or when pressure equalization tubes are present. In such cases the closed-loop water irrigation or air method is a suitable alternative. For all of these delivery systems, the irrigating medium (water or air) is set to specific temperatures above or below that of the body, typically temperatures of 44°C for warm and 30°C for cool are used for water systems and 50°C for warm and 24°C for cool are used for air systems. Irrigating the ear in this manner generates a vestibular nystagmus that can be measured and analyzed. The most widely accepted theory about the physiologic origins of the caloric response involves gravity and density changes that occur within the endolymph of the horizontal semicircular canal as a result of temperature change.

To perform the caloric irrigation test, the patient is placed in the supine position with the head elevated at 30 degrees above the horizontal plane. This position, termed the “caloric position,” places the horizontal semicircular canal in an almost perpendicular orientation to the ground making it most susceptible to endolymph movement. Air or water is then delivered into the external auditory canal causing an increase or decrease in the temperature of the tested labyrinth. During a warm irrigation, the less dense fluid of the horizontal canal in the endolymphatic space attempts to rise upward. Since the fluid cannot flow around the canal secondary to the cupula, the change in fluid density results in a pressure differential across the cupula that produces a deviation of the cupula toward the utricle, thereby caus-

ing stimulation of the horizontal canal. The reverse action occurs for the more dense area of cooled fluid, causing inhibition. This response pattern results in a directional mnemonic known as “COWS” indicating that Cool irrigations will produce a nystagmus beating in the Opposite direction of the irrigated ear and Warm irrigations will produce a nystagmus that will beat in the Same direction as the irrigated ear. Thus, a cool irrigation of the left ear will produce a right-beating nystagmus whereas a warm irrigation of the left ear will produce a left-beating nystagmus.

Caloric responses are interpreted by using a relative comparison of the maximum slow-phase eye velocity for right irrigations versus that of the left irrigations. These values are used to provide a percent comparison of response magnitude (termed unilateral weakness [UW] or reduced vestibular response) and directional bias of eye movement (termed directional preponderance [DP]) (Figure 21.8). A fixation index or fixation suppression of caloric evoked nystagmus may also be included by comparing the maximum SPV response without fixation to that of the minimum SPV response with fixation. Each of these parameters is discussed in greater detail below. It should also be noted that although four irrigations are typical for calculation purposes, there are situations where “ice water” (4°C) may also be utilized and situations where only two monothermal irrigations may be sufficient (Shepard and Telian, 1996).

Unilateral Weakness (Reduced Vestibular Response)

By comparing the relative strength of individual ear responses to the sum of responses for both ears, a UW can be determined using Jongkees’ formula:

Unilateral Weakness (UW)

$$= \frac{(RW + RC) - (LW + LC)}{RW + RC + LW + LC} \times 100 \quad (\text{Eq. 21.1})$$

where RW is right warm, RC right cool, LW left warm, and LC left cool. The results of this formula will show the relative strength of each horizontal canal, and thus it can be inferred if one side is “weaker” than the other. The SPV values of each response should be taken from the area of greatest magnitude on the tracings (e.g., the 10-second period that yields the strongest responses following irrigation). There are no universally accepted norms for classification of UW. Each laboratory should establish its own normative data. Some laboratories use a 20% cutoff. If one ear is 20% stronger than the other ear, a UW is said to be present in the weaker ear. Other laboratories use values that vary from 20% to 30%. This presents a statistical weakness in determining what is normal and what is not. However, the UW calculation is used by many as the most robust indicator of a peripheral vestibular disorder. It is important to remember that if a spontaneous nystagmus has been found in the preceding gaze stability tests, then the direction and degree of that spontaneous nystagmus must be corrected for when

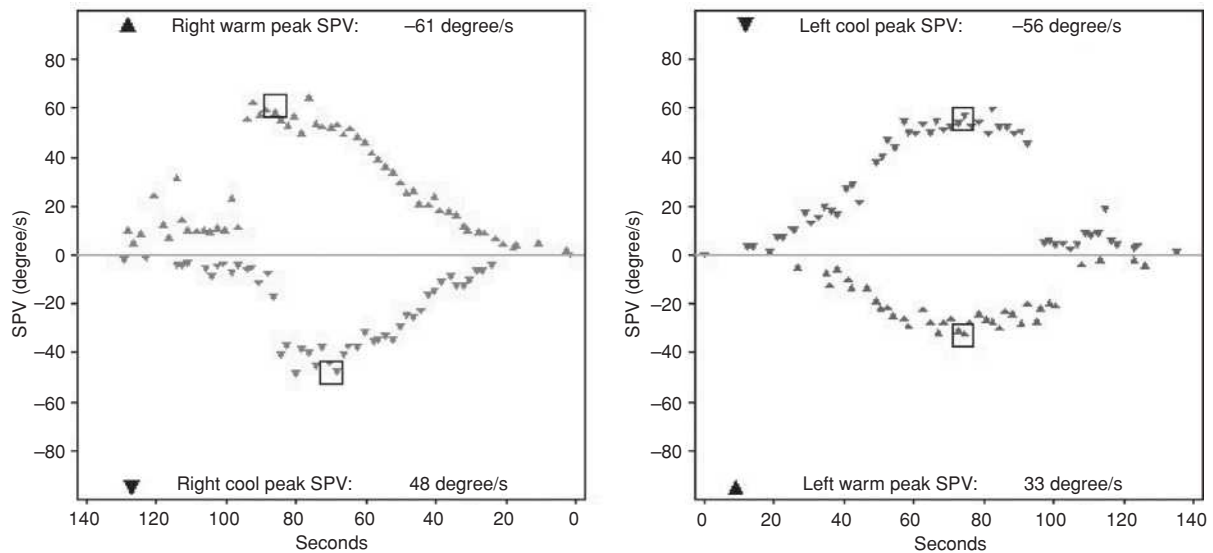

FIGURE 21.8 Plots of slow-phase velocity [SPV] from nystagmus provoked during caloric irrigations as a function of time. The *plotted triangles* represent SPV measurements of the eye movements from the nystagmus tracings. Data for the right ear, warm caloric irrigation, are shown at the **top left**. Data for the right ear, cool irrigation, are shown at the **bottom left**. Data for the left ear, cool, are shown at the **top right**. Data for the left ear, warm, are shown at the **bottom right**. The orientation of the triangular data points represent cool [30°C], ▼, or warm [44°C], ▲, irrigations. The velocity values provided in each box represent the average maximum SPV calculated from the peak areas of nystagmus shown by the *square markers* over the plotted triangle data points. Unilateral weakness equals 10% in the left ear and directional preponderance equals 18% to the right, both of which are within normal limits. [Courtesy of A.T. Still University, AFA Balance and Hearing Institute.]

calculating caloric results to avoid an artifactual error that leads to an incorrect interpretation.

Directional Preponderance

DP is perhaps the weakest of the three caloric parameters. Instead of looking at the overall response strength of each ear as done for the UW parameter, the DP calculation is used to detect the presence of a directional bias of the caloric-induced nystagmus. Since two irrigations are expected to produce right-beating nystagmus and two irrigations are expected to produce left-beating nystagmus, there should be equal values of right- and left-beating nystagmus generated. If the responses in one direction are stronger than in the other direction, a DP exists, indicating a bias within the system enabling nystagmus in one direction to be produced more easily than in the other direction. In determining if a DP exists Eq. 21.2 is used:

$$\text{Directional Preponderance (DP)} = \frac{(RW + LC) - (LW + RC)}{RW + RC + LW + LC} \times 100 \quad (\text{Eq. 21.2})$$

where RW is right warm, RC right cool, LW left warm, and LC left cool.

As with the calculation of a UW there are no accepted norms for determining a DP, and it is necessary for each lab to generate normative data. Note that what is being com-

pared is the strength of all right-beating nystagmus to that of all left-beating nystagmus. It is generally accepted that a difference of 30% or more is an indication of a DP in the direction of the larger value. The presence of a DP is considered a nonlocalizing finding in that it can be seen in both central and peripheral disorders, but can also be indicative of failure to correct for a spontaneous nystagmus.

Fixation Index/Fixation Suppression

A well-known feature of caloric-induced nystagmus is that in individuals with intact central function, the evoked nystagmus SPV can be strongly reduced with visual fixation. Typically, once the maximal caloric response has been identified, the patient is instructed to visually fixate on a small stationary target, which necessitates that the eyes be kept open. During this period of visual fixation, measurements of the SPV of the nystagmus are again taken. The values are compared to the strength of the SPV of the nystagmus immediately preceding the visual fixation (peak caloric response), which should be the same area measured for UW and DP. Usually, the strongest nystagmus produced by visual fixation occurs 60 to 90 seconds from the onset of the irrigation. It is recommended that fixation suppression be obtained for all four caloric irrigations and that it is ascertained that the patient is actually attempting to fixate. Some patients experience vertigo to an extent that they cannot, or will not,

make an attempt to perform the task. The patient should fixate for a duration of at least 15 seconds. A comparison of the SPV at the peak of the caloric response is compared to values during visual fixation. As with other measurements of caloric-induced nystagmus there is no general agreement as to what values are considered abnormal, but most clinicians use a 50% to 60% reduction in caloric-induced nystagmus as a sign of normalcy. Failure to adequately suppress caloric-induced nystagmus with visual fixation is a sign of a central vestibular lesion (Baloh and Kerber, 2011). Once again, it is strongly advised that individual clinic norms be established for the proper interpretation of these results.

It is also worth noting that caloric testing, like most tests, does have some inherent limitations. Caloric stimulation is not a true physiologic response. The normal vestibular system operates in a complimentary arrangement, such that if one side is stimulated, the opposite side is inhibited simultaneously. A caloric response is therefore not analogous to normal stimulation. Another limitation of the caloric test is that it only provides information about horizontal semicircular canal function and simulates very low frequencies (0.002 to 0.004 Hz) which are well below the normal operational range of the VOR. Therefore, absence of a caloric response to warm, cool, or ice water irrigations cannot be taken as an indication of complete lack of vestibular function. Rotational chair evaluation would be necessary in this case to better define the true extent of any bilateral peripheral vestibular loss. Despite these inadequacies, the caloric test remains a critical part of the traditional ENG/VNG battery.

Active Head Rotation

AHR evaluates the VOR at higher frequencies, typically 2 to 6 Hz. AHR is considered an “active” test because volitional movement by the patient is required for the stimulus. This is in contrast to rotational chair testing (discussed later) which is deemed a “passive” test because of the fact that the stimulus is delivered by a motor-driven chair and not by the patient. The equipment necessary to perform AHR testing includes infrared goggles or electrodes, an accelerometer attached to the goggles or to a headband, a computer with VOR analysis software, and a stationary visual target. It is important to note that the goggles or headband must be secured tightly to the patient’s head during AHR to minimize slippage of the motion sensor which could adversely affect data collection. The patient is seated in front of the stationary target with goggles open (vision allowed) and instructed to move his/her head back and forth, in rhythm with an audible stimulus. During this task, the subject is also instructed to keep his/her eyes focused on the stationary target. The AHR test can be performed in the horizontal or vertical planes, allowing for assessment of multiple semicircular canals. The audible stimulus begins at a slow frequency interval and gradually increases to a faster rate. Several trials are typically

performed to obtain sufficient data points. Gain, symmetry, and phase parameters of the VOR response are recorded and compared to normative data for each frequency. Different response patterns have been observed for various pathologies and are not described in detail here because it is beyond the scope of this chapter. AHR is generally well tolerated by most patients, but challenges can arise if the individual cannot tolerate rapid head rotation.

For head movements below 2 Hz, the smooth pursuit system is generally considered the dominant contributor to visual stabilization. For frequencies greater than 2 Hz, however, the VOR functions almost exclusively for that purpose (Grossman et al., 1989). As a result, the AHR test can be performed with vision allowed (goggles open) rather than with vision denied (goggles closed). Caloric irrigations and rotational chair testing evaluate frequencies below 2 Hz and can therefore be influenced by the central ocular-motor system; thus these tests are usually performed in darkness to prevent any visual contribution. AHR more closely approximates natural head movement and should therefore be better suited to characterize VOR function than the nonphysiologic caloric response which simulates speeds well below the operational range of the VOR, and rotational chair which only approaches the low end of natural head movement. The clinical use of AHR systems has been limited up to this point, however, because of concerns regarding sensitivity and specificity in identifying vestibular abnormalities as well as poor test–retest reliability (Fife et al., 2000).

Rotational Chair

Rotational chair testing involves stimulation of the vestibular system by turning the patient in an angular fashion around an earth-vertical axis (Figure 21.9). This is typically accomplished using a sinusoidal or constant velocity paradigm with and without incorporation of visual stimuli. Because rotary chair uses a physiologic stimulus and can be performed at a range of frequencies, it is often used to expand our evaluation of the peripheral vestibular system. Rotational studies can be useful in determining site of lesion, confirming clinical suspicion of diagnosis, counseling the patient, and evaluating rehabilitation potential. They may also be useful for special populations that cannot undergo traditional caloric testing or those with interaural caloric responses that cannot be reliably compared (e.g., young children, individuals with external or middle-ear pathology, individuals with perforations). It is important to note, however, that whereas rotary chair testing does provide some distinct advantages over nystagmography (ENG/VNG), in general it is viewed as complimentary and in most cases not likely to significantly alter patient management, except in the case of a bilateral vestibular loss.

A review of 2,266 patients was performed by Shepard and Telian (1996) investigating the clinical utility of rotary chair testing in the evaluation of peripheral vestibular system

FIGURE 21.9 Generic rotational chair setup. The chair is on a computer-controlled motor within an enclosure and can be rotated in either direction. A device for holding the head to the chair is shown. A means for producing optokinetic stimulation is shown as the drum in the ceiling. [Reprinted with permission from Shepard NT, Telian SA. (1996) *Practical Management of the Balance Disorder Patient*. San Diego, CA: Singular Publishing Group.]

function. Based on that review, there appears to be good evidence for obtaining, at minimum, low-frequency rotational data in certain patient populations with suspected peripheral vestibular system dysfunction. Based on current research, general criteria for when rotational chair testing may be of significant clinical use is given below (Ruckenstein and Shepard, 2000; Shepard and Telian, 1996):

- When either the ENG is normal and ocular-motor results are normal or observed abnormalities would not invalidate rotational chair results. Chair testing is used here to expand the investigation of peripheral system involvement and compensation status.
- When the ENG suggests a well-compensated status (no spontaneous or positional nystagmus), despite the presence of a clinically significant unilateral caloric weakness and ongoing symptom complaints. Chair testing is used here to expand the investigation of compensation in a patient with a known lesion site and complaints suggesting poor compensation.
- When warm and cool caloric irrigations are below 10 degree/s bilaterally, when caloric irrigations cannot be performed, or when results in the two ears may not be compared reliably because of anatomic variability. Chair

testing is used in these cases to verify and define the extent of a bilateral weakness or to further investigate the relative responsiveness of the peripheral vestibular apparatus in each ear when caloric studies are unreliable or unavailable.

- When a baseline is needed to follow the natural history of the patient's disorder (e.g., possible early Ménière's disease) or for assessing the effectiveness of a particular treatment, like that of chemical ablation of one or both peripheral vestibular systems.

When utilizing rotational protocols, it is important to remember that the peripheral vestibular system has a complimentary "push-pull" arrangement, so that if one side is stimulated with angular or linear acceleration, the opposite side is inhibited in its neural activity. Therefore, the primary disadvantage of rotational chair testing is its relative inability to yield much information regarding laterality of a lesion. Also, rotational equipment is very costly and takes up considerable space in the clinic so it is not always readily accessible.

A typical rotational chair protocol will likely include sinusoidal harmonic acceleration (SHA) tests performed at several frequencies, step velocity tests, and in some cases visual-vestibular interaction tests. These protocols are discussed in greater detail below. Before performing any rotational study, all equipment should be calibrated and the patient evaluated for any spontaneous or gaze-evoked nystagmus as the presence of which may bias the test results. Electro-oculography or video-oculography is used to monitor and record all jerk nystagmus that is generated in response to the angular chair acceleration stimulus. The slow component of the evoked nystagmus is the VOR and, as with ENG/VNG, is the portion of the eye movement for which velocity is calculated and used for analysis purposes.

SINUSOIDAL HARMONIC ACCELERATION

The SHA test evaluates the VOR over a range of frequencies, typically harmonics between 0.01 and 1.28 Hz. SHA testing is performed in complete darkness (vision denied) with the patient seated in the upright position and the head tilted forward-down, approximately 30 degrees, to achieve maximum stimulation of the horizontal semicircular canals. The patient is secured tightly at the head, torso, and legs prior to any rotation. Proper restriction of the patient's head and body is critical because the rotational stimulus is being delivered to the vestibular system via rotation of the entire body, thus both the head and body must be fixed for their movement to be congruent. The subject is brought to a constant velocity, typically 50 to 60 degree/s, at different rates and rotated sinusoidally for multiple cycles at each frequency. Either video or electrode recording technique is used to capture the SPV of the eye movements from each cycle of stimulation. The SPV responses from each cycle are added together and then divided by the total number of

FIGURE 21.10 Pictorial and formulated definitions of the three major parameters used for analyzing sinusoidal harmonic acceleration testing.

cycles performed to get an average response for the tested frequency. The frequency is then changed and the entire process repeated. Protocols may vary from lab to lab but the more cycles performed at a given frequency, the more reliable the data. Pragmatically however, the very slow cycles take a considerable amount of time to complete and therefore performing more than two or three cycles becomes time prohibitive. Unfortunately, the very low frequencies (<0.08 Hz) also produce the weakest response from the VOR and, therefore, have the poorest signal-to-noise ratio. In general, the very low frequencies are also the most likely to produce any unpleasant symptoms such as nausea. The frequencies from 0.16 Hz and above can be completed quickly

and easily, however, allowing responses from many cycles to be averaged. This is because the peak chair velocity is fixed for each rotation, so that as the frequency is increased, the subject experiences increasing acceleration with decreasing excursion of the chair.

Three parameters are measured for SHA testing: Gain, symmetry, and phase (Figure 21.10). Some systems may also include a spectral purity measure which details the quality of the data collected. Gain describes the amount of eye movement relative to head movement, symmetry is a comparison measure of rightward rotation to leftward rotation, and phase can be thought of as the reaction time of the eyes in response to head movement. Each measure is described in more detail below. The results of the SHA parameters are plotted by frequency and then compared with manufacturer or clinical normative data (Figure 21.11).

Gain

Gain represents a ratio of eye velocity to chair/head velocity and tells us about the overall responsiveness of the peripheral vestibular system (Figure 21.10). Patients with a unilateral loss of vestibular function often display a reduction in gain in the low frequencies with normalization in the higher frequencies. The principal use of gain measures, however, is to identify and quantify the extent of a bilateral reduction in peripheral vestibular function. Individuals with partial bilateral vestibular weakness may exhibit gain patterns similar to those of unilateral losses, whereas those with complete bilateral hypofunction will exhibit patterns that are reduced across all frequencies. The gain value and the phase component (discussed below) help to verify that severely reduced or absent caloric irrigation responses accurately reflect a true bilateral vestibular weakness and are not the result of an artifact or some other technical error. Gain measures may also play a significant role in determining the course of rehabilitation or prognosis for therapy success. It is important to

VOR Summary

FIGURE 21.11 Normal rotational chair results. The plot on the **left** shows gain [eye velocity divided by head velocity] as a function of frequency of chair sinusoidal stimulation. The plot in the **center** shows symmetry data in percentage as a function of frequency. The plot on the **right** shows phase angle in degrees as a function of frequency. The *darkened areas* represent abnormal performance based on a two standard deviation range above and below the mean. [Courtesy of A.T. Still University, AFA Balance and Hearing Institute.]

note that gain measurements can be negatively influenced by patient alertness, calibration, or technical errors such as light in the booth. Figure 21.11 shows normal results for gain as a function of sinusoidal harmonic stimulation.

Symmetry

Symmetry refers to the difference between the peak right-beating and peak left-beating slow-phase eye velocities divided by the total peak SPVs (Figure 21.10). Symmetry values are calculated by comparing eye velocity while rotating to the right (eye movement to the left) versus eye velocity while rotating to the left (eye movement to the right). This may seem contradictory, but it is important to remember that symmetry values are calculated and named by the direction of the eye movement that is produced by the VOR, which is the slow component. The situation is reversed when discussing DP of caloric irrigations. DP values are calculated by slow-component velocity but, by convention, are named by the direction of the fast phase of the nystagmus. Therefore, a patient who exhibits a right-beating DP (left slow-component velocity greater than right slow-component velocity) may show a left asymmetry on rotational chair testing, indicating that during chair testing, left slow-component velocity was greater than right slow-component velocity. Abnormal symmetry values, under most circumstances, should correspond with any direction-fixed spontaneous nystagmus and correlate with the DP of the caloric response. Asymmetric responses are typically indicative of an uncompensated peripheral vestibular weakness on the side of the stronger SPV response or an irritative lesion on the opposite side. In circumstances where the DP and asymmetry do not agree, the bias may be because of a peripheral lesion with incomplete dynamic compensation or, less likely, the presence of an uncompensated lesion in the central pathways. Figure 21.11 shows a normal result for the symmetry measurement.

Phase

Phase represents the timing relationship between the stimulus (chair/head velocity) and the response (eye velocity) (Figure 21.10). It is the value in degrees to which compensatory eye movements lead or lag movement of the head. Shepard and Telian (1996) report that this parameter has the greatest clinical value because of its ability to accurately identify peripheral system dysfunction but it is also the least intuitive of the three VOR metrics. If eye movement is perfectly compensatory to head movement, then the eyes will be 180 degrees out of phase with the head resulting in zero phase lead. The VOR, however, is a nonlinear mechanism so this only occurs for a limited range of frequencies. During the slower frequencies (<0.16 Hz) the compensatory eye movement will typically lead the head movement and at the faster frequencies the eyes will lag behind the head movement. Abnormally increased phase leads are common in individuals with peripheral vestibular disorders,

especially when viewed in conjunction with reduced VOR gain. Increased phase leads may also be seen in persons with damage to the central vestibular nuclei within the brainstem; therefore, increased phase leads should not be looked at exclusively to localize lesions to the labyrinth or cranial nerve VIII. The significance of an abnormally decreased phase lead is still not fully understood. Low phase leads may suggest a lesion in the nodulus region of the cerebellum, an area that influences the velocity storage integrator (Waespe et al., 1985), but they have also been reported in individuals with migraine-related dizziness and those with a history of motion sensitivity (Brey et al., 2008). Figure 21.11 shows a plot of phase angle as a function of frequency of rotation in a subject with normal SHA findings.

VELOCITY STEP TESTING

A second type of rotational method in common clinical practice is the velocity step or impulse acceleration test. For this test, the patient is seated in complete darkness (vision denied), head tipped forward-down 30 degrees, and secured in the same manner as the SHA protocol. The subject is quickly accelerated or “stepped” up to a constant velocity between 60 and 240 degree/s with an impulse acceleration of approximately 100 degree/s². Once the desired velocity has been obtained, the rotation continues for a period of 45 to 60 seconds at that speed. The VOR response to the initial acceleration is known as per-rotary nystagmus and the slow-component peak eye velocity (gain) is recorded. Over time, the per-rotary nystagmus will begin to decay and the subject will falsely perceive a slowing of the chair. The time (in seconds) at which the nystagmus SPV component decays to 37% of its original peak value is also recorded and is known as the vestibular time constant. Time constants are parameters that characterize the timing relationship between head movement and subsequent eye movement. After the constant velocity interval of 45 to 60 seconds has expired, the chair is stopped, using a rapid deceleration of equal magnitude to initial acceleratory impulse. Although the chair is now stationary, the subject will likely perceive motion in the opposite direction. The post-rotary VOR response will elicit nystagmus beating in the direction opposite to that of the initial acceleration and is known as the post-rotary nystagmus. The gain and time constant of the post-rotary period are measured in the same manner as the per-rotary period. Therefore, there will be two gain and two time constant measurements for a single rotation. After sufficient recovery time, the entire process is then repeated in the opposite direction so that one trial is performed in the clockwise or rightward direction and one in the counterclockwise or leftward direction. Clockwise acceleration stimulates the right horizontal canal and inhibits the left during the per-rotary phase and stimulates the left horizontal canal and inhibits the right during the post-rotary phase. The opposite is true for counterclockwise rotations.

Gain and time constant values obtained from the step protocol are analyzed and compared against clinical or manufacturer norms. Normal gain values typically fall within the range of 0.4 and 0.7 and normal time constants are generally greater than 10 seconds. Abnormally decreased time constants, particularly for 60 degree/s stimuli, may suggest unilateral, bilateral, or central vestibular deficits. Asymmetric or reduced gain values, particularly for 240 degree/s stimuli, may suggest unilateral peripheral vestibular deficits. For uncompensated peripheral lesions, both low and higher velocity step tests may demonstrate asymmetric gain values. It is also important to note that rotational step tests are heavily influenced by noise in the recording or physiologic systems and by the arousal of the patient prior to the acceleration because averaging is not used in this rotational paradigm. As a result, there will be patients for whom the estimates of time constant from the two protocols do not agree. Ideally, the step test and the sinusoidal acceleration tests can be used in parallel to increase the accuracy of estimates of the system time constant, individual periphery gains from the step procedure, and overall gain from the sinusoidal protocol, with possible asymmetrical peripheral responsiveness.

VISUAL-VESTIBULAR INTERACTION

Up to this point, all rotational chair studies discussed have been performed in complete darkness (i.e., vision denied) to ensure that only the VOR was being evaluated, without interference from the visual system and without possibility of central VOR suppression. The introduction of visual stimuli to the standard rotary evaluation allows the clinician to make judgments about the central vestibular-ocular relationship and may be useful in identifying patients with migraine-related dizziness, traumatic brain injury, and various central vestibular pathologies. There are two common visual-vestibular studies performed within the balance laboratory: Visual fixation (VFX) and visually enhanced vestibulo-ocular reflex (VVOR) tests.

The VOR suppression test or VFX evaluates a patient's ability to suppress vestibular-induced nystagmus by means of visual fixation. It is somewhat analogous to the fixation suppression (fixation index) that is assessed during caloric irrigations following measurement of peak SPV caloric-induced nystagmus. The patient is seated in the rotary chair, head tipped forward-down 30 degrees, and secured in the same manner as before, but this time with the goggles open rather than closed (vision allowed). Additionally, there is also the introduction of a visual target, typically a laser line or dot that is projected from the chair onto the enclosure or wall in front of the subject. The subject is asked to fixate visually on the target while the chair rotates sinusoidally back and forth. The target travels at the same speed of the chair thereby always remaining in front of the participant. The patient with normal vestibular function should be able

to maintain fixation on the lighted target reducing or eliminating any vestibular-induced nystagmus. A normal score typically results in at least 90% suppression of the VOR gain. The patient with abnormal vestibular function will be unable to suppress the vestibular-induced nystagmus and it will persist in large quantities. Failure to suppress (fixate) is a central sign typically associated with cerebellar dysfunction.

The VVOR test evaluates a patient's ability to integrate the visual pursuit and VOR systems effectively. This is the most "real-world" rotational test as it is the manner in which the vestibular system typically operates, combining visual and peripheral sensory inputs. The patient is secured in the same fashion as in the VFX test but this time an OPK stimulus is projected onto the enclosure around or wall in front of the subject. Unlike OPK testing performed during routine ENG/VNG, this OPK stimulus is held fixed (non-moving). The movement is supplied by the chair which is rotated sinusoidally back and forth, typically at frequencies in the 0.16- to 0.64-Hz range. The goal of the VVOR test is to effectively match eye speed to the speed of rotation while viewing the OPK stimulus. A normal patient will be able to accomplish this with eye speed approaching a gain of 1. Abnormal patients may show different patterns based on pathology. If a patient exhibits abnormally low gain during SHA testing but normal gain during VVOR, it implies that the patient is able to compensate for any defective VOR with voluntary pursuit and thus the central vestibular system is likely intact and the patient has a peripheral hypofunction. If, however, both SHA gain and VVOR gain are low at the same frequency, it is suggestive of central dysfunction most likely affecting the cerebellum or brainstem (Furman and Cass, 1996). More recent investigations using the VVOR protocol have also been used to help identify those with traumatic brain injury or migraine-related dizziness. For example, Arriaga et al. (2005) reported that 71% of patients diagnosed with migraine vestibulopathy had elevated VVOR gain, whereas only 5% of a control group had similar gain. VVOR appears to be the least sensitive of all the rotational tests but it can nevertheless assist in differential diagnosis because its failure demonstrates an inability of the CNS to successfully integrate visual and vestibular information effectively.

Otolith Function Testing

Despite the growing body of knowledge regarding the function of the vestibular labyrinth, clinical assessment of each vestibular end-organ is still somewhat incomplete. The most commonly used laboratory tests in clinical practice today such as caloric irrigation, rotational chair, and head impulse are based predominantly on lateral semicircular canal function. Research of otolith responses over the past three decades has employed different methods of stimulation including off-vertical axis rotations (OVAR), linear track, and parallel swing devices. Only recently have

tools for the investigation of the utricle and saccule begun to appear in more frequent clinical use. Since this area of investigation is still emerging in routine clinical use, the full extent and clinical utilization is not yet entirely established. For organizational simplicity, the two otolith organs will be considered separately though there is presumably some physiologic overlap.

SACCULAR EVALUATION

The primary method for evaluating saccular and inferior vestibular nerve function is by means of the vestibular-evoked myogenic potential (VEMP). VEMPs are short-latency electromyograms (EMGs) produced during application of high-intensity acoustic stimuli recorded via surface electrodes over contracted muscles. Saccular neurons respond not only to linear acceleration but also to sound pressure waves. This latter phenomenon allows for clinical investigation of the saccule by way of the vestibulocollic pathway. When a high-intensity acoustic stimulus is applied to the ear, there is a transient inhibition in tonic muscle activity ipsilateral to the side of stimulation. This temporary release from contraction can be measured via EMG on a commercially available evoked potential unit, allowing for assessment of each saccule independently. Responses can be elicited from different muscle groups but are typically recorded from the sternocleidomastoid (SCM) muscles of the neck and, when performed in this manner, are commonly referred to as cervical VEMPs (cVEMP).

There is currently no standard protocol for VEMP acquisition (Cheng et al., 2003; Li et al., 1999). Generally, VEMPs are obtained using a two-channel recording with the noninverting electrodes placed over the midpoint of the SCM muscles, inverting electrodes placed at the sternoclavicular junctions, chin or dorsum of the hand and a ground electrode placed on the forehead. A single polarity click or low-frequency tone burst at or above 90 dB nHL is delivered monaurally as the stimulus. Sustained contraction of the SCM is necessary to elicit a VEMP response so physical contribution from the patient is required. The SCM ipsilateral to the stimulated saccule must be forced into contraction by having the patient either lift or turn his/her head during stimulus presentation. It is important that the patient maintain sufficient EMG activity of the SCM throughout the test. VEMP responses are proportional to both stimulus level and the level of SCM activity so EMG monitoring with a target range of 30 to 50 mV is a recommended best practice (Akin et al., 2004).

The cVEMP waveform is a biphasic electrical response representing a release from muscle contraction temporally synchronized to the acoustic stimulus presentation. The response markers used to describe the waveform include peaks P13 (designated P1) and N23 (designated N1) which indicate the first positive and negative peaks of the response and their corresponding latencies (Figure 21.12). The

FIGURE 21.12 Normal cVEMP response elicited via air conduction at 95 dB nHL with a 500-Hz tone burst, showing P1 and N1 peaks with their respective latencies. [Courtesy of A.T. Still University, AFA Balance and Hearing Institute.]

response characteristics used to interpret the waveforms include P1–N1 latency, P1–N1 amplitude, threshold, and interaural asymmetry ratio. The cVEMP response is dependent on intact saccular and vestibular nerve function. The cVEMP has been found to be absent in cases of vestibular nerve section, but independent of cochlear function, as it is preserved in subjects with severe to profound sensory/neural hearing loss (Colebatch and Halmagyi, 1992). The VEMP is independent of cochlear function because it is the sound-sensitive neurons of the saccule, not the cochlea, that participate in the response. It should be noted that this holds true only for sensory/neural hearing losses since conductive pathologies can significantly reduce or eliminate VEMP responses because of the reduction in stimulus sound pressure ultimately reaching the inner ear.

The diagnostic utility of the VEMP is being investigated for a wide range of audio-vestibular and neurologic disorders. Response characteristics vary by pathology but certain patterns have begun to be identified. Absent responses and interaural amplitude differences tend to be the most common abnormalities described in vestibular disorders such as vestibular neuritis, vestibular schwannoma, and endolymphatic hydrops. Prolonged latencies have been described in those with central pathologies such as multiple sclerosis (Alpini et al., 2005) and brainstem lesion (Itoh et al., 2001). Of greatest use to date, however, has been the discovery of abnormally low thresholds in patients with superior semicircular canal dehiscence, large vestibular aqueduct syndrome, and Tullio phenomenon (Minor, 2005; Sheykholeslami et al., 2004).

In recent years, several investigators have described a VEMP response recorded from the extra-ocular muscles of the eye by activating the otoliths with acoustic or vibratory stimuli. This response, termed the ocular VEMP (oVEMP),

requires the patient to sit quietly and fix his/her gaze upward on a stationary visual target. In contrast to the cervical VEMP, which is an ipsilateral inhibitory response, oVEMPs appear to reflect a predominantly contralateral excitation of muscle activity. The oVEMP response characteristics are similar to those of the cVEMP in several ways but the exact anatomic origins are still somewhat debated. Mounting research suggests that oVEMPs may in fact reflect utricular activity thereby providing a means to clinically assess both otolithic organs independently, via the cVEMP and oVEMP measures.

UTRICULAR EVALUATION

The primary clinical method at this time for evaluating the function of the utricle is a test of subjective visual vertical (SVV). SVV is a psychophysical measure determined by having the patient adjust a vertical line or light array to what he/she perceives to be perfectly vertical (Böhmer and Mast, 1999; Friedmann, 1970). SVV may be obtained while the patient is seated upright and motionless or while exposed to rotational accelerative stimuli (per-rotary or dynamic SVV). The principle underlying SVV is that an individual's perception of verticality and ability to adjust a visual target to true vertical is because of the detection of the pull of gravity, primarily via the utricles. If a pathologic insult disrupts the peripheral functioning of the utricular organ or the central utricular pathways, a resulting change in the position of the eye in regards to the true horizontal occurs, along with a static ocular counter roll. During an acute insult, an individual may adjust the SVV line off the true vertical as much as 21 degrees, tilted in the same direction as the affected side and ocular counter roll (Böhmer and Rickenmann, 1995). However, as the acute phase of the lesion subsides and becomes more chronic, the individual's performance quickly returns to normal (Vibert et al., 1999). Rotational chair paradigms have been experimented with in recent years in an attempt to allow for investigation of the utricular system under more chronic conditions. This has led to the implementation of eccentric per-rotary SVV protocols. An eccentric displacement paradigm where the patient estimates SVV while exposed to centripetal acceleration, commonly referred to as an off-axis rotation or unilateral centrifugation, was first introduced by Wetzig et al. (1990). For individuals with normal vestibular function, the off-axis SVV tilts symmetrically during unilateral centrifugation. That is, when the subject is placed off-axis to the right, the SVV is tilted toward the left; and when placed off-axis to the left, the SVV is tilted toward the right. Patients with chronic unilateral utricular loss exhibit an SVV asymmetry when measured during unilateral centrifugation. When the lesioned ear is placed off-axis, the SVV does not shift because the utricle does not respond to the gravito-inertial force. Because of the relative newness of this procedure, clinical protocols and normative data are not yet widely distributed.

Computerized Dynamic Posturography

A large percentage of patients that are seen in the balance laboratory require some assessment of postural control. Postural stability can be evaluated in a number of different ways each with its own unique methods and equipment. Because of the breadth of this topic, we will limit our discussion here to one of the most common formal assessment tools utilized in balance clinics today: Computerized dynamic posturography (CDP) as devised by EquiTest®. In general, CDP utilizes dynamic forceplates to detect the horizontal and vertical forces exerted by a subject's feet on the platform on which he/she is standing. The forceplates have the ability to rotate up or down or to translate forward or backward to provoke movement from the subject's center of mass. Rotation can also be initiated by the individual's own anterior-posterior body sway. The forceplates are supplemented by a moveable visual surround which can similarly be made to move either independently or as a result of the subject's movement. The CDP system collects and analyzes center of gravity and sway responses and provides numeric data which can then be compared with established norms. Posturography is not a diagnostic site-of-lesion test but is useful in assessing functional abilities and often as an adjunct in the design and monitoring of vestibular and balance rehabilitation programs. CDP may also be beneficial in the identification of patients who are exaggerating their functional abilities. Generally speaking, CDP consists of three distinct assessment protocols: The sensory organization test (SOT), the motor control test, and the adaptation test (ADT), each described in short below.

SENSORY ORGANIZATION TEST

The SOT measures a subject's postural responses to a variety of visual, vestibular, and somatosensory altered conditions by means of patient-initiated floor and visual surround movements. The test consists of six specific conditions following a pattern of progressively more difficult scenarios accomplished by reducing or distorting information used for the maintenance of balance (Figure 21.13). The first three conditions offer uninterrupted, accurate, foot support surface information but with different visual inputs. Condition 1 is performed with eyes open, whereas in condition 2, the eyes are closed. Under condition 3, the eyes are open but the visual surround moves synchronously with the anterior-posterior sway movements of the patient. Condition 3 therefore presents a situation of visual conflict, where visual information is of no significant help in maintaining postural control. Conditions 4, 5, and 6 use the same sequence of visual conditions but with the foot support surface now giving misleading information. As with the movement of the visual surround in condition 3, when testing under conditions 4, 5, and 6, sway movements of the patient in the anterior-posterior

FIGURE 21.13 Six test conditions for the sensory organization portion of dynamic posturography. In the first three conditions, accurate foot somatosensory cues are available to the patient in all of the tests. The first and second conditions are simply eyes open and eyes closed. Condition 3 provides for orientationally inaccurate visual information in that, if the patient sways anterior-posterior, the visual surround moves with the patient [sway referenced]. In conditions 4, 5, and 6, inaccurate foot somatosensory cues are provided by tilting the platform equal to the patient's sway in the sagittal plane [sway referenced]. Then, for each of these latter three conditions, eyes open, eyes closed, and sway-referenced visual surround are presented, respectively. [From NeuroCom Int., Inc. Instruction Manual, with permission.]

plane drive the movement of the support surface. In this way, somatosensory information is of limited use in maintaining balance. Typically, three trials are performed for each condition and the average performance is taken as representative of the patient's postural control ability under that sensory condition. A composite equilibrium score for all trials of all conditions is also generated. Figure 21.14A shows an example of the graphical representation of these results in a patient with normal CDP findings.

In addition to the quantitative equilibrium score, CDP studies are also interpreted using pattern recognition. Abnormal scoring on any of the six conditions is grouped to define a pattern of instability that can be functionally interpreted. Table 21.4 presents the most frequent patterns and a commonly used nomenclature. By far, the most common pattern is the vestibular dysfunction pattern. It is important to recognize, however, that SOT only provides information regarding which sensory system cues the patient is unable to utilize for maintenance of postural control. In other words, it provides a relative measure of the patient's ability to utilize the sensory input cues of vision, vestibular, and somatosensation to maintain balance, but does not provide relative information as to which of the sensory systems has lesions, causing postural control abnormalities. Therefore, SOT

A

B

FIGURE 21.14 Results of dynamic posturography testing in a patient with all results interpreted as normal. The bar graph in the top panel (A) plots a percentage equilibrium score for each of the six SOT conditions [see Fig. 21.13]. A score of 100 indicates no sway in the sagittal plane and a 'Fall' indicates that sway reached a magnitude equal to the theoretical limits of sway for the patient in the sagittal plane. The composite bar on the far right shows the numerical average of scores from the six conditions. The bar graphs in the bottom panel (B) show the motor control test results for latency to onset of recovery scores for medium and large forward and backward translations. The latencies are given in milliseconds and shown by the black bars for left leg and right leg for both sizes of platform translations. [Reprinted from NeuroCom Int., with permission.]

information should be interpreted only to reflect which input information the patient is able, or conversely unable, to use for the task at hand.

MOTOR CONTROL TEST

The motor control test (MCT) provides information about patients' ability to react to unexpected displacement of their center of mass. The unexpected displacement is created by abrupt horizontal translations of the support surface on which they are standing. Typically, three small, medium, and large translations are presented in increasing magnitude for both the forward and backward directions. When the support surface translates unexpectedly in this manner, the body center of mass remains approximately stationary becoming offset to the base of support. Rapid automatic postural corrections are then necessary to restabilize the body and prevent a fall. The postural responses are quantified and analyzed based

TABLE 21.4

Abnormalities of Sensory Organization Testing

Pattern	Abnormality	Description
Vestibular dysfunction pattern	Abnormal on conditions 5 and 6 (alternatively condition 5 alone)	Vestibular dysfunction pattern indicates the patient's difficulty in using vestibular information alone for maintenance of stance. When provided with accurate visual and/or foot somatosensory information, stance is within a normal range
Visual vestibular dysfunction pattern	Abnormal on conditions 4, 5, and 6	Visual and vestibular dysfunction pattern indicates the patient's difficulty in using accurate visual information with vestibular information or vestibular information alone for maintenance of stance. When provided with accurate foot support surface cues, stance is within a normal range
Visual preference pattern	Abnormal on conditions 3 and 6 (alternatively condition 6 alone)	Visual preference pattern indicates the patient's abnormal reliance on visual information, even when inaccurate. When provided with accurate foot support surface information together with accurate or absent visual cues or absent vision and vestibular information alone, stance is within a normal range
Visual preference/ vestibular dysfunction pattern	Abnormal on conditions 3, 5, and 6	Visual preference and vestibular dysfunction pattern indicate the patient's difficulty in using vestibular information alone and the patient's abnormal reliance on visual information, even when inaccurate. When provided with accurate foot support surface information together with accurate or absent visual cues, stance is within a normal range
Somatosensory/vestibular dysfunction pattern	Abnormal on conditions 2, 3, 5, and 6	Somatosensory and vestibular dysfunction pattern indicates the patient's difficulty in using foot support surface information with vestibular information or vestibular information alone for maintenance of stance. When provided with accurate visual information, stance is within a normal range
Somatosensory/vestibular dysfunction pattern	Abnormal on conditions 2, 3, 5, and 6	Somatosensory and vestibular dysfunction pattern indicates the patient's difficulty in using foot support surface information with vestibular information or vestibular information alone for maintenance of stance. When provided with accurate visual information, stance is within a normal range
Severe dysfunction pattern	Abnormal on four or more conditions not covered in the above descriptions, for example, conditions 3, 4, 5, and 6; or 2, 3, 4, 5, and 6; or 1, 2, 3, 4, 5, and 6	Severe dysfunction pattern indicates the patient's difficulty with stance independent of the sensory information (vestibular, visual, and/or somatosensory) provided. Note that these situations many times involve a dominant feature such as significantly abnormal conditions 5 and 6 or they may involve equally distributed difficulties on all conditions affected
Inconsistent pattern	Abnormal on conditions 1, 2, 3, or 4, or any combination and normal on conditions 5 and 6	Inconsistent pattern indicates that performance of the patient is difficult to explain with normal or typical pathophysiologic conditions and could imply volitional or nonvolitional exaggerated results

on latency of onset of translation to that of active recovery. Other information commonly gathered from the motor control protocol includes abnormal weight bearing and inability to properly scale the strength of the postural responses to the increasing size of the stimulus.

The MCT protocol is used primarily to evaluate the long-loop pathways of the body. The long-loop pathways begin with the stretch receptors in the lower limbs, project to the motor cortex, and then are relayed to the upper and lower body muscles involved in maintenance of balance. When abnormal latencies from unexpectedly induced sway are noted, then problems in the long-loop pathway should be considered. Prolonged latencies are a relatively nonspecific finding, however, in that they may indicate an abnormality of the afferent or efferent neural pathways but they can also be seen in individuals with various somatosensory disorders and musculoskeletal conditions (Shepard et al., 1993). Figure 21.14B shows an example of the graphical representation from a patient with normal MCT latency findings.

ADAPTATION TEST

The ADT evaluates a patient's ability to adapt to a familiar stimulus specifically, unexpected rotations about the ankle. Five rapid toes-up or toes-down translations are presented to the subject with the expectation that reaction scores should improve on successive trials. For this protocol, as with the SOT protocol, reaction forces detected by the force plates in the foot support surface are measured. The principal parameter examined is the latency from onset of unexpected translation to that of active recovery. Individuals who show poor adaptation over successive trials are likely to be at increased risk for falls.

FUTURE DIRECTIONS

Assessment of patients with dizziness and balance disorders has undergone significant change over the past decade. The introduction of newer and more reliable tests of otolith function, such as the cervical and ocular VEMP and subjective visual vertical test, has allowed us to expand our clinical investigation of the vestibular apparatus into areas that were previously unattainable. In addition, new commercially available computerized head impulse and DVA systems have increased our ability to objectively quantify VOR function. In fact, when these measures are performed in combination, we now have the ability to clinically assess all three semicircular canals, both otolith structures, and both branches of the vestibular nerve in each ear, independently. This allows for a more robust functional assessment of the labyrinth as a whole, resulting in better therapeutic guidance and improved outcomes for patients.

Advancing knowledge with concomitant technologies comes at an opportune time, as vestibular assessment is also becoming increasingly more common in patient populations who may not have previously been evaluated. This includes

those populations with suspected traumatic brain injury and those with suspected stroke. Several position papers and consensus statements have been released in recent years by groups such as the American Academy of Neurology and the National Athletic Trainers' Association recommending evaluation of balance and vestibular function following concussive head injury. Recent research by Newman-Toker et al. (2013) has suggested that head impulse testing, in conjunction with gaze nystagmus assessment and prism cross-cover tests of ocular alignment, may be more sensitive than MRI for detecting early vertebrobasilar stroke.

Each year, approximately 8 million physician and emergency room visits are attributed to complaints of dizziness and imbalance. When considering future directions in assessment of patients with dizziness and balance disorders; growth in demand, advances in scientific evidence and technology, as well as the impact of healthcare and wellness initiatives will continue to play a role in making this an important area for audiology education and clinical services.

Case studies can be found on thePoint at <http://thePoint.lww.com>.

FOOD FOR THOUGHT

1. Virtually all newborns in the United States are now screened for hearing loss before leaving the hospital. CDC's National Goals for EHDI Programs still recommend that "hospitals and others [report] information about risk factors for hearing loss to the state, who will monitor the status of children with risk factors and provide appropriate follow-up services." What are the pros and cons of continuing to monitor the status of children with risk factors with respect to issues such as identifying childhood hearing loss, costs, demands on the health care system, and burden for families?
2. Although the percentage of children failing a newborn hearing screening test who are lost to follow-up and or documentation is slowly declining, it remains a very significant issue. What approaches, programs, or initiatives are likely to significantly reduce the percentage of children being lost to follow-up?
3. There continues to be a critical shortage of audiologists who have the expertise, experience, and desire to provide comprehensive audiological services to infants and young children. What can be done to increase the number of fully qualified pediatric audiologists?

Vestibular Rehabilitative Therapy

Richard Gans

INTRODUCTION

The National Institutes of Health (NIH) (2009) estimates that 40% of the US population will experience an episode of dizziness severe enough to motivate patients to seek the attention of a physician. Vestibular disorders account for approximately 85% of these symptoms. This chapter will address current practices in treating these disorders, based on a thorough understanding of the materials found in Chapter 20 (Neurophysiology of the Vestibular System) and Chapter 21 (Evaluation of Dizziness and Balance Disorders).

The vestibular system is subject to insult, trauma, and disease (Table 22.1). The disorder or disease process may cause the vestibular system to suffer a reduction or loss of function in one or both labyrinths. Most otologic disorders, however, will typically affect only one labyrinth at a time. The damage or change may occur either as a loss of sensory receptors within the end organ or within the nerve itself. The sudden loss or reduction of function will typically produce debilitating vertigo with associated autonomic and parasympathetic nervous system responses of nausea, emesis (vomiting), and diaphoresis (profuse sweating), symptoms similar to those occurring with intense motion sickness. Fortunately, the acute phase of most conditions will pass within hours; however, other symptoms may linger for days and weeks or, as in the case of Meniere's, be problematic for years. During the acute phase of the condition, patients will require medical and pharmacologic management, usually preferring to stay quiet and immobilized until they recover

their homeostasis and manage to move about without distress.

STATUS OF VESTIBULAR DYSFUNCTION

As described in Chapter 20, patients with vestibular disorders may have had insult or damage to either the peripheral (labyrinth part of the inner ear) or central (brainstem or cerebellum) portions of the vestibular mechanism. Common inner ear disorders that cause vestibular dysfunction include labyrinthitis, vestibular neuritis, herpes zoster oticus (shingles), vestibular migraine, labyrinthine ischemia, and Meniere's disease. Many of these patients experience either a relatively short phase of acute vertigo or are post-surgery for treatment of intractable inner ear disease such as Meniere's disease. Once out of the acute phase, they may be left with chronic symptoms affecting their sense of spatial orientation, gaze stabilization, or balance.

Vestibular disorders affect three output modalities: (1) The vestibuloocular reflex (VOR), which controls eye movement and gaze stabilization during active head movement; (2) the vestibulospinal reflex (VSR), which influences postural stability, translated through the musculoskeletal system and antigravity muscles; and (3) the vestibulocollic reflex (VCR), responsible for signals from the otolithic gravity sensor and the neck muscle proprioceptors. Patients with vestibular disorders may present with defects of gaze stabilization problems during active head movement, exaggeration or hallucination of motion, or prolonged unsteadiness, usually when challenged by uneven surfaces, by quick turns, or with reduced vision.

For those with slow, insidious vestibular changes that gradually increase over years, patients will not experience vertigo, but rather a loss of equilibrium and increased unsteadiness while walking, a condition which often occurs in older adults or those with a variety of nonvestibular or nonotologic-related disease processes (Table 22.2). Individuals who have had bilateral vestibular losses secondary to aminoglycoside toxicity usually present with an associated complaint of oscillopsia during head movement.

Vestibular rehabilitation therapy (VRT) has been shown to be a highly effective management strategy for

TABLE 22.2

Diabetes
Microvascular disease

patients with chronic symptoms related to a labyrinthine event (Herdman, 2001). Numerous investigators have demonstrated the efficacy of VRT for various populations (Gans, 2013). To provide the most efficacious treatment possible, the clinician must understand the status of the disorder, beginning with a comprehensive interview and thorough case history. Information is needed about the onset of the initial event, any subsequent attacks as well as their duration (minutes vs. hours), and any associated symptoms during the attack or episode, that is, hearing loss or tinnitus.

Prior to the referral for and undertaking of VRT, it will be necessary to define and categorize the status of the vestibular involvement. The ideal candidate for VRT is a patient with stabilized, but noncompensated unilateral vestibular dysfunction (UVD), conditions which are described in the following section.

Stabilized versus Nonstabilized

A stabilized condition can best be described as one that is no longer producing attacks or episodes of debilitating vertigo and other otologic or parasympathetic responses, such as acute nausea and emesis. This group of symptoms has been described as the labyrinthine storm. Once the acute phase has passed, most conditions such as vestibular neuritis or labyrinthitis become stabilized. The anatomical and physiological damage to the system is typically caused by either a viral or bacterial infection of the labyrinthine fluids or a viral/bacterial inflammation of the vestibular portion of CN VIII. The patient may have symptoms related to the chronic VOR dysfunction, but no longer is subject to attacks.

Meniere's disease is perhaps the best example of a chronic nonstabilized vestibular disease that may persist in an active or agitated state for years. Another example of a nonstabilized disease is a nonoperable acoustic neuroma, or vestibular schwannoma. Since benign paroxysmal positional vertigo (BPPV) (see Chapters 20 and 21) is a biomechanical phenomenon, rather than a neurophysiological state, it does not fit into the categorization of a stabilized- versus nonstabilized-type lesion. BPPV is treated with a high level of success, 97% or greater in most patients using canalith repositioning maneuvers (CRM) once the affected ear and semicircular canal involvement are properly identified. A comprehensive presentation of the CRM protocols with step-by-step instructions may be found in Roberts and Gans (2008).

Compensated versus Noncompensated

The central nervous system (CNS) will, within days, weeks, or months, accommodate to the asymmetrical labyrinthine function and, without any external help, will reset or retune the VOR function. Central compensation is believed to occur through the plasticity of the CNS within the brainstem and cerebellum. It has been described as a neurophysiological motor relearning phenomenon and has been documented in the literature with animal and human models (Kramer et al., 1998; Lisberger, 1998).

Patients who have a spontaneous recovery of the VOR function subsequent to an acute vestibulopathy are considered to have a compensated lesion. Although these patients will continue to present with abnormal findings (i.e., reduced labyrinthine reactivity or caloric weakness on a VNG caloric; described in Chapter 21), they will have no subjective report of exaggerated sense of motion, oscillopsia, or visually provoked symptoms. On tests of VOR function such as vestibular autorotation testing, they will present with normal gain and phase, just as if they were otherwise normal. Tests of dynamic visual acuity (DVA, discussed later in this chapter) will appear normal, despite the caloric weakness.

The caveat to clinicians is that a reduced labyrinthine reactivity does not mean that it is the origin of the patient's complaints. Patients may have normal caloric responses because either the horizontal canal was not involved or the problem is in the higher frequency sensitivity of the system. The caloric test evaluates only the ultra low frequency (0.003 Hz) sensitivity of the horizontal semicircular canal, making it less than a comprehensive assessment of total end organ function, as noted in Chapter 21.

A noncompensated condition describes a patient who continues to have symptoms, regardless of nonfunctional test results. As the peripheral labyrinthine end organ system operates as a gravity and velocity detector, symptoms are typically produced with change in head or body position or active head movement, usually in a particular plane of movement or speed. Since compensation does not behave as an all-or-nothing phenomenon, patients may progress over time so that the nature of their present gravity- or movement-triggered complaints is different and has changed. They may be getting better, but are not completely better or normal in their ability to perform even simple everyday activities. It is not uncommon for them to report that "I am better than I was, but I still don't feel right."

Several factors may affect one's ability to compensate naturally over time. Most individuals who experience a vestibular event (e.g., vestibular neuritis) recover fully over a period of weeks without the need for VRT. The factors that may compromise or inhibit compensation include physical or psychologic dependence on antimotion drugs or sedatives such as valium, lack of movement and activity, and a predisposition to motion intolerance commonly seen within

families or among individuals with a history of migraine, which is also familial.

IDENTIFYING VRT CANDIDATES

Those patients who find their everyday function is adversely affected or limited by this stabilized, but noncompensated asymmetry in vestibular function are the ideal candidates for VRT. The vestibulopathy may affect the full range of acceleration, or frequency, or just regions of acceleration, similar to a frequency-specific hearing loss within the cochlea. Likewise, the direction of the acceleration may also be involved. Typically, the patient's symptoms will be more provoked with acceleration toward the involved or impaired labyrinth. The manifestation of a vestibulopathy will often result in a VOR deficiency. The VOR is responsible for stabilizing eye/head position at frequencies starting at about 0.6 Hz. The errors that occur in the VOR function may affect the gain or accuracy and the phase or timing of the reflex. Correct VOR function is dependent on the brain's ability to correctly signal the extraocular eye muscles to correspond their response with the initiating head movement. The hydromechanical movement of the fluid within the semicircular canals initiates this signal.

The inability of the eyes to be correctly positioned with active head movement causes a retinal slippage. This results in an oscillopsia, in which the image to be viewed appears to jump or jiggle. These patients often state, "My eyes feel as if they need new shock absorbers." It may be restricted to the plane of the involvement. The extraocular eye muscles are correlated with the specific plane of the balance canals.

VRT consists of systematic repetitive exercises and protocols that extinguish or ameliorate patients' motion-provoked symptoms, as well as enhancing postural stability and equilibrium. VRT is not new; it has reached past its half-century mark. Cawthorne (1944) and Cooksey (1946) both discuss the benefit of active eye and head movement exercise for patients who experienced labyrinthine problems. Since then, research and clinical experience have greatly advanced the scientific application of this treatment methodology. See Gans (2013) for a comprehensive summary of this research.

CLINICAL ASSESSMENT OF VESTIBULAR FUNCTION

Chapter 21 provides an in-depth review of the clinical assessment of vestibular function. For this chapter, please note that patient evaluation may include a variety of assessment tools that are specific to revealing VOR and VSR abnormalities, without the use of technology. These evaluation protocols may be used by audiologists, physicians, and physical and occupational therapists alike. Many are considered classic "bedside" protocols, or in some communities or emerging economies may be the only evaluation techniques available. Table 22.3 presents a review of standardized and easily per-

formed tests shown to have high sensitivity in demonstrating noncompensated vestibulopathy as well as corresponding VRT diagnosis-based strategies. These may include tests of gaze stabilization and visual acuity with active head movement. Tests of VSR function, such as the modified Clinical Test of Sensory Integration of Balance (CTSIB) (Shumway-Cook and Horak, 1986), have shown excellent sensitivity for UVD patterns. Traditionally performed tests, such as VNG calorics, or less commonly performed rotary chair, may not reveal a high-frequency UVD. Patients who experience VOR problems at a higher frequency can often be identified with tests that disrupt visual acuity during active head movement (Roberts and Gans, 2007; Roberts et al., 2006; Schubert et al., 2002) or tests that quantify the VOR gain and phase (O'Leary and Davis-O'Leary, 1990).

DVA or gaze stabilization tests hold significant promise in simple and straightforward analysis of VOR function. All too often, patients with undetected UVD whose history and symptoms strongly correlate with a stabilized, but noncompensated UVD are dismissed as being a nonvestibular patient, as a result of an unremarkable caloric or VNG study. Tests of DVA have a wide range of application for both civilian and military populations. The military and NASA, specifically during the space shuttle years, were in the vanguard of research because of the concerns of astronauts flying with undiagnosed or untreated VOR problems (Hillman et al., 1999). DVA is also used in the identification and outcome measures with posttraumatic head trauma and concussion (Alsalaheen et al., 2010; Heitger et al., 2009).

Subjective Handicap Scales and Patient Reports

In addition to the invaluable data collected from a case history, patient rating scales are used to identify and quantify the functional disability created by physical ailment or illness. Disease or activity-specific and global health status patient handicap scales provide a valuable resource for establishing baseline, as well as serial or outcome measures. Table 22.4 provides several scales used and clinically documented in the vestibular literature. The results of these self-reporting measures often provide excellent insight for clinicians in determining candidates for VRT or for those who may require further testing, as indicated by inclusion in a thorough clinical assessment. These clinimetrics (i.e., subjective patient rating scales) are standardized to measure a disease-specific disability or an overall quality of life.

PHYSIOLOGICAL BASIS OF VRT

The underlying physiological basis for VRT is the plasticity of the CNS. VRT does not actually involve a regeneration or treatment of the damaged vestibular end organ itself. Instead, it works by allowing the CNS and the brain to acclimate or adapt to asymmetrical/conflicting input from the

TABLE 22.3

Clinical Assessment of Vestibular Function

Evaluation	Sensitivity	Findings	Cause	VR Protocols
Clinical Test of Sensory Integration of Balance [CTSIB] [Shumway-Cook and Horak, 1986]	High	Fall on foam w/o vision	Inability of the weakened vestibular system to maintain postural stability with degraded somatosensory input and no visual input	Substitution protocols will reduce visual and/or surface dependence forcing vestibular input to be maximized
Head Thrust [Halmagyi et al., 1990/1991]	High	Corrective saccade in the direction of head acceleration	Asymmetrical labyrinthine input to the VOR	Adaptation including gaze stabilization. The abnormal corrective saccade will likely also degrade performance on Dynamic Visual Acuity Test
Bidirectional Full Visual Field [80%] Optokinetic [OKN] Test	Moderate	Reduced OKN when stimuli move toward involved ear	Asymmetrical vestibular-optokinetic reflex indicating a weakened labyrinthine input	Adaptation. May suggest visual-vestibular integration protocols be included—VRT protocols should create visual conflict
Dynamic Visual Acuity Test [Herdman, 2001; Roberts and Gans, 2008; Schubert et al., 2002]	High	Degraded visual acuity with active head movement horizontal and/or vertical in VOR frequency range	Abnormal VOR gain at test frequencies	Adaptation with emphasis on gaze stabilization protocols in the plane and frequency of the deficiency
Provoked Vertigo Test includes positioning [modified Hallpikes for PC-BPPV], lateral positions for HC-BPPV, and static symptoms w and w/o vision and lateral positions with a 20-s head shake [vision denied]	High	Positive for PC-BPPV and/or HC-BPPV Static positions provoked [w and w/o vision] nystagmus/symptoms—labyrinthine or CNS patterns	Patterns of BPPV with transient nystagmus/vertigo consistent with and correlated to head-ear-canal position	Canalith repositioning maneuver [CRM] as appropriate for ear, canal, and patient's biomechanical/physical needs
Dizziness Handicap Inventory [DHI] [Jacobson and Newman, 1990]	High	Used as the “gold standard” self-report clinimetric for the patient's subjective level of disability relative to noncompensated vestibulopathy	Scoring comprises three areas: Function, physical, and emotional as well as an overall score	Provides pre-therapy baseline and validation of outcomes at time of discharge. Also identifies aspects of psychologic overlay which may need to be addressed either during or following central compensation

TABLE 22.4

Subjective Handicap Instruments

Dizziness Handicap Inventory [DHI] [Jacobson and Newman, 1990]
Health Survey Questionnaire–SF-36 [Ware, 1988]

Vestibular Disorder Activities of Daily Living Scale [Cohen, 2000]
Activities-Specific Balance Confidence Scale [Powell and Myers, 1995]

two vestibular systems. Possible mechanisms include the spontaneous rebalancing of the tonic activity within the vestibular nuclei, recovery of the VOR through adaptation, and the habituation effect (a lessening of response to the same stimuli over time). Theoretically, central compensation should occur within 90 days following dysfunction or loss of one of the vestibular systems. Many lesions, particularly those that occur with rapid onset, do not benefit from this compensation phenomenon.

Understandably, patients are often reluctant to perform therapeutic activities involving active head motions that produce symptoms of dizziness. This reluctance likely delays the development of central compensation. Motion intolerance or heightened motion sensitivity has been determined to be a genetic trait and is estimated to be a common aura seen in at least two-thirds of individuals with migraines (Selby and Lance, 1960). In essence, their central mechanisms are less likely to benefit from natural compensations because their “hard-wiring” is already less than desirable as a motion sensor. Simply put, they are not more likely to have a vestibular event, but if they do, they are less likely to compensate without assistance.

Another complicating factor includes the use of commonly prescribed drugs such as meclizine, antvert, valium, and other pharmaceuticals that suppress either peripheral vestibular or CNS function. These drugs will delay or prevent the CNS from relearning or adapting to asymmetrical sensory input. Unfortunately, the dizzy patient, in his/her heightened state of anxiety about becoming dizzy (especially while at work or driving), becomes reliant on pharmaceuticals that assist in suppressing distressing symptoms.

VRT is most effective when it is used with individuals who are no longer in the acute phase of a condition. The patient who is in the midst of a labyrinthine storm secondary to labyrinthitis, vestibular neuritis, or active Meniere's disease will receive little or no benefit from VRT. Ideally, patients will be in a stabilized condition when beginning VRT.

These patients present symptoms that are provoked by active head movement, often at a particular frequency of motion and in a particular direction. For instance, it may be intolerable to view numerous telephone poles while riding in an automobile. Commonly, patients express a sensation

of motion sickness when looking at certain patterns of floor tiles or wall coverings. A common complaint is the difficulty in turning one's head from side-to-side while walking down an aisle at a grocery store.

**DIAGNOSIS-BASED STRATEGIES**

Several researchers (e.g., Black et al., 2000; Cohen, 1992; Shepard and Telian, 1995) have supported and promoted the application of specific rehabilitation strategies to specific functional disabilities. Many well-meaning practitioners continue to use the 60-year-old Cawthorne (1944) and 30-year-old Brandt-Daroff (1980) exercises for dizzy patients, regardless of the patient's diagnosis or condition. Clinical experience and contemporary research strongly indicate that the success of vestibular rehabilitation is related to applying the correct treatment methodology to the appropriate corresponding dysfunction. Table 22.5 identifies those appropriate treatment methodologies with their corresponding functional components.

Diagnosis-based strategies as an individualized or customized therapeutic approach have been shown to produce successful outcomes (Gans, 1996). These strategies link the underlying physiological changes that occurred because of the disease or insult with the patient's functional symptoms. There are three approaches to therapy: (1) Adaptation with subsets of gaze stabilization and habituation; (2) substitution; and (3) canalith repositioning maneuvers (CRM). These approaches may be used independently or in conjunction with one another, depending on the patient's needs.

Adaptation

Adaptation will reset or retune the VOR by repetitive activities. These activities will include those situations or movements that provoke the very symptoms the patient has been trying to avoid. Examples of the exercises are shown in

TABLE 22.5

Diagnosis-Based Strategies

Functional Symptom	Treatment Protocol
Oscillopsia (blurred or distorted vision with active head movement)	Adaptation –gaze stabilization: Resets VOR gain
Vestibular recruitment (exaggerated or hypersensitivity to movement or sense of after-motion)	Adaptation –habituation: Extinguishes noxious signal
Visual and surface dependence (vision and touch substitute for vestibular)	Substitution: Forces increased vestibular function

FIGURE 22.1 Adaptation. [Courtesy of Gans RE. [2010] *Vestibular Rehabilitation: Protocols and Programs*. Tampa Bay, FL: AIB Education Press.]

Figure 22.1. A complex activity will incorporate gaze stabilization exercises, mostly coordinated head and eye movement preferably while walking at different rates and on a variety of planes.

A good example of this exercise would be to have the patient sit on a balance ball with a slight bounce, while turning the head from side to side and while also reading two separate word lists (e.g., grocery lists). Activities that disrupt the predictability of gaze stabilization or somatosensory input will be useful. Gaze stabilization exercises may progress from easy to more difficult as a progression, beginning with the patient performing side-to-side head turns while seated on a stationary chair and moving on to those while seated on a ball.

Baseline, serial, or final performance can be evaluated with any technique that evaluates the VOR function. This may be as simple as testing DVA with a Snellen eye chart or the American Institute of Balance (AIB) Dynamic Visual Acuity Test or as complicated as using the technologically advanced vestibular autorotation testing that provides a computerized analysis of the eye and head velocity. An important subset of adaptation is that of habituation as shown in Figure 22.2.

These exercises reduce the hallucination of motion or movement as well as extinguishing the sensation of after-motion. This response is based on neural plasticity within the brain and works only through the systematic repetition of the movements and acceleration with speed or direction that provoke the symptoms. The brain is exposed to the noxious stimuli repeatedly in a short time span. The patient's subjective reports of the intensity of the motion and duration of after-motion are utilized to determine treatment efficacy.

Substitution

Substitution protocols as shown in Figure 22.3 will strengthen the weakened systems by reducing the dependence on the remaining ones. In the case where a sensory modality is deficient or absent, these protocols will work to strengthen or make the remaining systems more accurate in their response to a dynamically changing environment. A patient with a weakened vestibular system is forced to make that system more dominant by reducing or challenging the somatosensory input, for instance by standing on a trampoline. The visual sense could be further disrupted or diminished by

having the patient close his/her eyes or watch a moving visual stimulus while maintaining his/her balance.

Evaluation of a patient's performance may include tests of postural stability on dynamic (moving or changeable) surfaces with absent vision. A simple version of this test is Schumway-Cook and Horak's (1986) classic CTSIB, which utilizes a standardized foam base of support (BOS) on which patients stand, first with eyes open and then closed. The hallmark of a noncompensated vestibulopathy will be the patients' inability to maintain their balance when they close their eyes while standing on the foam base. The premise is that individuals with intact vestibular function should be able to maintain their balance while standing on a dynamic surface even when they close their eyes. Through substitution, the vestibular system is being tested and forced to overcome the challenge of the dynamic BOS and absence of visual input. A more complex test is the computerized dynamic posturography, originally used by NASA in the early 1980s to evaluate balance function of returning shuttle astronauts (Paloski et al., 1992). This test trains patients on a Balance Master unit, providing them with visual feedback about their limits of stability (LOS) and balance function during therapy.

CASE STUDY

The following case study and clinical pathway are provided as an example of a typical vestibular patient's symptoms and treatment.

History and Symptoms

A 52-year-old male was referred to the clinic by his primary care physician with a chief complaint of acute positional vertigo. His physician obtained a magnetic resonance imaging (MRI) and blood work profile, all of which were reported as normal. His history included episodes of vertigo, the first of which began approximately 4 months prior. The initial episode lasted for approximately 7 to 8 days, with severe nausea and emesis throughout the episodic period, followed by a spontaneous recovery of the vertigo and symptoms, until approximately 2 months later.

The second attack also lasted about 7 to 8 days. The only other condition or symptom the patient related occurring during these acute episodes was a significant outbreak of cold sores. Following the last attack (within 4 to 5 days), the patient reported an acute episode of vertigo when he would lie flat or turn his head while lying down. This vertigo would last only seconds. His complaints also included a sensation that the world was "jiggling" when he looked from side to side or when he walked. He felt as though his eyes "don't have any shock absorbers." Although the sensation of his "bouncing world" was not as frightening as the acute positional vertigo, it was annoying and limited his activity level. No hearing loss was associated with the attacks or subsequent to them, nor was there a history of migraine or migraine equivalent.

Clinical Findings

Video-oculography revealed a left posterior canalithiasis during modified Hallpike positioning. A 43% left unilateral weakness was revealed on the caloric portion of VNG testing. Vestibular autorotation testing indicated abnormal (hypo-function) gain in the horizontal and vertical plane. Computerized dynamic visual acuity test (CDVAT) produced a 25% decrease in visual acuity with active head movement in the horizontal plane. All other audiologic studies were unremarkable. The patient had normal hearing acuity for all test frequencies. Normal immittance studies and distortion product otoacoustic emissions were also obtained.

Recommendations

The treatment strategy with this patient was twofold. First, the recurring attacks and nature of symptoms (including outbreak of cold sores) were suggestive of a viral vestibular neuritis, and an otologist was consulted. Following positive lab results for the herpes simplex type 1, the patient was placed on an antiviral medication prescription and a daily regimen of a lysine supplement by the otologist to control or inhibit further outbreaks. The patient was referred back to the clinic for treatment of the left posterior canal BPPV and noncompensated left UVD.

Treatment and Outcomes

The patient's VRT continuum of care included treatment of the left PC-BPPV and a noncompensated left vestibulopathy. During the first visit, the left posterior canal BPPV was treated with a Gans repositioning maneuver (GRM) (Roberts and Gans, 2008; Roberts et al., 2006). The patient was rechecked and re-treated on the same visit, which has been shown to increase the success rate to 97% in the first treatment visit. At the second visit, the video-oculographic recording was used to ensure that the BPPV had been cleared. The patient was then able to proceed with all aspects of a rigorous VRT program, which included adaptation with both gaze stabilization and habituation protocols as well as substitution.

The patient participated in an outpatient program provided by the trained physical therapist twice a week for 4 weeks, along with a supplement of home-based activities. At week 3 (20 days post initiation of the program), he reported a 100% reduction in symptoms. Retesting of vestibular autorotation and computerized dynamic visual acuity testing indicated a recovery and return to normal function on both tests. Additionally, scores on the Dizziness Handicap Inventory (Table 22.4) confirmed absence of subjective disability in him with a total score of 0%. The patient was pleased with these results and was discharged from clinical care. He was encouraged to follow up both with his primary care physician and the otologist, should he have a recurrence of the acute-phase vestibular neuritis. He was encouraged to resume his home-based vestibular rehabilitation protocols if at any time he felt a return of any of the oscillopsic symptoms during active head movement.

SUMMARY

With 60 years of research, clinical experience, and a growing patient acceptance, VRT has been demonstrated to be an important and effective nonmedical treatment for the symptoms of noncompensated vestibular disorders. Our understanding of the importance of intact VOR function in human equilibrium and new and simplified tests of this system will allow us to continue to quickly identify and treat this population. New research in cochleovestibular hair cell regeneration may someday make VRT unnecessary. In the meantime, it presents as one of the simplest and most successful treatment options available.

FOOD FOR THOUGHT

1. What are the two most common medical–otologic conditions that cause vertigo?
2. Which type of patient is the best candidate for VRT?
3. Describe how substitution-based therapy protocols can help strengthen a weakened vestibular system.

SECTION III

Special Populations

Newborn Hearing Screening

Karl R. White

INTRODUCTION

The importance of identifying children with permanent hearing loss as early as possible was emphasized more than 70 years ago when Ewing and Ewing (1944) noted

... an urgent need to study further and more critically methods of testing hearing in young children . . . during this first year the existence of deafness needs to be ascertained . . . training needs to be begun at the earliest age that the diagnosis of deafness can be established. (pp 309–310)

Since then much time and effort has been devoted to finding the most efficient and accurate procedures, protocols, and equipment for screening, diagnosing, and treating children who are deaf or hard of hearing (DHH).*

In 1960, with support from the Children's Bureau in the US Department of Health, Education, and Welfare, the American Speech and Hearing Association convened an expert working group to develop guidelines for "Identification Audiometry." With respect to infants, the report of this group concluded that

In the testing of a child from birth until approximately two months of age use can be made of the startle response . . . In a baby with good hearing and an intact central nervous system any sudden moderately loud sound will bring about a widespread response: the ongoing muscular activity is inhibited, the hands are pronated, the eyelids blink, etc. These startle responses are so uncomplicated, relatively speaking, that they may be easily observed. (Darley, 1961, p 21)

Efforts of many people over the next 30 years would prove that hearing screening for infants and young children was not as easy as it appeared to the participants of that conference in 1960.

In fact, 5 years later at the Toronto Conference on "The Young Deaf Child: Identification and Management" (Ireland

and Davis, 1965), Hardy reported the results of one of the first prospective screening studies of over 1,000 newborns at Johns Hopkins Medical Hospital in Baltimore. Hardy was hardly optimistic. In his opinion, the testing of newborns, with the procedures they were using, was a useless effort and they planned to discontinue it.

Many others were having similar experiences. Indeed, progress in finding accurate and feasible methods for identifying infants and young children who were DHH was painfully slow during the next 25 years. In response to a conclusion by the National Institutes of Health Consensus Development Panel (1993) that recommended "screening of all newborns . . . for hearing impairment prior to discharge," Bess and Paradise (1994), in a widely cited *Pediatrics* article, argued that ". . . universal newborn hearing screening in our present state of knowledge is not necessarily the only, or the best, or the most cost-effective way to achieve [early identification of hearing loss] and more importantly . . . the benefits of universal newborn hearing screening may be outweighed by its risks." By 1996, the US Preventive Services Task Force, while acknowledging that "congenital hearing loss is a serious health problem associated with developmental delay and speech and language function," concluded that "there is little evidence to support the use of routine universal screening for all neonates."

By the late 1990s, however, there was a combination of advances in screening and diagnostic equipment, action by various professional organizations, legislative initiatives, and government-funded demonstration programs in various countries. This resulted in a dramatic improvement in our ability to identify and provide services to infants and young children who were DHH and their families.

This chapter summarizes the principles that should guide any health-related screening program, briefly reviews the global situation related to infant hearing screening, and describes the current status of early hearing detection and intervention (EHDI)[†] programs in the United States with particular attention to the evidence-based practices for

*Many different terms are used to refer to children with permanent hearing loss (e.g., deafness, hearing impairment, hearing loss, auditory disorders). Recognizing that there are limitations to any single term, this chapter will use the term "children who are deaf or hard of hearing (DHH)" except in those cases where a source is quoted.

[†]Recognizing the importance of linking hearing screening programs to diagnostic and treatment programs, most people have replaced the term "universal newborn hearing screening program" by the more inclusive term "early hearing detection and intervention" (EHDI) program. This change recognizes that screening is just the first step in the process needed to help children who are DHH reach their full potential.

establishing and operating efficient and effective hearing screening programs for infants.

PRINCIPLES OF EFFECTIVE PUBLIC HEALTH SCREENING PROGRAMS

Almost 50 years ago Wilson and Jungner (1968) proposed principles that have become the accepted criteria for deciding if and how to implement public health screening programs. The report, commissioned by the World Health Organization (WHO), came at a time that technologic advances in medicine had made screening a topic of growing importance and controversy.

Their suggestions are worth considering whenever the design and operation of screening programs are being considered. According to Wilson and Jungner,

In theory, therefore, screening is an admirable method of combating disease . . . In practice, there are snags . . . The central idea of early disease detection and treatment is essentially simple. However, the path to its successful achievement (on the one hand, bringing to treatment those with previously undetected disease, and, on the other, avoiding harm to those persons not in need of treatment) is far from simple though sometimes it may appear deceptively easy. (p 7 and 26)

In what has deservedly become a classic in the public health literature, Wilson and Jungner outlined the following 10 criteria for deciding whether a condition was appropriate for screening. They noted that these criteria were “especially important when case-finding is carried out by a public health agency, where the pitfalls may be more numerous than when screening is performed by a personal physician” (p 26). As discussed in this chapter, even though there is still room for improvement, screening to identify infants who are DHH meets all of those criteria. Thus, it is not surprising that hearing screening programs for infants continue to expand around the world.

1. The condition to be detected by screening should be an important health problem. Congenital hearing loss is the most frequent birth defect in the United States, affecting about 3 newborns per 1,000 (White et al., 2010). Worldwide, permanent hearing loss affects approximately 1% of young children in industrialized nations and the incidence is probably higher, but not well documented, in developing countries. When not detected early in life, children who are DHH lag behind their peers in language, social, and cognitive development; fail more frequently in school; and often do not acquire the skills to be successfully employed.
2. There should be an accepted treatment for cases identified. As documented in the other chapters of this book, educational, audiologic, and medical treatments

for children who are DHH are straightforward and relatively inexpensive. Even for children needing more expensive treatments, there is clear evidence that the benefits significantly outweigh the costs.

3. Facilities for diagnosis and treatment should be available. Although there are still shortages of clinicians and intervention programs, most children who are DHH in the United States have access to high-quality treatment programs and well-trained professionals. In many ways, demand is driving supply. As more and more children are identified earlier and earlier, the number of well-trained professionals and access to effective treatment programs are improving.
4. There should be a recognizable latent or early symptomatic stage. In other words, it should be possible to identify the condition while there is still time to do something to improve the outcome. Hearing screening enables us to identify infants who are DHH before there are outward signs of the hearing loss, such as delayed language development. The earlier children who are DHH are identified and receive treatment, the better the outcomes. This is true for all types and degrees of hearing loss.
5. There should be a suitable screening test. Physiological screening tests for hearing are sensitive, specific, and relatively inexpensive.
6. The test should be acceptable to the population. Hearing screening tests can be completed in less than 15 minutes per child, are painless, and have no negative side effects. Parents express a high degree of satisfaction with hearing screening tests.
7. The natural history of the condition should be understood. Because permanent hearing loss occurs relatively frequently and the consequences are so obvious, the condition has been studied for hundreds of years and the natural history is well understood.
8. There should be an agreed policy on whom to treat as patients. Because hearing loss of any degree and type affects language, social, and cognitive development, there is widespread agreement about the importance of identifying and treating all children who are DHH.
9. The cost of case-finding (including diagnosis and treatment of those diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole. Hearing screening and diagnosis are relatively inexpensive and there is now good evidence that the cost of identification and treatment is small compared to the benefits.
10. Case-finding should be a continuing process and not a “once and for all” project. Although most major initiatives during the last 20 years have focused on newborn hearing screening, there is increasing emphasis on hearing screening for preschool and school-aged children.

The criteria suggested by Wilson and Jungner in 1968 are still relevant today. They provide a useful framework

by which hearing screening programs can continue to be refined and outcomes can be improved.

GLOBAL STATUS OF NEWBORN HEARING SCREENING

Policy makers and healthcare providers in many different countries have recognized the benefits and feasibility of newborn hearing screening programs. At least seven countries (Austria, the Netherlands, Oman, Poland, Slovakia, the United Kingdom, and the United States) provide hearing screenings for more than 90% of their births and nine other countries screen 30% to 89% of their births (Australia, Belgium, Canada, Germany, Ireland, Philippines, Russia, Singapore, and Taiwan). At least 60 other studies have published reports of smaller scale universal newborn hearing screening (UNHS) programs in their countries and are working toward establishing national systems (NCHAM, 2013a; White, 2011).

The WHO has long been a strong advocate of hearing screening for infants and young children. The 48th World Health Assembly urged member states “to prepare national plans for early detection in babies, toddlers and children” (Resolution 48.9) and the WHO recommended “that a policy of universal neonatal screening be adopted in all countries and communities with available rehabilitation services and that the policy be extended to other countries and communities as rehabilitation services are established” (WHO, 2010).

In 2009 an international group of experts convened by the WHO proposed guiding principles for action related to infant hearing screening. The report noted that in spite of the global progress that has been made toward UNHS, there are still many countries where the implementation of such a program is considered too costly and/or its value is questioned. Even in countries where a significant number of newborns are screened for hearing, there are often no consistent approach or quality control procedures, oversight is frequently not implemented, and resources for follow-up are often limited. However, the WHO noted that the operation of effective hearing screening programs for infants and young children is not always related to resources—some wealthy countries have fragmented and ineffective programs, whereas other less-wealthy countries have very successful EHDI programs. The report noted that, “Quality assurance issues in particular are vital to successful newborn and infant hearing screening and related interventions—in some settings, it is estimated that the poor training and performance of screeners renders up to 80% of screening useless” (WHO, 2010).

Although the WHO report concluded that all newborns should be screened for hearing loss using a physiological measure such as otoacoustic emissions (OAE) or automated auditory brainstem response (A-ABR), it acknowledged that some countries cannot implement such programs because

		Screening methods		
		Questionnaire completed by family	Behavioral	Physiological
Infants to be screened	Targeted by:			
	Geographical subset			
	NICU babies			
	Babies with risk factors			
Population based				

FIGURE 23.1 Hearing screening options recommended by World Health Organization [2010].

of limited financial resources or because appropriate equipment and personnel are not available. In such situations, the WHO recommended that some combination of targeting particular subgroups of the population or the use of questionnaires completed by family members or behavioral testing be considered (see Figure 23.1).

Questionnaires can be used to ask parents or other caregivers about the response of the infant to sounds and the infant’s use of language, including early indicators of language such as babbling and other vocalizations. Infants and young children who perform poorly on such measures can then be referred for more comprehensive audiologic assessment. Whereas some researchers have reported encouraging results for such questionnaires in screening children for hearing loss (e.g., Newton et al., 2001), others have recommended against using questionnaires because of relatively high false-positive and false-negative rates (e.g., Li et al., 2009; Watkin et al., 1990). The usefulness of questionnaires may depend, in part, on the age of children being screened, the degree of hearing loss targeted for detection, and the knowledge of parents or caregivers about normal language development. Even though questionnaires are relatively inexpensive, more evidence about their specificity and sensitivity is needed before wide-scale use can be recommended. In those situations, where physiological screening is impossible, questionnaires will likely result in some children who are DHH being identified, but the negative effects associated with potential false negatives and false positives are of great concern.

Behavioral measures, such as noisemakers or other more sophisticated audiologic procedures and equipment, can also be used to identify infants and young children who are DHH. However, such methods also have relatively large numbers of false negatives and false positives when used with babies less than 12 months of age. For example,

Watkin et al. (1990) did a retrospective analysis of over 55,000 2- to 15-year-old children in England who had completed a behavioral evaluation for hearing when they were 7 to 12 months of age. Of the 39 children later identified with severe to profound bilateral hearing losses, only 44% were identified when they were 7 to 12 months old based on the behavioral evaluation. The remaining children were identified later based on school-age screening programs, parental concern, or by healthcare providers. For children with mild to moderate bilateral hearing losses and children with unilateral hearing losses, the behavioral evaluation at 7 to 12 months of age identified only 25% and less than 10%, respectively. Even when home visitors are specifically trained to do behavioral evaluations of hearing in a home setting, most young children who are DHH will be missed using such procedures.

The WHO report also recommended that when it is not feasible to implement universal hearing screening programs for all newborns, countries should consider starting with a hearing screening program that focuses on a subset of infants and young children. For example, when newborn hearing screening programs are being established, it is not unusual to focus on babies in a particular geographical region because they are more accessible or equipment and personnel are more available. Because the incidence of permanent hearing loss is much higher among neonates who require intensive medical care during the first few days of life, hearing screening programs can focus on those admitted to a neonatal intensive care unit if they are unable to screen all babies.

There is a great deal of evidence that babies with certain “risk indicators” have much higher rates of permanent hearing loss than those who do not. The Joint Committee on Infant Hearing (JCIH, 2007) has identified 11 risk indicators (e.g., family history of permanent childhood hearing loss, being in a neonatal intensive care unit for more than 5 days, presence of craniofacial anomalies) that are associated with permanent congenital or delayed-onset hearing loss. Even though only about 10% of all newborns exhibit one or more of these risk indicators, about 50% of the infants who are DHH will be in this group. Unfortunately, hearing screening programs that target only infants with risk indicators have not been successful in identifying many of the babies with hearing loss in this high-risk group. For example, Mahoney and Eichwald (1987) reported the results of a newborn hearing screening program that targeted all babies with a high-risk indicator born in their state over an 8-year period. Information about the presence of risk indicators was incorporated into the state’s legally required birth certificate so information about risk indicators was collected on virtually all babies. A computerized mailing system and follow-up phone calls were used to offer all parents of children with risk indicators a free diagnostic audiologic assessment at local health department offices. Also a mobile van traveled around the state to provide free diagnostic testing

for families in the rural parts of the state. Mahoney and Eichwald (1987) reported that only about 50% of the families who had a baby with a risk indicator made appointments for an audiologic assessment and only about 50% of those actually came to the appointment. The program was discontinued after 8 years because of the small number of babies identified (the prevalence of babies identified as being DHH was less than 0.30 per 1,000 or about 10% of the babies who were likely DHH in that cohort).

Before implementing a hearing screening program that targets only those babies with one of the JCIH-recommended risk indicators, it is important to remember that 95% of the babies who have one of the risk factors do not have hearing loss and that approximately half the babies who do have congenital hearing loss will not exhibit any risk factors (Mauk et al., 1991). Thus, even if a risk-based newborn hearing screening program worked perfectly, it would only identify half of the babies with permanent hearing loss. However, the yield from operational high-risk hearing screening programs has been much lower. Furthermore, the risk factors that are most predictive of hearing loss in babies will vary from country to country, so it is important to have local data about the sensitivity and specificity of risk factors before using this as a method of identifying children who are DHH.

Alternatives to UNHS based on physiological measures such as OAEs or A-ABRs do need to be considered in some situations. However, unless and until better data are available to demonstrate acceptable sensitivity and specificity of alternative approaches (e.g., parent questionnaires, behavioral measures, and programs targeting high-risk babies) program planners should recognize that most previous programs using these methods have had significant limitations. Such alternatives should be viewed as an interim step toward establishing a UNHS program. Recognizing that different approaches will need to be taken in different circumstances, the WHO report (2010) emphasized that all newborn hearing screening programs should have

- Clearly stated goals with well-specified roles and responsibilities for the people involved
- A clearly designated person who is responsible for the program
- Hands-on training for people who will be doing the screening
- Regular monitoring to ensure that the protocol is being correctly implemented
- Specific procedures about how to inform parents about the screening results
- Recording and reporting of information about the screening for each child in a health record
- A documented protocol based on local circumstances

It is also important to remember that successful newborn hearing screening programs have been implemented in many countries in many different ways. Despite the variety

FIGURE 23.2 Percentage of newborns screened for hearing loss in the United States during the last 30 years.

of circumstances in which they operated, WHO (2010, p 34) noted that

[T]he aims of [newborn hearing screening] programmes are widely accepted as both highly worthwhile and attainable and . . . should be expanded to include all neonates and infants. Although universal newborn hearing screening using OAE or A-ABR should be the goal for all countries, interim approaches using targeted screening based on questionnaires, behavioural methods and/or physiological methods guided by evidence from well-conducted pilot studies will also be beneficial. Whatever approach is used, it is important that the EHDI programme is linked to existing health care, social and educational systems, and that the procedures and outcomes of the programme be documented so that ongoing quality assurance activities can be implemented and experiences shared.

THE CURRENT STATUS OF EHDI PROGRAMS IN THE UNITED STATES

EHDI programs have expanded dramatically in the United States during the last 20 years. In 1999 the US Department of Health and Human Services established the following goal related to EHDI programs as a part of its objectives for *Healthy People 2010*:

Increase the proportion of newborns who are screened for hearing loss by age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention services by age 6 months.

This goal represented a major shift in the belief that children who are DHH could be identified earlier and provided with services that would enable them to be as successful as their normally hearing peers. The value of identifying

congenital hearing loss during the first few months of life had been recognized for decades, but the belief that this goal could be achieved was relatively new.

When Dr. C. Everett Koop, Surgeon General of the United States, in 1989 called for increased efforts to identify congenital hearing loss during the first few months of life (Northern and Downs, 1991) he stated:

. . . hearing impaired children who receive early help require less costly special education services later . . . I am optimistic. I foresee a time in this country . . . when no child reaches his or her first birthday with an undetected hearing impairment.

Many people were surprised by Dr. Koop's enthusiasm and his optimism that UNHS programs could be successfully established given the fact that fewer than 3% of all newborns in the United States were being screened for hearing loss at that time. Over the next 25 years, Dr. Koop's enthusiasm proved to be well founded as shown by the fact that more than 98% of all newborns in the United States are now screened for hearing loss (Centers for Disease Control and Prevention (CDC), 2013, see Figure 23.2). Understanding the factors that led to such a significant change can be useful as work continues to make hearing screening programs more effective and efficient.

Factors Contributing to the Expansion of Newborn Hearing Screening Programs

The establishment, expansion, and improvement of newborn hearing screening programs in the United States have been facilitated by (1) policy initiatives by government, professional associations, and advocacy groups, (2) financial assistance from the federal government, (3) improvements in technology, (4) legislative initiatives, and (5) the demonstrated success of early implementations.

POLICY INITIATIVES

The value of identifying children who are DHH as early as possible is not a new concept for healthcare providers and administrators in the United States. For example, the Babidge Report issued by the US Department of Health, Education, and Welfare in 1965 recommended the development and nationwide implementation of “. . . universally applied procedures for early identification and evaluation of hearing impairment.” Four years later in 1969, based on the pioneering work of Marion Downs (Downs and Hemenway, 1969), the Joint Committee on Infant Hearing (JCIH, 2007) was established by a group of professional associations (e.g., American Speech and Hearing Association, American Academy of Pediatrics, American Academy of Otolaryngology—Head and Neck Surgery, among others). Even though the JCIH had no formal authority and few resources, they became, and have remained, a powerful force in advocating for earlier identification and better treatment of children who are DHH.

When it was first established, the JCIH focused on screening high-risk babies because inexpensive and effective hearing screening technology was not yet available. As new hearing screening technologies became available in the late 1980s, more resources were devoted to early identification of children who were DHH. These efforts were stimulated in part by a recommendation from the congressionally mandated Commission on Education of the Deaf (Toward Equality, 1988) that “the Department of Education, in collaboration with the Department of Health and Human Services, should . . . assist states in implementing improved screening procedures for each live birth.”

A few years later, *Healthy People 2000* established a goal to “reduce the average age at which children with significant hearing impairment are identified to no more than 12 months”:

. . . it is difficult, if not impossible, for many [children with congenital hearing loss] to acquire the fundamental language, social, and cognitive skills that provide the foundation for later schooling and success in society. When early identification and intervention occur, hearing-impaired children make dramatic progress, are more successful in school, and become more productive members of society. The earlier intervention and habilitation begin, the more dramatic the benefits. (HHS, 1990, p 460)

Although similar goals had been discussed for 30 years, this one was different because it was linked to a federal mandate that progress toward each objective had to be tracked and reported at regular intervals.

Another major step forward happened in 1993 when a Consensus Development Panel convened by the National Institutes of Health recommended that “all infants [who are DHH] should be identified and treatment initiated by six

months of age” and concluded that UNHS was the best way to accomplish this goal. To the surprise of many, progress was slow. It would be another 12 years before more than 90% of the newborns in the United States were screened prior to discharge (see Figure 23.2).

That so much time elapsed between the recommendation by NIH and the achievement of UNHS was in part because of the lack of research evidence about the value of and experience for such broad-scale implementation of newborn hearing screening. In the words of one skeptic in a commentary entitled, *Universal Newborn Hearing Screening: Should We Leap Before We Look?* (Paradise, 1999, pp 670–671):

Across the nation pediatricians are being importuned, and indeed propelled, to implement universal newborn hearing screening, despite a total lack of information concerning ultimate costs and, particularly, risks . . . I feel compelled to try here once again to be heard, quixotic though it may seem in the face of such apparently formidable odds. My main objections to a universal screening program for presumably normal, low-risk newborns remain essentially unchanged . . . recent reports from screening programs offer no basis for greater optimism about reducing the numbers of false-positive identifications.

FEDERAL SUPPORT FOR EHDI INITIATIVES

Partly because there was so little research about and experience with newborn hearing screening programs, significantly more federal funding was devoted to research, demonstration, and technical assistance projects related to newborn hearing screening during the late 1980s and early 1990s. Some of the best known were the Rhode Island Hearing Assessment Project (White and Behrens, 1993), the Marion Downs Hearing Center (MDHCF, 2013), and the National Center for Hearing Assessment and Management at Utah State University (NCHAM, 2013b) but there were many others.

SUCCESSFUL IMPLEMENTATION OF SCREENING PROGRAMS

Although the concerns about newborn hearing screening expressed by Bess and Paradise (1994) and Paradise (1999) were widely criticized (e.g., White and Maxon, 1995), Bess and Paradise were correct in pointing out that there was very little research in 1993 from large, systematically implemented UNHS programs to support the recommendations of the NIH Consensus Development Panel. Besides the Rhode Island Hearing Assessment Project (White and Behrens, 1993), the available evidence about newborn hearing screening was based on small samples of infants (primarily from NICUs) over short periods of time. The controversy about the NIH recommendations generated by Bess and Paradise stimulated a great deal of activity between 1994 and 1999 as

the percentage of babies being screened for hearing loss prior to hospital discharge increased steadily (see Figure 23.2). By 1998 there was a growing body of research supporting the feasibility, cost-efficiency, and benefits of newborn hearing screening (e.g., Finitzo et al., 1998; Mehl and Thomson, 1998; White, 1997) and dozens of large-scale UNHS programs had become operational in various states. Since that time, more and more research has been published showing the benefits of newborn hearing screening (e.g., McCann et al., 2009), and the United States Preventive Services Task Force now “recommends screening of hearing loss in all newborn infants” (USPSTF, 2008, p 143).

TECHNOLOGIC ADVANCES

Technologic breakthroughs in hearing screening equipment in the late 1980s were a major contributor to the growth of newborn hearing screening programs. Without the improvements in OAEs and A-ABRs, the many policy initiatives, federally funded projects, and clinical screening programs that combined to demonstrate the practicality and efficacy of UNHS programs, this success would never have happened. The advances in technology are likely to continue.

ENDORSEMENTS BY PROFESSIONAL AND ADVOCACY GROUPS

Published research studies combined with statewide UNHS programs that were identifying hundreds of babies at ever younger ages led to more endorsements and policy statements by government, professional, and advocacy organizations—including the American Academy of Pediatrics, the American Speech-Language-Hearing Association, the American Academy of Audiology, the National Association of the Deaf, March of Dimes, and the American College of Medical Genetics (see NCHAM, 2013c for a summary of endorsements by various organizations).

By the end of 2001, EHDI programs were clearly established as a part of the public health system in the United States, with all 50 states having established an EHDI program (White, 2003). Also in 1998, the federal Maternal and Child Health Bureau (MCHB) began requiring states to report the percent of newborns they had screened for hearing loss before hospital discharge as one of 18 core performance measures states must report annually to receive federal MCHB block grant funding (MCHB, 2002).

LEGISLATION RELATED TO NEWBORN HEARING SCREENING

The preceding activities were important in creating an atmosphere where many newborn hearing screening programs could be implemented, but legislative and administrative actions in the late 1990s and early 2000s contributed to expanding the reach and sustainability of these programs.

There are now 43 states with statutes or rules related to newborn hearing screening. A recent analysis by Green et al. (2007) concluded that states with legislation were much more likely to be screening 95% or more of their babies than those without legislation. Copies of each statute and/or rule as well as an analysis of the provisions of each statute is available at NCHAM (2013d). Several points about existing legislation are worth noting:

1. Most legislation (34 of 43 states) was approved after 1998. The increase in legislative activity was probably influenced by the publication of the Position Statement by the American Academy of Pediatrics (1999) and the increased amount of research evidence about the efficacy, accuracy, and feasibility of newborn hearing screening programs.
2. The existence of legislation is neither necessary nor sufficient to guarantee an effective EHDI program as demonstrated by the fact that some states that have not passed legislation have EHDI programs that are functioning as well or better than some states with statutes.
3. Only 28 of 43 states (65%) require all babies to be screened. Some statutes set the standard as low as 85% of all newborns which raises questions about equal access to hearing screening—at least in those states.
4. The fact that only seven states (16%) require parents to provide written informed consent suggests that most states view hearing screening as a routine part of newborn health care.
5. Twenty-nine of 43 states (67%) require hospitals to report data from newborn hearing screening to the State Department of Health—suggesting that these states are treating EHDI as a public health program.
6. Twenty-one statutes (49%) indicate that newborn hearing screening must be a covered benefit of health insurance policies issued in the state. However, because of how insurance reimbursement is done, many hospitals do not receive money for screening because payments are made as a lump sum for all services associated with the birth. The federal Affordable Care Act stipulates that newborn hearing screening is a covered preventive service. More information about the implications of the Affordable Care Act for how EHDI programs actually function and what services are available to children and families is available at NCHAM (2013e).

It is also important to note that legislation specifies the minimum requirements of state policy, but often does not describe what is actually happening in the state’s EHDI program. For example, the Rhode Island EHDI program has one of the nation’s best tracking and reporting systems, reports data to the Department of Health, and has an advisory committee, even though none of these are required by the Rhode Island hearing screening legislation (NCHAM, 2013d).

National Goals for EHDI Programs

As a result of work done by the MCHB, the CDC, and the JCIH, most people have stopped using the phrase “universal newborn hearing screening” (UNHS) in favor of “early hearing detection and intervention” (EHDI). The change is important because it underscores that successfully identifying and serving infants and young children who are DHH requires more than an effective newborn hearing screening program. To be effective, the screening program must be connected to a system that includes audiologic diagnosis and appropriate medical, audiologic, and educational intervention. Newborn hearing screening programs should also be coordinated with the child’s primary healthcare provider (PHCP) (often referred to as the child’s Medical Home); a tracking and surveillance system; and a process for monitoring/evaluating how the system is functioning.

Newborn hearing screening programs in the United States are almost always hospital based because that is where the vast majority of babies are born. The basic process is similar, even though the specifics, as discussed later in this chapter, vary to a considerable degree. For example, screening may be done by nurses, technicians, audiologists, or someone else. Some programs use OAEs, some use A-ABRs, and some use both. Screening is almost always done before the baby is discharged from the birth admission, but it can be completed at different times of the day depending on the hospital’s routine and in different locations (e.g., the nursery, the mother’s room, a room designated specifically for screening). Some hospitals do diagnostic evaluations for babies who do not pass the screening test, and others refer those babies elsewhere. Because newborn hearing screening has become a part of routine medical care for newborns, the screening procedures must conform with the hospital’s practices related to such matters as safety, privacy, and infection control.

As newborn hearing screening programs expanded during the mid-1990s, it became clear that screening was only the first step in an intertwined process of identifying infants with hearing loss and providing them and their families with timely and appropriate services. Understanding how to best implement and maintain this first step (screening) requires a brief discussion of the other steps (many of which are discussed in more detail in other chapters of this book). A brief YouTube video shows these procedures (www.infantheating.org/videos/ncham.html#sb).

In collaboration with state EHDI program coordinators and representatives from other federal, professional, and advocacy agencies, CDC has developed National EHDI Goals, Program Objectives and Performance Indicators that are based on EHDI guidelines from various states and the position statements of the Joint Committee on Infant Hearing (JCIH, 2007) and the American Academy of Pediatrics (AAP, 1999). These National Goals (CDC, 2004) are sum-

marized in Table 23.1 and each is discussed in the remainder of this section.

GOAL NO. 1: ALL NEWBORNS WILL BE SCREENED FOR HEARING LOSS

CDC (2013) reported that 98.4% of newborns were screened in 2011 (excluding infant deaths and parent refusals). Interestingly, no particular protocol or type of screening equipment is preferred by most people. As shown in Table 23.2, a survey conducted by NCHAM (2013f) showed that 50.3% of all screening programs were using OAE testing, and 62.4% were using A-ABRs (percentages sum to more than 100% because some programs use both OAE and A-ABR). Approximately 40% percent of programs did all of their screening prior to hospital discharge, whereas about 60% of programs used a two-stage protocol in which screening was not completed until an outpatient screening was done following discharge. The variety of screening protocols being used suggests that no single protocol is “best” for all situations. Because, the JCIH (2007, p 904) now recommends “ABR technology as the only appropriate screening technique for use in the NICU [neonatal intensive care unit]” the percentage of programs using A-ABR is expected to increase.

Deciding what type of equipment and which protocol to use in a newborn hearing screening program depends on the circumstances and preferences of the program administrators. In situations where an outpatient screening is a part of the protocol and it is difficult to get babies to come back, A-ABR has an advantage because refer rates at time of discharge are typically lower (but, the cost of equipment and consumables is somewhat higher). It is also important to consider what degree of hearing loss is targeted by the screening program. Most of the currently available A-ABR screening equipment uses a 35-dBnHL click for the stimulus which means that many babies with mild hearing loss will likely pass the screening test (Johnson et al., 2005). In most states, the decision about what type of hearing screening equipment and protocol to use is left to the discretion of the hospital screening program administrator. In fact, NCHAM (2013f) found that only 67% of state EHDI coordinators even keep track of what equipment and/or protocol was used by hospital-based screening programs.

A small, but important subgroup that is not being well served by current EHDI programs are babies who are born at home. With 1% to 2% of all births in the United States occurring outside the hospital, this represents 40,000 to 80,000 babies per year. Only 21 states reported that they had a systematic program in place to screen these babies, and those states only screened an estimated 41% of out-of-hospital births (NCHAM, 2013f). Midwives are well-positioned to screen and follow-up with babies born outside of the hospital, but Goedert et al. (2011) reported that most respondents to a national survey of the American

TABLE 23.1

National Goals for EHDl Programs (CDC, 2004)

<p>Goal 1. All newborns will be screened for hearing loss before 1 mo of age, preferably before hospital discharge</p>	<p>Hospitals will have a written protocol to ensure all births are screened, results are reported to the infant's parents and PCHP, and referred infants ($\leq 4\%$) are referred for diagnostic evaluation. Demographic data will be collected for each infant and appropriate educational material provided to parents. States will reduce/eliminate financial barriers to screening and ensure screening of out-of-hospital births</p>
<p>Goal 2. All infants who screen positive will have a diagnostic audiologic evaluation before 3 mos of age</p>	<p>States will develop audiologic diagnostic guidelines and maintain a list of qualified providers to ensure infants referred from screening receive a comprehensive audiologic evaluation before 3 mos of age and are referred to appropriate services. States will provide appropriate education and/or training about diagnostic audiologic evaluation to parents, PCHPs, and audiologists</p>
<p>Goal 3. All infants identified with hearing loss will receive appropriate early intervention services before 6 mos of age (medical, audiologic, and early intervention)</p>	<p>States will develop policies and resource guides to ensure all parents of children with hearing loss receive appropriate medical (including vision screening and genetic services), audiologic, and early intervention services (based on the communication mode chosen by the family). States will ensure that early intervention service providers are educated about issues related to infants and young children with hearing loss</p>
<p>Goal 4. All infants and children with late-onset or progressive hearing loss will be identified at the earliest possible time</p>	<p>Hospitals and others will report information about risk factors for hearing loss to the state, who will monitor the status of children with risk factors and provide appropriate follow-up services</p>
<p>Goal 5. All infants with hearing loss will have a medical home as defined by the American Academy of Pediatrics</p>	<p>A primary care provider who assists the family in obtaining appropriate services will be identified for all infants with confirmed hearing loss before 3 mos of age. The state will provide unbiased education about issues related to hearing loss for parents and medical home providers</p>
<p>Goal 6. Every state will have an EHDl Tracking and Surveillance System that minimizes loss to follow-up</p>	<p>A computerized statewide tracking and reporting system will record information about screening results, risk factors, and follow-up for all births. The system will have appropriate safeguards, be linked to other relevant state data systems, and be accessible to authorized healthcare providers</p>
<p>Goal 7. Every state will have a system that monitors and evaluates the progress toward the EHDl goals and objectives</p>	<p>A systematic plan for monitoring and evaluation will be developed and implemented by an advisory committee to regularly collect data and provide feedback to families and ensure that infants and children with hearing loss receive appropriate services</p>

TABLE 23.2

Protocols Used in EHDl Programs

Before Hospital Discharge	After Hospital Discharge	Percent of Newborns Screened
OAE	–	11.6
ABR	–	23.3
OAE/ABR	–	6.7
OAE	OAE	21.4
OAE	ABR	4.2
ABR	OAE	2.8
ABR	ABR	23.2
OAE/ABR	OAE/ABR	6.4
Other protocol	–	0.3

College of Nurses-Midwives members were not well informed about the importance of newborn hearing screening and had significant gaps in their knowledge about screening procedures, steps for referral, and the availability of resources when newborns did not pass the test.

GOAL NO. 2: REFERRED INFANTS WILL BE DIAGNOSED BEFORE 3 MONTHS OF AGE

For babies who do not pass the newborn screening test, audiologic diagnosis should be completed as soon as possible, but no later than 3 months of age. Figure 23.3 shows that in states with well-developed EHDl programs the average age of diagnosis for children who are identified as DHH has dropped dramatically over the last 25 years.

Unfortunately, CDC (2013) reported that in 2011 for the country as a whole, state EHDl programs were not able

FIGURE 23.3 Age in months at which permanent hearing loss was diagnosed. References to the studies cited may be found at <http://thePoint.lww.com>.

to document whether diagnostic evaluations were actually completed for 35.3% of the infants who needed them (see Figure 23.4). Most states (90%) have developed written guidelines for conducting diagnostic audiologic evaluations, and most (78%) had compiled a list of centers or individuals

who were qualified and had appropriate equipment and experience to do diagnostic audiologic evaluations for infants under 3 months of age (NCHAM, 2013f).

Unfortunately, there is no general agreement on what constitutes a qualified pediatric audiologist, and these lists

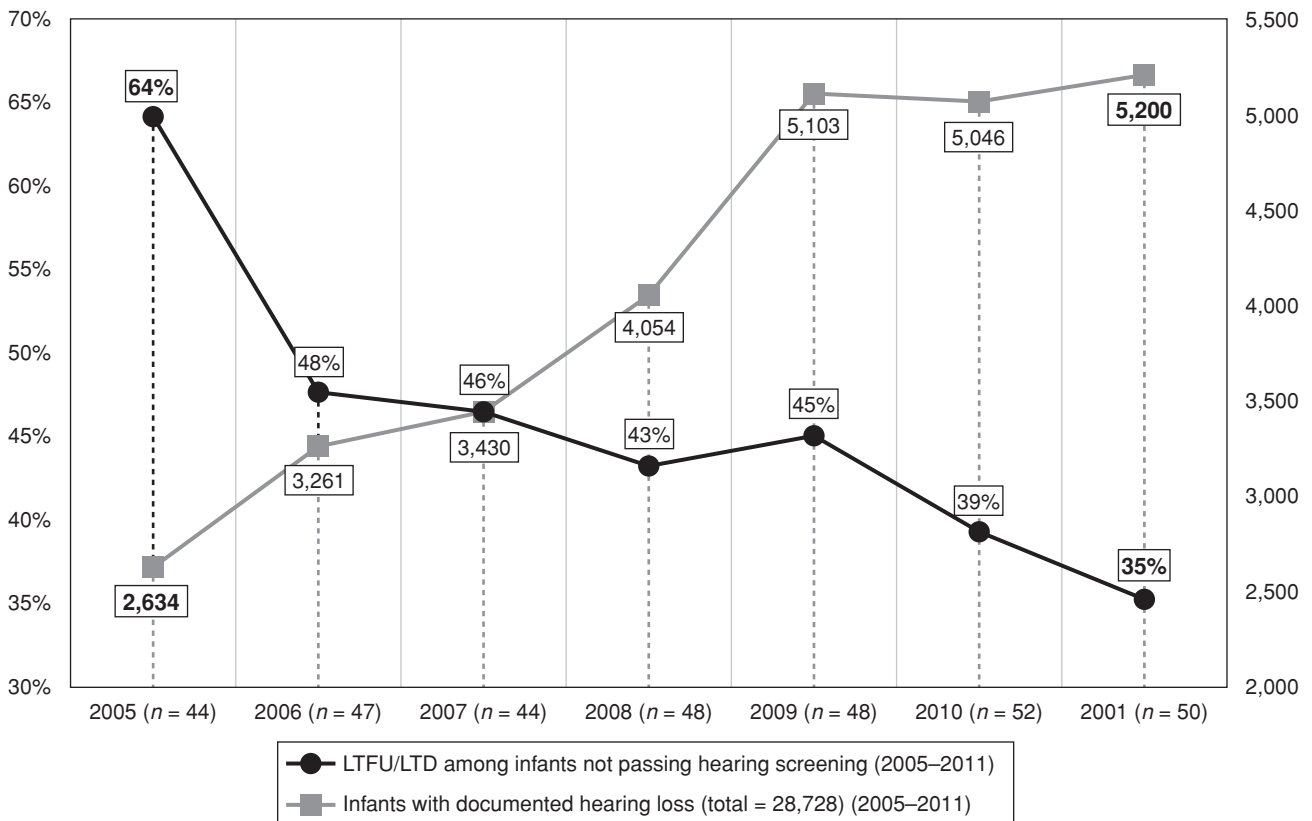

FIGURE 23.4 Number of children who are DHH identified and LTFU/LTD rates from 2005 to 2011.

are mostly composed of self-defined pediatric audiologists. Most state EHDI coordinators (79%) said it would be “beneficial if there were a license or certification for audiologists who specialize in diagnostic assessments and/or hearing aid fitting for infants and toddlers.” In 2011, the American Board of Audiology launched the Pediatric Audiology Specialty Certification (PASC) that is supposed to address this need. The PASC was “developed to elevate professional standards in pediatric audiology, enhance individual performance, and recognize those professionals who have acquired specialized knowledge in the field of pediatric audiology” (American Board of Audiology, 2013). The program is still new (only 43 audiologists were certified as of November 15, 2013), so time will tell whether the availability of the PASC improves pediatric audiology services.

Recently, CDC made a web-based service available to help parents and others find qualified pediatric audiologist throughout the nation. Developed in conjunction with collaborators from ASHA, AAA, JCIH, Hands & Voices, NCHAM, and others, the EHDI-PALS (EHDI-Pediatric Audiology Links to Services) provides up-to-date information about facilities that offer pediatric audiology services. All of the facilities listed must report that they have appropriate equipment and expertise to serve children and have licensed audiologists. Similar to other web-based search tools, EHDI-PALS users are asked to answer few simple questions that help pinpoint their location and need. Then the program generates a list of the nearest audiology facilities that match the request. Each listing comes with information about that facility including types of services offered, availability of language interpretation services, payment options, and appointment availability. The service is free and is not linked to any commercial products or services. The system can be accessed at <http://www.ehdipals.org/>.

In a national evaluation of newborn hearing screening and intervention programs reported by Shulman et al. (2010) the following factors were identified as contributing to poor follow-up rates for audiologic diagnosis:

1. Lack of qualified audiologists to do diagnostic evaluations
2. Lack of appropriate equipment
3. Lack of knowledge among health providers about the importance and urgency of follow-up testing
4. Difficulties with transportation, ability to pay, and motivation on the part of families
5. Poor communication among PHCP, audiologists, and the state EHDI program

GOAL NO. 3: PROVISION OF APPROPRIATE MEDICAL, AUDIOLOGIC, AND EDUCATIONAL INTERVENTION BEFORE 6 MONTHS OF AGE

Providing appropriate medical, audiologic, and educational services to infants and young children who are DHH is a complex, multifaceted undertaking. The shortage of exper-

rienced and qualified pediatric audiologists often interferes with fitting appropriate hearing technology as early as desired. Another problem is that many PHCPs are not up-to-date regarding early identification of hearing loss. For example, JCIH (2007) recommends that all infants with confirmed hearing loss be referred to a geneticist and an ophthalmologist who has “knowledge of pediatric hearing loss.” However, when almost 2,000 PHCPs who care for children in 22 different states and territories responded to a question on a 2005 survey about to whom they would refer a newborn patient who had been “diagnosed with a moderate to profound bilateral hearing loss . . . [when] no other indications are present,” only 0.6% said they would refer to an ophthalmologist and 8.9% to a geneticist. When asked at what age an infant could be fit with hearing aids, only 47.3% knew that hearing aids could be fit on children under 4 months of age (Moeller et al., 2006). In a similar survey completed in 2013 (NCHAM, 2013g), a national sample of over 2,000 PHCPs from 26 states responded similarly—only 2.2% and 9.3% would refer to an ophthalmologist or a geneticist, respectively, and only 39.1% knew that children under 4 months of age could be fit with a hearing aid. Clearly, more work needs to be done educating PHCPs so that they can be better partners in providing and supporting families who have children who are DHH.

According to state EHDI coordinators, appropriate educational intervention programs for infants and toddlers with hearing loss are also not as widely available as needed. Part C of the federal Individuals with Disabilities Education Act (IDEA) requires all states to provide appropriate early intervention programs for all infants and toddlers with disabilities. Most children in Part C-funded early intervention programs are enrolled based on the fact that they exhibit significant delays from normal development. Infants and toddlers who are DHH often do not exhibit measurable delays in language, cognitive, or social skills until they are 18 to 24 months of age. Even though federal regulations provide for serving children who have “established conditions that are likely to lead to developmental delays,” only 5 of the 51 state plans for Part C provide an operational definition of how children who are DHH would qualify for such services (White, 2006). Of greater concern, CDC (2013) reported that in 2011 state EHDI coordinators were only able to document that 63% of infants and toddlers who the EHDI program had identified as being DHH were enrolled in Part C programs and only 68% of those could be documented as having been enrolled before 6 months of age.

GOAL NO. 4: INFANTS AND CHILDREN WITH LATE-ONSET OR PROGRESSIVE HEARING LOSS WILL BE IDENTIFIED AT THE EARLIEST POSSIBLE TIME

In describing hearing loss, the terms “late onset” and “progressive” are frequently used together which may lead to

some people assuming that they are synonyms for the same condition. They are not. A progressive hearing loss is one that gets worse over time, whether the hearing loss is congenital or late onset. The term “late-onset hearing loss” should only be used when normal hearing was present at birth and a permanent hearing loss occurred later.

The Joint Committee on Infant Hearing (JCIH, 2007, p 899) recommends that

Infants who pass the neonatal screening but have a risk factor should have at least 1 diagnostic audiology assessment by 24 to 30 months of age. . . . All infants should have an objective standardized screening of global development with a validated assessment tool at 9, 18, and 24 to 30 months of age. . . . Infants who do not pass the speech-language portion of a medical home global screening or for whom there is a concern regarding hearing or language should be referred for speech-language evaluation and audiology assessment.

In 2004 (the latest data available), only 14 states were collecting risk indicator information from “all hospitals” and 17 states were collecting it for “some hospitals.” Eight states reported that they received risk indicator data for ≥85% of all births. In many cases the state EHDI program reports the presence of the risk indicator to the child’s PHCP and/or parent and takes no further action. States that were collecting risk factor data reported that they tried to do audiologic monitoring for 57% of the children that had risk indicators. Unfortunately, they were only able to complete “at least one audiologic monitoring during the first year of life” for 40% of those children where an attempt was made (NCHAM, 2013f). In a recent review of the literature, Beswick et al. (2012) found surprisingly little good evidence about costs or benefits of monitoring children who pass a newborn hearing screening test, but have one or more of the risk factors for hearing loss. They called for more large-scale, population-based research to assist with the development of evidence-based guidelines for monitoring the hearing status of children who have passed newborn hearing screening.

Clearly, detection of late-onset hearing losses should be a part of a comprehensive EHDI program. Although more work is needed to determine how this can be done most efficiently, recent research suggests that screening with OAEs is a viable alternative. Eiserman et al. (2008) reported results by lay screeners for more than 4,000 children in Early Head Start programs in four states using portable OAE equipment. One hundred and seven children (23.6 per 1,000 screened) were determined to have fluctuating conductive hearing losses requiring medical and/or audiologic treatment, and seven children (1.54 per 1,000 screened) were diagnosed with permanent hearing loss, including four who had passed their newborn hearing screening test. Foust et al. (2013) and Bhatia et al. (2013) reported on separate screening programs in which portable OAE equipment was used in federally funded clinics serving low-income and unin-

sured children in metropolitan areas. Foust and colleagues reported 3.55 children per 1,000 identified with permanent hearing loss based on 846 children screened, and Bhatia and colleagues reported 2.45 children per 1,000 identified with permanent hearing loss based on almost 2,000 children screened. These studies provide good evidence that OAEs are a viable tool for doing hearing screening of infants and young children. In its latest national survey of physicians, NCHAM (2013g) found that 29% report that they are doing hearing screening of infants and young children in their offices, and 66% of these report using OAE equipment as a part of their screening protocol.

GOAL NO. 5: ALL INFANTS WITH HEARING LOSS WILL HAVE A MEDICAL HOME

The American Academy of Pediatrics advocates that all children should have access to health care that is accessible, family centered, comprehensive, continuous, coordinated, compassionate, and culturally effective—often referred to as the Medical Home (Jackson et al., 2013). It is clear that services for infants and toddlers with hearing loss would be much better if families of children who are DHH were connected soon after birth to a PHCP who is familiar with their circumstances, is knowledgeable about the consequences and treatment of children who are DHH, and is known and trusted by the family.

Unfortunately, according to state EHDI coordinators, this is not the case for many infants and toddlers with hearing loss. Shulman et al. (2010) reported that only 73% of coordinators said that hospitals in their state contacted the PHCP when a child did not pass the newborn hearing screening test. NCHAM (2013f) reported that the name of the PHCP who will care for the baby during the first 3 months of life was known only for about 75% of newborns discharged from the hospital. Furthermore, many PHCPs are not well informed about issues related to early identification of hearing loss (NCHAM, 2013g). This is not surprising given the rapid changes that have occurred in our knowledge about identification and treatment of children who are DHH during the last 15 years. It is unrealistic to expect all PHCPs to remain up-to-date about a condition that affects only about 3 babies per 1,000. Thus, states must find ways of providing this information to PHCPs on an “as needed” basis. The American Academy of Pediatrics is actively working with state EHDI coordinators to develop such informational materials, but much remains to be done. According to MCHB (2010), State Title V Directors estimated that only 43% of children with special healthcare needs receive healthcare services in a setting that meets the minimal requirements for a medical home. State EHDI coordinators estimated that results about hearing screening tests were sent to medical home for 73% of the births, but it is unclear how frequently these results reached the correct PHCP (Shulman et al., 2010). In fact, NCHAM (2013g) found that 46% of

physicians said they never received information from the state EHDI program, and 68% reported that they never sent information to their state EHDI program.

GOAL NO. 6: EVERY STATE WILL HAVE A TRACKING AND SURVEILLANCE SYSTEM TO MINIMIZE LOSS TO FOLLOW-UP

CDC currently awards funding to 52 states and territories to assist with the development and enhancement of improved tracking and data management systems that can be linked with other state public health information systems. A recent survey of public health agencies concluded that information from EHDI programs was the child health information most likely to be integrated with other health systems, but continued effort and improved coordination among agencies is still needed (Bara et al., 2009).

As noted in Figure 23.4, Loss to Follow-up/Loss to Documentation remains a serious problem with state EHDI programs being unable to document the hearing status of 35% of the newborns who do not pass the hearing screening test. Shulman et al. (2010) reported that hospitals report the results of hearing screenings to the state EHDI program using various methods, including paper forms, software developed specifically for this purpose, adaptations to the bloodspot screening cards, or electronic birth certificates. Some state EHDI programs mandate how reporting is to be done, but most allow each hospital to choose which system they will use. This means that only half the EHDI programs received screening results from all hospitals through a single method, the most common being a faxed or mailed paper form.

More systematic approaches such as those used in other countries would likely have better results. For example, well-established UNHS programs in the United Kingdom (UK National Screening Committee, 2013), Poland (Radziszowska-Konopka et al., 2008), and the Netherlands (Nederlandse Stichting voor het Dove en Slechthorende Kind [NSDSK], 2007) report national screening rates of more than 95% with loss to follow-up/loss to documentation rates of less than 10%. It is interesting to note that low loss to follow-up/loss to documentation is achieved even though in England about 20% of the babies are not screened in the birth hospital and in the Netherlands 70% of the babies are screened at home, which would seem to be even more challenging for follow-up. Only four states in the United States (CA, IN, MA, and MI) reported loss to follow-up/loss to documentation rates of less than 10% in 2011 (CDC, 2013).

Eighty-five percent of EHDI programs received data about the screening outcomes of individual babies which means that most state EHDI programs are able to assist in follow-up with individual families. Linkages with other public health data systems are also expanding with 15 states reporting in a 2004 NCHAM survey that they had some

type of linkage with newborn dried bloodspot screening programs, 13 with vital statistics and 4 each with immunization registries and early intervention programs (NCHAM, 2013f; Shulman et al., 2010). As these linkages are refined and stabilized, it will eliminate duplication and will mean that services to families can be better coordinated.

GOAL NO. 7: ALL STATES WILL HAVE A SYSTEM TO MONITOR AND EVALUATE PROGRESS TOWARD THE EHDI GOALS AND OBJECTIVES

Closely related to the development of tracking and data management systems is the implementation of systematic evaluation and quality assurance programs. As visualized in the CDC National Goals, an EHDI advisory committee in each state should assist with developing and maintaining the EHDI system. Almost all states have an EHDI Advisory committee that meets at least quarterly and has representation from diverse stakeholders including audiologists, parents of children with hearing loss, PHCPs, and early intervention providers. These committees have made good progress in overseeing the development of educational materials for PHCPs and parents. Coordinators in 78% of the states reported that they had good to excellent materials for educating parents about the states' EHDI programs. More work is needed in developing materials to educate PHCPs about EHDI and to educate parents of children who are DHH about communication options where only 53% and 56%, respectively, of EHDI coordinators said that they had good to excellent materials. Shulman et al. (2010) reported that 83% of the states had developed materials in languages other than English.

Systematic evaluation and monitoring of state EHDI programs is an area where more work is needed. NCHAM (2013f) found that states were using a variety of methods to gather information about the EHDI program, but only 18 states reported that a systematic evaluation of their state's EHDI program had been completed during the last 5 years. Interestingly, 10 of these 18 evaluations were internal evaluations conducted by state EHDI program staff and only 8 resulted in a written report.

Making progress toward achieving EHDI goals presumes that there is adequate funding to sustain the program. Unfortunately, most EHDI programs are on somewhat tenuous financial footing. NCHAM (2013f) found that almost two-thirds of the resources for operating EHDI programs came from the MCHB grants and CDC cooperative agreements that are viewed by Congress as temporary sources of support. Only 17% of the financial resources for state EHDI programs came from state appropriations and only six states provided more than half of the resources for their EHDI program from nonfederal sources. Shulman et al. (2010) reported that 42% of EHDI coordinators were unsure whether the program could be continued if federal funding were to be discontinued.

OPERATING EFFECTIVE NEWBORN HEARING SCREENING PROGRAMS

The preceding discussion about the goals of the EHDI system helps define where EHDI programs are headed and how well they are doing. Much has also been written about how to implement and operate an effective newborn hearing screening program (e.g., AAA, 2011; JCIH, 2007; White and Muñoz, 2013). Instead, of repeating similar information here, the following section discusses several issues about the operation of newborn hearing screening programs that are often overlooked.

Recognizing Newborn Hearing Screening as the Standard of Care

A newborn hearing screening program will only be successful if all the stakeholders are supportive and recognize its value and importance. One of the strongest rationales for providing a medical service is if it is recognized as the medical/legal “standard of care.” Arguably, UNHS programs have now achieved that status, and hospitals and State Departments of Public Health are exposing themselves to significant liability risks if they are not operating effective hearing screening programs for all newborns.

Marlowe (1996) was one of the first to suggest that newborn hearing screening was becoming the actual medical/legal standard of care in the United States:

Every medical and allied health practitioner and every hospital administrator should be keenly aware that they are held to a hypothetical standard of care whenever their professional conduct is being evaluated legally. . . . Definition of a standard of care is complicated by the fact that it is not usually articulated in a specific, identifiable form and it may be subject to clarification on a case-by-case basis should legal actions arise.

Even though there have not yet been court cases that definitively establish newborn hearing screening as the legal standard of care, healthcare providers and hospital administrators should be aware that newborn hearing screening seems to meet each of the following guidelines that have been used in the past for establishing a practice as the standard of care.

EXPECTATIONS FOR A REASONABLE PRACTITIONER UNDER SIMILAR CIRCUMSTANCES

An often cited case in determining what constitutes a standard of care in a particular situation was the 1898 *Pike v.*

Honsinger case, in which the Court of Appeals decision stated that

A physician . . . impliedly represents that he possesses . . . that reasonable degree of learning and skill . . . ordinarily possessed by physicians in his locality . . . [It is the physician’s] duty to use reasonable care and diligence in the exercise of his skill and learning. . . . [he must] keep abreast of the times . . . departure from approved methods and general use, if it injures the patient, will render him liable.

The fact that newborn hearing screening is now being provided for over 98% of all newborns and have been successfully functioning in many parts of the United States for 15 years means that it would be difficult for any healthcare provider to successfully argue that UNHS programs should be viewed as experimental or unproven.

SUPPORT FROM GOVERNMENTAL, PROFESSIONAL, AND ADVOCACY GROUPS

It is difficult to think of healthcare procedures that are not yet routinely implemented which have been endorsed by so many different authoritative groups ranging from the American Academy of Pediatrics to the National Institutes of Health to the March of Dimes—all of whom have concluded that UNHS is feasible to implement, results in earlier identification of hearing loss, and can be done with equipment which is accurate, practical to use, and economical.

AVAILABILITY OF APPROPRIATE TECHNOLOGY TO IMPLEMENT THE PRACTICE

Ginsburg (1993) suggested that one of the criteria for establishing a standard of care

. . . is when an inexpensive reliable device comes onto the market, the technology and concept of which have already been adopted by a group who specializes in the concept . . . a guideline becomes a standard of care when the device behind the guideline is available and readily usable. (p. 125)

Newborn hearing screening equipment is widely available, relatively inexpensive, and continually improving which means that it easily meets Ginsburg’s standard of being “available and readily usable.”
